IN Australia chronic liver disease, with sometimes a high death rate, has occurred in flocks of sheep which have grazed pastures containing the summer-growing annual plant, *Heliotropium europaeum* L., for two or more consecutive seasons. Pyrrolizidine alkaloids have been isolated from the plant and their structures determined[1,2]. The plant may contain up to 3 per cent of alkaloid, mostly as N-oxides[3]. We have studied the disease in grazing sheep[4–6] and by administration of the purified individual alkaloids to rats[7–9], and we have defined the essential pathology as an atrophic hepatosis with megalocytosis of the parenchyma cells.

By extending these investigations to a wide range of pyrrolizidine alkaloids we have concluded that only those which are allylic esters are hepatotoxic, and have put

forward the hypothesis that they act in the tissue cell as alkylating agents by a mechanism involving alkyl-oxygen fission[10].

The relatively small amount of liver damage suffered by sheep after grazing on pure stands of *H. europaeum* for only one season suggested to us that much of the alkaloid must be destroyed in the rumen, and we have, therefore, sought to determine the products arising from heliotrine, in the rumen contents of sheep several hours after an oral dose. We found the major product to be a 1-methylene derivative, 7-α-hydroxy-1-methylene-8α pyrrolizidine (1), together with some unchanged heliotrine and the hydrolysis product, heliotridine. We had isolated the optical enantiomer of the base (1) from *Crotalaria goreensis*[11] and found it devoid of hepatotoxic properties both in acute tests and in a prolonged course of repeated injection in rats. We have synthesized (1) and found it likewise to have no acute hepatotoxic action. Although chronic testing of this enantiomer is not yet completed, no pyrrolizidine alkaloid has been found to cause a hepatosis if it did not produce liver necrosis in the acute test.

To study this conversion *in vitro* we incubated heliotrine with rumen liquor under conditions commonly used in artificial rumen studies. A sample of rumen contents was taken from a sheep with a rumen fistula, filtered through cheese-cloth, lightly centrifuged (400*g*, 3 min) and incubated at 39° C with a constant stream of carbon dioxide bubbling through it. Under these conditions the heliotrine (0·5 mg/ml.) was recovered unchanged even after 48 h incubation. However, since the administration of cobalt by mouth to sheep, which materially raises the vitamin B_{12} content in the rumen[12], has been clearly shown to protect sheep against *Phalaris* staggers[13] and since this disease is believed to be due to a toxic substance produced by the plant *Phalaris tuberosa*[14], we examined the effect of adding 0·4 μg/ml. vitamin B_{12} (Glaxo–Allenbury's preparation of cyanocobalamin, 'Cytamen 1000') to the prepared rumen liquor with which the heliotrine was incubated.

Under these conditions the heliotrine was all converted within 24 h to the 1-methylene derivative (1), which was isolated and identified by gas chromatography and infrared spectrum. We also found that there was a partial conversion without added B_{12} in rumen liquor that was strained but from which the B_{12}-rich particulate matter was not removed by light centrifuging. On the other hand, if all the micro-organisms were removed by centrifuging at 4,000*g* for 1 h the heliotrine was recovered unchanged after 24 h incubation even when 1 μgm B_{12}/ml. had been added. The rate of conversion of heliotrine to (1) was increased as the B_{12} concentration was increased up to 1 μgm/ml. It was decreased as the *p*H was lowered from 6·7. In all instances there was a lag period of 6–10 h during which no breakdown of heliotrine occurred. Neither the rate of conversion nor length of the lag-period was affected by addition of glucose. The lag-period was not eliminated by pre-incubation of the rumen liquor with B_{12} for 24 h before addition of heliotrine. Vitamin B_{12b} (hydroxocobalamin) was less effective in concentrations up to 5 μgm/ml.

Other pyrrolizidine alkaloids have been examined by incubation for 24 h with filtered and lightly centrifuged rumen contents with and without the addition of 1 μgm/ml. of B_{12}. The alkaloids were broken down only in the pots to which B_{12} was added, and in each instance in which the product has been characterized it has proved to be the 1-methylene derivative. Thus, of the other alkaloids from *H. europaeum*, lasiocarpine was converted to 7α-angelyloxy-1-methylene-8α-pyrrolizidine; supinine and heleurine, esters of supinidine rather than heliotridine, yielded 1-methylenepyrrolizidine. Heliotrine-*N*-oxide was reduced to heliotrine in the absence of added B_{12}, but in its presence (1) was the only product.

Two retronecine bases tested, echimidine, isolated from *Echium plantagineum* L.[15], and monocrotaline, from *Crotalaria retusa* L.[16], were stable in our test system unles B_{12} was added, and then they were converted to 1-methylene derivatives as judged by colour reactions on pape chromatograms.

These experimental observations are being continue and extended and detailed results will be publishe elsewhere, but this preliminary report is made because c the possible practical applications which they suggest.

Since it has been shown that adequate cobalt is provide for the protection of sheep against *Phalaris* staggers ove extended periods by the deposition of heavy pellets containing cobalt in the 'rumen-reticulum'[17], our result suggest that these pellets, which are available commercially, may well protect sheep and cattle from chroni intoxication by pyrrolizidine alkaloid-containing plant such as *Heliotropium*, *Senecio* and *Crotalaria* species. W have set up field trials and pen experiments to assess th protective action of cobalt pellets in sheep exposed t heliotrope poisoning, but since the chronic diseas develops only slowly, results will not be available for a least two years.

We thank Glaxo–Allenbury's (Aust.) Pty., Ltd., for gift of vitamin B_{12b}.

Axenic Culture of Two Trichomycetes from Californian Mosquitoes

THE Trichomycetes are a group of primitive fungi which with a few exceptions, live attached by holdfasts to the gut linings of arthropods. We have encountered twc Trichomycetes, *Rubetella culicis* (Tuzet et Manier, 1947 and *R.* sp., inhabiting the rectums of mosquito larvæ in California; both these fungi have been found infesting several species of mosquitoes.

To our knowledge, the only successful axenic culture heretofore made with any member of the Trichomycetes was by Whisler[1], who cultured the ectocommensal *Amoebidium parasiticum*, from *Cladocera* on a tryptone agar medium. Tuzet, Rioux and Manier[2] attempted tc culture *R. culicis* and observed some elongation of hypha filaments; however, they did not obtain germination o conidia.

Our first isolation of *R. culicis* (Fig. 1) was made from a fourth-instar larva of *Ædes melanimon* Dyar collected from an irrigated pasture in Merced County. *Rubetella* sp (Fig. 2) was first isolated from a fourth-instar larva o *Culiseta incidens* (Thomson) collected from rock pools in the foothills of the Sierra Nevada Mountains in Fresnc County.

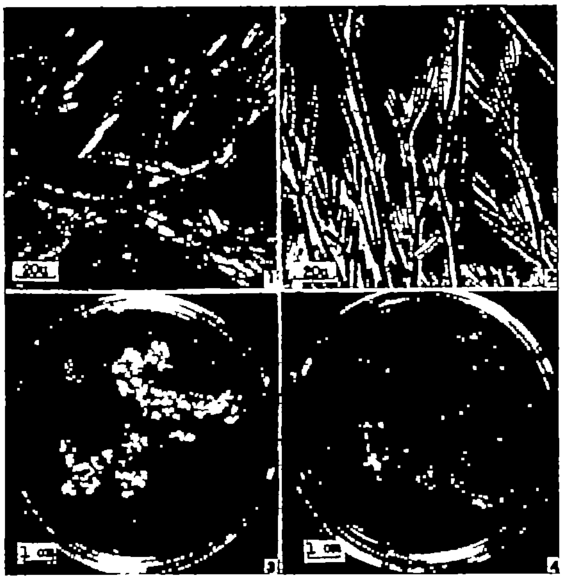

Fig. 1. *Rubetella culicis* from the rectum of *Aëdes melanimon*
Fig. 2. *Rubetella* sp. from the rectum of *Culiseta incidens*
Fig. 3. Culture of *Rubetella culicis* in thioglycollate broth
Fig. 4. Culture of *Rubetella* sp. in thioglycollate broth

Heavily infested larvæ were surface disinfected with a 1 : 1,250 concentration of 'Roccal' solution (Withrop Laboratories, New York), rinsed in sterile distilled water, and blotted on sterile filter paper. The rectums of the arvæ were removed by dissection and placed in a drop of 0·675 per cent saline solution, containing about 1,000 µg of streptomycin and 3,000 units of penicillin *G* per c.c. The rectums were transferred to a sterile slide where they were dissected open with fine needles; individual thalli 1–2 mm n diameter were scraped free from the chitinous rectal ining and transferred through 5 successive baths of sterile saline solutions containing antibiotics. Finally, the thalli were placed in culture medium.

Our first successful culture was established on *SNB*-9 medium, a biphasic blood agar medium developed by Diamond and Herman[3] for the culture of hæmoflagellates. Equally good growth was later obtained on Difco brain-heart infusion agar slants, using a broth overlayer composed of 2 per cent neo-peptone and 0·675 per cent sodium chloride in water; good cultures were also obtained using Difco *N.I.H.* thioglycollate broth.

Initial isolates required about 2 weeks to reach 5 mm in diameter; conidial production usually occurred after the cultures were a month old. The production of aberrant conidia was common; however, sub-cultures were readily accomplished, and mosquito larvæ were readily infested in the laboratory by exposing them to older cultures containng heavily conidiating thalli.

The colonies of both species of *Rubetella* appeared soft, white, and compact on agar; however, each species took on a characteristic form in broth. *R. culicis* colonies were almost spherical and billowy (Fig. 3), while *Rubetella* sp. colonies were more stringy or lacy in form (Fig. 4).

The axenic culture of these fungi has provided an imporant step in the elucidation of their nutritional requirements, life-cycles and relationships with their hosts.

This investigation was supported in part by research grant *E*–3496 from the National Institute of Allergy and nfectious Diseases of the U.S. National Institutes of Health.

MICROBIOLOGY

Cellulose Acetate Membranes for detecting Peroxidase in Mycobacteria

A QUICK and simple test for detecting peroxidase in cultures of mycobacteria has been outlined recently[1]. The test consists in exposing micro-organisms in or on a suitable culture medium to a reaction mixture of catechol and hydrogen peroxide in an acetate buffer at a *p*H of 4·0. In the presence of oxygen the catechol is oxidized by peroxidase, forming a dark brown compound, probably benzoquinone. This change in colour sharply distinguishes peroxidase-positive organisms from peroxidase-negative ones, which remain colourless. The test can also be carried out in a liquid medium, but where suitable solid or semi-solid media are used, colonies of each type can be distinguished in mixed cultures. As the presence or absence of peroxidase is intimately bound up with susceptibility or resistance to isoniazid, the demonstration of sensitive and resistant colonies in a mixed population without exposure to isoniazid is made easy.

In experimental work where artificial mixtures of isoniazid-sensitive and resistant strains have been used, best results were obtained where colonies have been numerous but discrete and uniform in size. In addition a medium is required which is easy to prepare, consistent in performance and capable of furnishing a rapid growth which is convenient to handle should further tests be needed. With the view of these requirements several media have been investigated, namely, Fisher[2], Kirchner[3], Tarshis[4], and Dubos and Davis[5]. Of these, the last has proved the most suitable.

The modification of Tirunarayanan and Vischer's method described here makes use of cellulose acetate membranes laid on a nutrient medium in the manner detailed by Knox and Smith[6] for the detection of penicillinase-producing organisms.

For the detection of peroxidase, Dubos and Davis medium containing 0·4 per cent bovine albumin and 0·5 per cent agar was used, poured into plastic Petri dishes and overlaid, when set, with 5-cm or 8-cm Oxoid membrane filters. Plates were allowed to dry (closed) overnight at 37° C and inoculated with 2 drops (0·04 ml.) from a mixed aqueous 10^{-4} dilution of 6–7 day-old stock Dubos cultures of *H*37*Rv* isoniazid-sensitive and resistant strains. These manipulations were carried out in an inoculating cabinet with air extraction. Incubation in large air-tight

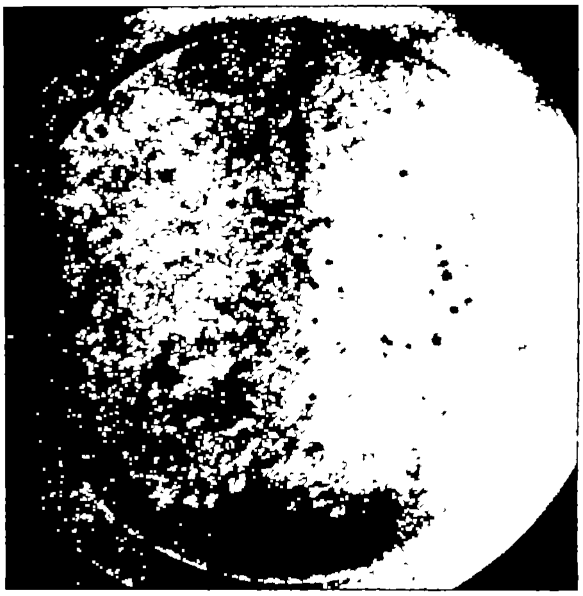

Fig. 1. (× *c*. 1·5

glass or metal containers has proved more successful and convenient than individual sealing of plates, and contamination rates have been very low. Sufficient growth for the catechol test has been obtained after 10 days' incubation, but in general a 14- to 21-day period is to be preferred. Colonies of tubercle bacilli grown on Dubos/membrane agar were smooth, convex, well separated and white in colour. With the strains used, colonies of peroxidase-negative, isoniazid-resistant cells were generally larger than colonies of the sensitive strain.

The catechol test was simply performed by transferring the growth-bearing membrane to a second Petri dish containing two or three thicknesses of 9-cm Whatman No. 1 filter papers impregnated with the reaction mixture, which was made up as follows: 0·2 M sodium acetate, 2 ml.: glacial acetic acid diluted 1 in 85, 8 ml.; 2 per cent catechol (aqueous), 2 ml.; 1 in 100 hydrogen peroxide (30 vol.), 1 ml. Darkening of peroxidase-positive colonies occurred after 15 min or so at room temperature, and the change in colour was at a maximum in 30 min–1 h. Peroxidase-negative colonies remained quite colourless and this contrast was maintained for several hours at least. Incubation at 37° C did not appear to hasten the reaction.

The sensitivity of the test is such that one peroxidase-positive colony is readily detectable among 400–500 peroxidase-negative colonies on a membrane of 8 cm size after 2–3 weeks' incubation, while one negative colony can be differentiated from some 200–300 positive under similar conditions. As peroxidase-positive colonies represent the isoniazid-sensitive cells, it will be seen that a small number of isoniazid-sensitive individuals may readily be detected among large numbers of isoniazid-resistant cells when neither of them has been exposed to the action of the drug.

Sub-cultures made from cells treated with the reaction mixture at the time when the test was read failed to grow, and it seems that exposure to the reagent kills them. It follows, therefore, that further testing involving growth is not possible with cells used in the reaction, but this disadvantage could be overcome by means of replica plating techniques.

Reversal of o-Nitrobenzoic Acid Inhibition of Microbial Growth by Amino-Acids

SEVERAL benzene derivatives reportedly inhibit microbial growth by blocking essential metabolic reactions but, in some instances, the site of inhibition has not been established. High concentrations of *p*-aminobenzoic acid inhibit certain bacteria[1,2] and the bacteriostatic activity toward *Escherichia coli* strain *W* is reversed by *p*-hydroxybenzoic acid and, to a limited extent, by shikimic acid or 5-dehydroshikimic acid[1]. *p*-Aminobenzoic acid also suppresses growth of *Saccharomyces cerevisiae*, which can be reversed by aromatic amino-acids such as phenylalanine, tyrosine and tryptophan[3]. Utilization of *p*-aminobenzoic acid as an oxidizable substrate by a *Flavobacterium*[4] is competitively inhibited by *p*-aminosalicylic acid[5], and it has been suggested that *p*-aminosalicylic acid competes with the substrate for the specific transport mechanism(s)[6].

Inhibition of *Aspergillus niger* by *m*-dinitrobenzene is influenced by the age of the culture and can be reversed by casein hydrolysate or a mixture of amino-acids similar in composition to casein hydrolysate[7]. The toxic effect 2,4-dinitrophenol on *E. coli* can be counteracted by a amino-acid mixture similar in composition to that obtaine from cow's liver[8]. *m*-Nitrobenzoic acid inhibited oxidatio of *o*-nitrobenzoic acid by *Nocardia opaca* and utilizatio of *p*-nitrobenzoic acid by *N. erythropolis*[9]. Similar studie revealed the *para*-isomer did not inhibit oxidation *o*-nitrobenzoic acid and the *ortho*-isomer did not influenc oxidation of the *para* form.

Investigations have revealed that *o*-nitrobenzoic ac inhibits growth of a *Flavobacterium* capable of usin *p*-nitrobenzoic acid as the sole source of carbon an energy for aerobic growth. This investigation was undertaken to elucidate the mechanism of this antagonism.

Growth studies were conducted in a defined mediu composed of: sodium chloride, 0·1 per cent; potassiu dihydrogen phosphate, 0·32 per cent; dipotassiu hydrogen phosphate, 0·42 per cent; and *p*-nitrobenzoi acid as the carbon and nitrogen source. When succini acid replaced *p*-nitrobenzoic acid as the carbon an energy source, 0·2 per cent ammonium chloride wa added as the nitrogen source. All substrates were use in a final concentration of 0·02 M unless indicated otherwise. The medium was adjusted to *p*H 7·0, autoclave at 121° C for 15 min, and mineral salts added as previous described[6]. The amino-acids and other additives wer sterilized separately and added aseptically.

Inoculum cells were grown on *p*-nitrobenzoic acid aga slants, washed by centrifugation, suspended in steril 0·01 M potassium phosphate buffer (*p*H 7·0), and on drop added to each reaction tube. All tubes were incubated on a reciprocating shaker at 37° C. Growth wa followed by measuring optical density at 540 mμ in Bausch and Lomb Spectronic 20 spectrophotometer.

Addition of *o*-nitrobenzoic acid (0·06 M and 0·12 M) t the medium containing *p*-nitrobenzoic acid (0·02 M) a the source of carbon and energy resulted in a marke inhibition of growth (Fig. 1). The degree of suppressio is a function of the inhibitor concentration. Control indicated the organism was unable to utilize *o*-nitrobenzoic acid as a substrate for growth.

Investigations were made to determine if growth wa inhibited when compounds not structurally related to the

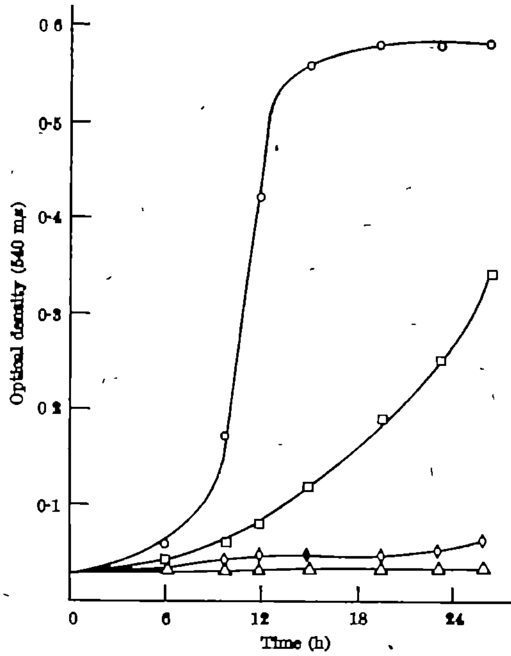

Fig. 1. Effect of *o*-nitrobenzoic acid on growth of *Flavobacterium* sp. using *p*-nitrobenzoic acid (0·02 M) as carbon and nitrogen source. ○, *p*-NO_2; □, *p*-NO_2 + *o*-NO_2 (0·06 M); ◇, *p*-NO_2 + *o*-NO_2 (0·12 M); △, *o*-NO_2 (0·12 M)

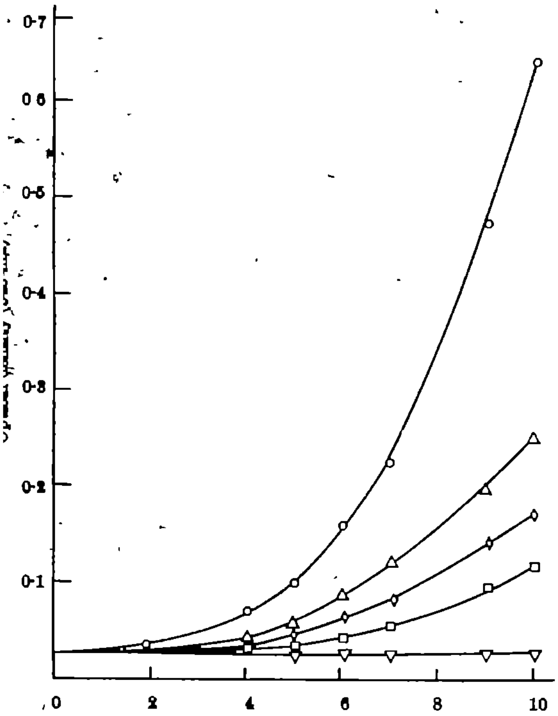

Fig. 2. Effect of *o*-nitrobenzoic acid on growth of *Flavobacterium* sp. using succinic acid (0·02 M) as carbon source. ○, Suc; △, Suc + *o*-NO₂ (0·02 M); ◇, Suc + *o*-NO₂ (0·04 M); □, Suc + *o*-NO₂ (0·06 M); ▽, *o*-NO₂ (0·06 M)

itrobenzoic acids were used as substrates. Fig. 2 shows ıat *o*-nitrobenzoic acid also inhibited growth when 02 M succinic acid was used as the substrate.

Viable cell counts were made during the 6 h immeately following inoculation of the medium to determine *o*-nitrobenzoic acid was killing the cells. Growth was easured spectrophotometrically and, concurrently, aliıots were withdrawn and the number of viable cells termined by plate counts on nutrient agar. No sigficant decrease in viable cells was observed in systems ntaining the inhibitor, denoting that *o*-nitrobenzoic acid es not kill the cells but impairs growth by interfering ith an essential metabolic process. Washed cell suspenons, used in respirometric studies, oxidized succinic or nitrobenzoic acid at the same rate in the presence or sence of *o*-nitrobenzoic acid. Thus, the inhibitor does t influence uptake of the substrate by the cells or the te of substrate oxidation.

Growth studies were conducted in which the substrate inhibitor ratio was varied. Results indicated that the gree of inhibition was related to inhibitor concentration igs. 1 and 2). Increasing the substrate concentration ither (succinic or *p*-nitrobenzoic acid) while maintaining e same inhibitor concentration did not decrease the hibition. Since similar inhibition trends were obtained gardless of concentration of substrate, these results tablish that the inhibition was dependent on the conntration of inhibitor and not the ratio of substrate to hibitor.

Reversal investigations with various additives were ıdertaken using the succinate–salts medium in the esence and absence of 0·04 M *o*-nitrobenzoic acid. esults indicated casein hydrolysate (0·05 per cent) or a ixture of 17 amino-acids completely reversed the inhibon. Additional studies demonstrated a combination of e amino-acids (DL-aspartic and L-glutamic acid, DL-ethionine, L-leucine, glycine) gave good reversal of the hibition but was not so effective as the mixture of amino-acids (Table 1). The results indicate that either glutamic or DL-aspartic acid could be omitted from the edium but not both. Growth was evident when either glycine, DL-methionine, or L-leucine was omitted from the mixture but reversal was not equivalent to the growth obtained with the five amino-acid mixture. Thus the presence of DL-methionine, L-leucine, and glycine enhances reversal but these amino-acids do not appear to be absolutely essential. L-Cystine or L-cysteine was unable to replace methionine in the mixture.

Table 1. INFLUENCE OF AMINO-ACIDS ON *o*-NITROBENZOIC ACID INHIBITION OF MICROBIAL GROWTH

Medium components*	Optical density 540 mμ	
	10 h	14 h

Suc + *o*-NO₂ + Glut	0·14	0·36
Suc + *o*-NO₂ + Gly	0·05	0·16
Suc + *o*-NO₂ + Meth	0·07	0·19
Suc + *o*-NO₂ + Leu	0·06	0·17
Suc + *o*-NO₂ + Asp, Glut	0·14	0·40
Suc + *o*-NO₂ + Gly, Meth, Leu	0·08	0·28

* Succinic acid (Suc), 0·02 M; *o*-nitrobenzoic acid (*o*-NO₂), 0·04 M; DL-aspartic acid (Asp) and L-glutamic acid (Glut), 40 μg/ml.; L-leucine (Leu) and DL-methionine (Meth), 16 μg/ml.; and glycine (Gly), 8 μg/ml.

† 17 Amino-acid mixture. DL-alanine, DL-aspartic and L-glutamic acid (80 μg/ml.); L-arginine, DL-isoleucine, L-lysine, DL-methionine, DL-phenylalanine, DL-serine, DL-threonine, DL-tryptophan (16 μg/ml.); DL-valine, glycine, L-histidine, L-leucine, L-proline, L-tyrosine (8 μg/ml.).

Other diverse biological compounds including vitamins and co-factors were tested, but none significantly reversed the inhibition.

These findings establish that *o*-nitrobenzoic acid is not bactericidal to *Flavobacterium* cells but inhibits growth by interfering with an essential metabolic reaction(s). Since the inhibition can be reversed by certain amino-acids, one mechanism by which *o*-nitrobenzoic acid apparently suppresses microbial growth is by interfering with synthesis or interconversion of specific amino-acids.

This work was aided by contract *Nonr*-3443(00)*NR* 103–504 between the Office of Naval Research, Department of the Navy, and Oklahoma State University (Agricultural Experiment Station Project 1027).

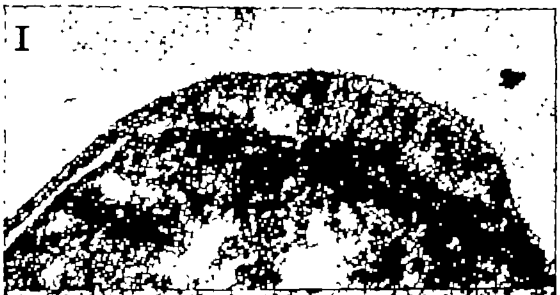
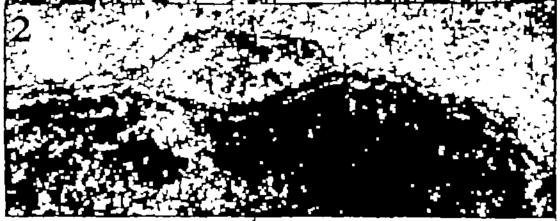
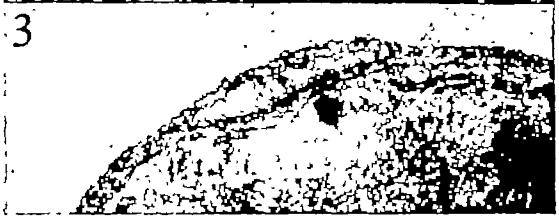
An Organelle confined within the Cell Wall of *Nitrosocystis oceanus* (Watson)

ONE of us isolated a nitrifying organism from the open ocean and called it *Nitrosocystis oceanus*[1]. In the course of examining this organism, observations were made on the fine structures shown in sections of embeddings made in 'Vestopal W' following the preparative prescriptions of Ryter and Kellenberger[2,3]. A number of structural peculiarities were observed, which will be described in a separate paper, and among them there was a structure that seems to be without precedent so far as we are aware. It was an organelle of regular and recognizable form lying between the major layers which make up the cell wall of this bacterium.

A high proportion of sections of these cells shows a peripheral separation of the layers of the cell wall con-







4

Fig. 3. Micrograph showing participation of the inner cell wall membrane in the structure of the organelle. (× c. 70,000)

Fig. 4. Diagram based on the micrographs observed. *CW*, Cell wall; *PM*, plasma membrane

taining a number of more or less distinct bars of material running between inner and outer wall (Fig. 1). Many cells show two or three of these, and it must be assumed that each cell has several of them disposed over its surface. The ovoid profiles in the sections have a long axis of about 0·5μ and a short axis of about 0·1μ. These structures can be followed through serial sections, and several of them occupy 4–6 sections so that the other dimension would be of the order of 0·25–0·5μ. It would appear, then, that these structures are plaques within the cell wall and are oval or round in plan.

The absolute boundaries of the structure are formed by the outermost membranous component of the cell wall, which is a very thin layer of about 25 Å thickness, and the inner boundary consists of a triple structure (two dense layers separated by one of low density) that has an overall thickness of 70–95 Å. In the normal portion of the wall these two layers are separated by an interposed layer of about 60 Å thickness, and it seems obvious that this layer must thicken when this organelle is formed (Fig. 2). However, the organelle does have other components: membranous structures and whatever substance it is that separates them. Some sections show vertical bars consisting of two slightly separated unit membranes. Others show ring profiles close to the outer border, and a great many others look almost empty. A few of these latter wit little complicating structure show the possible origin o the bars or tubes as intrusions from the inner side of a expansion of the inner double membrane of the cell wal (Figs. 3 and 4). It may be a bit more complex than thi because in a few instances (Fig. 1) one can recognize tha there is a single or possibly double unit membrane laye lying just outside the inner border of the organelle as w have described it here. It may then be, since the spac ings are very similar, that the membranous componen of the inside of the structures is formed by intrusions of thi new layer and perhaps even that this layer encompasses th whole structure. It is somewhat difficult to decide eve in serial sections what forms the exact border of th structure and whether it is self-enclosed.

The chemical complexity of the bacterial cell wall ha long been recognized[4]. It is a structure in itself that ha some of the attributes of an organelle and may eve require some of itself as a starter or scaffold on whic the new structure is built[5]. Certainly it seems to play a essential part in cell division, and it seems to confer othe attributes such as shape on the cell, thus contributing t the individuality of this cell in nature. This seems t imply that it must not only have structure but also balanced anabolic and catabolic machinery within itse to deal with some of its own needs; to allow acceptanc and incorporation of the building blocks that the ce provides, and control of the edifice that is built. It is the perhaps less surprising that this discontinuous structur may be found within bacterial cell walls; or, perhaps on should say that it is surprising that discontinuous structures have not been found before within bacterial cell wall considering all the complicated things that bacteria hav to accomplish in order to wrest a living out of obdurat environments.

We have no idea of what the function of this particula structure might be. It seems to be regular and frequen enough to expect some function to be found. For th moment it must be added to the list of beautiful structure without obvious function, to be found in nearly all sort of living cells. One is reminded somewhat of the elegantl ordered fibres of the 'organite antapical' which wer described in *Thiovulum majus* by Fauré-Fremiet an Rouiller[6].

However, the work of de Boer, la Rivière and Houwink has shown more clearly than ever that this structure lie below the plasma membrane of the cell and that it divide so that the resulting daughter organelles are partitione with the cells at division.

Our cell wall organelle is definitely outside of the plasm membrane and has not yet been noted to show any patter symptomatic of division. Since it is not yet recognizabl defined in light microscopy it is rather hard to get evidenc on this latter point. Despite all the unknowns it seem certain that this is an unprecedented organelle because o the site in which it is formed and maintained.

This work was supported in part by funds from th Medical Research Council of Canada, by the U.S. Atomi Energy Commission under contract *AT*(30–1)–1918 an by a National Science Foundation research grant *G*–1339

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 14

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 4.30 p.m.—Mr. J. M. Winchester and Mr. R. Pearson: "Development of Packages for Pesticides".

BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. B. Braithwaite: "Believing (as Opposed to Considering) Natural Laws".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION P.G.36 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. J. Thomson: "Modern Transducers with an Electrical Output".

UNIVERSITY OF LONDON (in the Eugenics Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Paul Turan (University of Budapest): "Analysis and Diophantine Approximation".* (Further lectures on January 15 and 16.)

INSTITUTION OF MECHANICAL ENGINEERS, LUBRICATION AND WEAR GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Oil Mist Lubrication".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. E. J. H. Corner, F.R.S.: "The Royal Society Expedition to Kinabalu".

Tuesday, January 15

INSTITUTION OF AGRICULTURAL ENGINEERS (at the Royal Society of Arts, John Adam Street, London, W.C.2), at 11 a.m.—Whole-day Meeting—Technical Papers.

UNIVERSITY COLLEGE, LONDON (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. L. S. Penrose, F.R.S.: "Finger-prints, Palms and Chromosomes".*

SOCIETY OF CHEMICAL INDUSTRY, joint meeting of the LONDON SECTION and the SURFACE ACTIVITY GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. F. Stone: "Physical Methods of Examining Catalysts".

Wednesday, January 16

COLOUR GROUP (GREAT BRITAIN) (in the New Physics Department, Imperial College of Science and Technology, London, S.W.7), at 3 p.m.—Dr. B. H. Crawford: "Some Measurements of the Colour Temperature of Daylight at Teddington"; Mr. C. J. Chamberlin: "Notes on the Related Colour Temperature on North Daylight in Southern England"; Dr. S. T. Henderson: "The Spectrum of Daylight".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. V. D. Barnett and Mr. T. Lewis: "A Study of the Relation between G.C.E. and Degree Results".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. K. Hoselitz: "Masers".

BRITISH INSTITUTION OF RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Prof. P. Bruel: "Instruments in Acoustics".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. H. L. Penman, F.R.S.: "Irrigation in Great Britain" (Fernhurst Lecture).

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, London, S.W.7), at 6 p.m.—Mr. K. Fletcher: "Precise Measurement of Temperature and Humidity".

OIL AND COLOUR CHEMISTS' ASSOCIATION, LONDON SECTION (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Dr. Baysung Hsu: "Some Physical Aspects of the Printability of Paper".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the Science Museum, South Kensington, London, S.W.7), at 7 p.m.—Lt.-Col. B. D. Shaw: "Chemistry is Fun" (Seventh Ladies' Evening).

Thursday, January 17

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. N. Korakas: "Magnetite Formation during Copper Matte Converting"; Dr. G. R. Davis: "Results of Comparative Sampling Methods at Kilembe Mine, Uganda, during the Exploration Phase" and "Observations on Sample Preparation".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. H. P. F. Swinnerton-Dyer: "Rational Points on Cubic Curves—Some Experimental Results".

CHEMICAL SOCIETY (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Prof. F. H. Westheimer: "The Mechanism of the Enzymic Decarboxylation of Acetoacetic Acid" (Centenary Lecture.)

INSTITUTION OF MECHANICAL ENGINEERS, APPLIED MECHANICS GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Can We Design for Short Endurance Fatigue?"

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. P. B. Caplin: "The Manufacture and Use of Pitch Fibre Pipes".

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Dr. David Morley: "A Medical Service for Children under Five, in West Africa".

Friday, January 18

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), from 10.30 a.m. to 6.30 p.m.—Three-session meeting and discussion on "The Origin and Constitution of the Planets". Speakers: Sir Edward Bullard, F.R.S., Dr. R. W. Girdler, Sir Harold Jeffreys, F.R.S., Prof. W. H. McCrea, F.R.S., Dr. P. J. Message, Dr. H. W. Menard, Prof. S. K. Runcorn, Prof. H. Suess (Heidelberg), Dr. D. C. Tozer and Prof. Harold Urey (U.S.A.).*

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, W.1), at 5.30 p.m.—Mr. J. E. Clegg: "The Navigation of Satellites and their Launching Vehicles".

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "How Should Engineering Education Take Account of Developments in the Newer Materials?—Item 1, Plastics".

Saturday, January 19

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. Eva Crane: "The World of Bees and Beekeeping".*

Monday, January 21

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. Peter Salway: "Exploring the Roman Fenland".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. P. C. Clemmow: "Magnetohydrodynamic Waves in the Ionosphere".

INSTITUTE OF METAL FINISHING (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. B. E. Bunce: "Drying of Electroplated Parts".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at Enfield Technical College, Queensway, Ponders End), at 7 p.m.—Dr. A. G. Maddock: "Actinide Chemistry".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT (with an honours degree in biochemistry or equivalent in AGRICULTURAL BIOCHEMISTRY—The Secretary, The University, Aberdeen (January 17).

UNIVERSITY RADIATION PROTECTION OFFICER (with a good honours degree, together with experience in work involving ionizing radiations); in addition to radiation protection duties, the Protection Officer will be expected to undertake a limited amount of teaching and/or research duties—The Registrar, The University, Liverpool, quoting Ref. No. CV/231/N (January 19).

ASSISTANT LECTURER (with an honours degree in chemistry or agricultural chemistry or equivalent, and preferably experience in biochemistry and/or animal nutrition) IN AGRICULTURAL CHEMISTRY, for duties which include lecturing and practical teaching to degree and diploma students and some advisory work—The Secretary, School of Agriculture, West Mains Road, Edinburgh (January 23).

ASSISTANT LECTURER or LECTURER IN PURE MATHEMATICS—The Registrar, The University, Sheffield (January 24).

LEVERHULME STUDENT (with a postgraduate diploma in chemical engineering or equivalent qualifications) IN CHEMICAL ENGINEERING—The Registrar, King's College (University of London), Strand, London, W.C.2 (January 25).

PRINCIPAL SCIENTIFIC OFFICER (with a first- or second-class honours degree, evidence of high scientific calibre in locust or allied research, and considerable experience of control in the field) to take charge of the Field Research Section in the Anti-Locust Research Centre, London—The Civil Service Commission, 17 North Audley Street, London, W.1, quoting Ref. S/5603/63 (January 25).

LECTURER IN PHYSICS—The Registrar, King's College (University of London), Strand, London, W.C.2 (January 31).

READER (with considerable research experience, preferably in solid state physics or in biophysics) IN PHYSICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (January 31).

SENIOR LECTURER (with a registrable medical qualification, preferably a higher qualification, and teaching and research experience in general medicine) IN MEDICINE at the University of Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 31).

EDWARD A. DEEDS JUNIOR FELLOW FOR RESEARCH IN ENGINEERING, CHEMISTRY, PHYSICS, MATHEMATICS or any cognate subject—The Secretary, University of St. Andrews, Queen's College, Dundee (February 2).

SENIOR LECTURER or LECTURER (candidates for the senior post should have several years experience of teaching and examining in botany in an academic institution) IN BOTANY at University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 2).

SENIOR LECTURER or LECTURER (with research qualifications in analysis) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of North Wales, Bangor, North Wales (February 2).

EXPERIMENTAL OFFICER (preferably with experience in bacteriology), to assist in phytoplankton and microbiological research—The Director, Scottish Marine Biological Association, Marine Station, Millport, Isle of Cumbrae, Scotland (February 8).

LECTURER IN PURE MATHEMATICS, and a LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Manchester 13 (February 9).

CHAIR OF CHEMISTRY; CHAIR OF ZOOLOGY; CHAIR OF BOTANY; and CHAIR OF GEOGRAPHY at Fourah Bay College (The University College of Sierra Leone)—The Secretary, University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 15).

SENIOR LECTURER or LECTURER (with an appropriate honours degree or equivalent qualifications; and a higher degree for appointment as Senior Lecturer) IN MATHEMATICS at Wollongong University College, The University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and The Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (February 15).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN PHYSICS, CHEMISTRY, BIOCHEMISTRY, ENGINEERING, METALLURGY and PHARMACOLOGY or any related subjects—The Registrar, The University, Liverpool, quoting Ref. No. CV/234/N (February 23).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, CHEMICAL OCEANOGRAPHY, ENGINEERING or PHYSICS—The Secretary and Registrar, The University, Southampton (February 28).

LECTURER IN PURE MATHEMATICS—The Secretary, The Queen's University, Belfast, Northern Ireland (February 28).

LECTURER (medically qualified) IN BACTERIOLOGY IN THE DEPARTMENT OF MICROBIOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (February 28).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN CHEMISTRY, PHYSICS, METALLURGY, ENGINEERING, GEOLOGY, AGRICULTURAL SCIENCE or related subjects—The Registrar, The University of Wales, University Registry, Cathays Park, Cardiff (March 4).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, ENGINEERING, PHARMACOLOGY or PHYSICS—The Secretary, Royal College of Science and Technology, Glasgow (March 5).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, ENGINEERING, PHARMACOLOGY, PHYSICS or CHEMICAL TECHNOLOGY (Chemical Engineering)—The Secretary, The University, Edinburgh (March 15).

ASSISTANT PHYSICIST (with a B.Sc. or higher degree) with the Wellington Hospital Board, Wellington, New Zealand—The High Commissioner for New Zealand, New Zealand House, 415 Strand, London, W.C.2.

BIOCHEMIST (graduate, with an honours degree in chemistry) IN THE CHEMICAL PATHOLOGY DEPARTMENT, for duties which will include routine investigation and participation in research—The Senior Consultant Pathologist, Queen Elizabeth Hospital for Children, Hackney Road, London, E.2.

BIOCHEMIST (probationary or basic grade) (with a first- or second-class honours degree in biochemistry or chemistry, or equivalent qualifications) IN THE DEPARTMENT OF PATHOLOGY—The Group Secretary, The Royal Hospital, Wolverhampton.

DEMONSTRATORSHIPS, RESEARCH ASSISTANTSHIPS; SCHOLARSHIPS, FELLOWSHIPS, BURSARIES, and STUDENTSHIPS IN THE DEPARTMENT OF CHEMISTRY, for students working for the Ph.D. degree—Prof. F. L. M. Pattison, Head, Department of Chemistry, University of Western Ontario, London, Ontario, Canada.

GRADUATE RESEARCH ASSISTANT, to work on the chemistry of medicinal natural products—Dr. G. E. Francis, Department of Biochemistry, The Medical College of St. Bartholomew's Hospital, Charterhouse Square, London, E.C.1.

LECTURER IN ASTRONOMY, to establish a small department—The Principal, Victoria College, Victoria, B.C., Canada.

MIDLAND SILICONES RESEARCH STUDENT IN INORGANIC CHEMISTRY, for work which will involve the preparation and study of new types of compounds containing silicon—The Professor of Chemistry, Westfield College (University of London), Hampstead, London, N.W.3.

NATIONAL RESEARCH COUNCIL and other POSTDOCTORAL FELLOWSHIPS TENABLE IN THE DEPARTMENT OF PHYSICS—Prof. M. J. Johns, Chairman, Department of Physics, McMaster University, Hamilton, Ontario, Canada.

PHARMACOLOGIST or PHYSIOLOGIST (with an honours degree), to study active polypeptides in acute parasitic infections—The Administrative Secretary, School of Tropical Medicine (University of Liverpool), Pembroke Place, Liverpool 3.

PHYSICIST or ELECTRONIC ENGINEER (honours graduate) IN THE DEPARTMENT OF MEDICAL PHYSICS (University of Edinburgh and South-Eastern Regional Hospital Board), to work on a variety of electronics and instrumentation problems in the field of medical diagnosis and research—The Secretary, South-Eastern Regional Hospital Board, 11 Drumsheugh Gardens, Edinburgh 3.

PROFESSOR OF PHYSICS or ASSOCIATE PROFESSOR OF PHYSICS (with a strong background in the theory of atomic and molecular spectra, electron collision processes, etc.)—The Director, Geophysical Institute, Box 938, College, Alaska, U.S.A.

READER (with substantial research experience) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—Dr. J. H. Calderwood, Royal College of Advanced Technology, Salford, Lancs.

RESEARCH FELLOW IN NUCLEAR PHYSICS, for work at high or low energies—The Assistant Registrar, Faculty of Science, The University, Edgbaston, Birmingham 15.

RESEARCH STUDENT (with a good honours degree or G.R.I.C.) IN THE DEPARTMENT OF CHEMISTRY, for work on catalytic organic reactions—Dr. D. Bryce-Smith, The University, Reading.

SENIOR PHYSICIST—The Personnel Officer, St. Bartholomew's Hospital, London, E.C.1.

SENIOR TECHNICIAN (with technical experience in histology, or an interest in assisting with general animal experimental work) IN THE HENRY DALE LABORATORY FOR EXPERIMENTAL SURGERY at the Royal National Orthopaedic Hospital, Stanmore—The Secretary, Institute of Orthopaedics, 234 Great Portland Street, London, W.1.

EDUCATION BY MASS MEDIA IN EMERGENT COUNTRIES

THE recently issued report of the Council for Technical Co-operation in South and South-East Asia on Techal Co-operation under the Colombo Plan in 1961–62* knowledges the help given by several private American undations, such as the Ford Foundation, in rekindling mmunity spirit and co-operation in depressed neighurhoods of large cities in India and Pakistan, and the ia Foundation in promoting social science research in kistan and basic agriculture and rural development in etnam. Particular reference is made to the Rockefeller undation's support of a programme for the improveent of English language teaching in the Philippines gun in 1957, for which a second grant of 430,500 dollars s been given. A major feature of the report is the phasis placed on technical training, and here even more an in the provision of experts and equipment the uestion of effective communication is all-important.

A survey of training facilities at the technician-level in e area made in 1960–61 (the Mills Report) and financed a generous grant from the Ford Foundation has not ly focused attention on the urgent need to improve the tput of middle-grade technicians in the area but has o emphasized the need to eliminate or minimize the ychological, administrative and other difficulties in the ay of maximum utilization of training facilities in the ea. Effective communication is no less important in inging home to the leaders and people of the countries the region the nature of the challenge which the accelered economic development they are seeking represents. e necessary conditions for a fuller and better life for e peoples of the area cannot be created without a wideread understanding of this moral challenge, any more an the shortage of trained manpower required for a gher tempo of economic development can be achieved ithout efficient communication.

In this context it should be noted that the report gards education as probably the most important single ctor in achieving rapid economic development and chnological progress, and that there has been a sigficant increase in the sharing of training facilities within e area—on which the Mills Report already mentioned rected particular attention. This Report, moreover, while ncerned especially with the economic advantages of ilizing skill and knowledge already available within the ea instead of seeking assistance from outside, did not il to emphasize the need to take due account of human ctors such as traditions and prejudices. This is all part the general problem of effective communication, and it against this background that the establishment of the homson Foundation is to be especially welcomed.

This Trust was established by Mr. Roy Thomson in ovember by a grant of £5 million essentially to enable ritain, with her facilities and wide experience through e Commonwealth, to help the developing countries train emselves in establishing effective media of mass comunication—extensive enough, and of adequate quality, satisfy the rising demand. The Trustees, of whom Lord Kilmuir is chairman, include Field Marshal Lord Alexander, Lord Williamson, Mr. K. R. Thomson and Mr. J. M. Coltart, and the Trust Deed defines the purpose of the Trust as "the provision of facilities for and the encouragement of education and technical and vocational training and for the dissemination of news and information regarding the affairs of the world for the purpose of promoting the general advancement of knowledge and mental and spiritual enlightenment of all peoples with a view to achieving closer understanding between them and encouraging and enabling them to play an informed and responsible part in their own affairs and in the affairs of the world". It includes also the provision, or maintenance for this purpose, of schools, technical colleges, training centres and other educational establishments and facilities, the provision of educational books, lectures, television and wireless programmes, and all other media for the dissemination of learning, and the provision of courses and facilities for training teachers, journalists and others employed in any industry or service connected with the dissemination of news or information to the public.

That the Trust is particularly intended to help the emergent nations is made clear in a leaflet which outlines the purpose and plan of the Trust. In the belief that education is the greatest need of the developing nations and that effective use of mass media is the best means of providing the education that will enable these hundreds of millions of normally backward peoples to make as much progress in the next decade as the Western World has made in the past century, the establishment of an honest information and truthful Press allied with radio and television stations, magazines and books, all imbued with the essential quality of integrity, is seen as the primary need. Illiteracy and isolation make conventional methods of teaching inadequate and too slow; television, radio and newspapers are regarded as the necessary effective weapons.

It is, of course, the urgency of the situation that leads the Foundation to stress the importance of the mass media, and the real purpose is to have available the literature that will be required by the millions of youngsters now learning to read and write as new countries adopt compulsory education. Moreover, while aid in this field requires experience as well as capital, it needs also honesty of purpose, and here the private foundation has an overwhelming advantage over Government aid. Television cannot build a relation of trust with the viewer unless it is seen to be disinterested and at the service of the public. For this reason the Foundation intends to devote much of its resources to television as an instrument of education, although it is also hoped to enable the new nations to develop their own Press and television.

The new television services overseas will need trained men from their own countries, and for these the Thomson Centre, which is being established near Glasgow, will primarily cater. It is designed so that the actual studios used in overseas operations are exactly recreated and trainees will take courses in programming, engineering and administration. It is also proposed to supplement the local training of journalists by co-operating in the establishment in Britain of a residential training centre near Glasgow, such as the National Council for the Training of Journalists advocates, where aspiring journalists can receive intensive training. It is also proposed to make available highly qualified journalists, newspaper technicians and administrators to assist countries in training the requisite personnel for establishing and developing newspapers, magazines and similar periodicals. The Foundation will itself produce television programmes, particularly for education, and make available television engineers, producers, etc., to assist in training the requisite personnel for establishing and developing television services. Besides assisting in the provision of all kinds of educational literature, including text-books, the Foundation will offer scholarships at British and Commonwealth universities to promising students expecting to take up careers in mass media in the hope that students who thus benefit from a wide and deep education will be firmer in their attachment to freedom and integrity and more fully aware of their responsibility to the public.

---

* Department of Technical Co-operation. Technical Co-operation under Colombo Plan: Report for 1961–62 of the Council for Technical Cooration in South and South-East Asia, Colombo, October 1962. Pp. 92. ondon: H.M.S.O., 1962.) 5s. net. See also p. 237 of this issue of ture.

The magnitude of the contribution which the proposed Trust will make to a field as yet comparatively neglected may not be immediately apparent. However, the British Government's contribution under the Colombo Plan alone in 1961–62 of some £1,572,000 included £362,571 for equipment, and the £844,000 for trainees and £365,000 for experts covered 80 new training places out of 273 in the field of transport and communications under the Plan, which also supplied 253 experts in this field, of which telecommunications can only be a fraction; it is obvious that the Foundation could make a very significant contribution to a field which is still comparatively neglected. Moreover, technical assistance under the plan in this field is concerned in the main with the provision of equipment and experts for the actual transmission rather than with programmes and the effective use of the means of broadcasting and television.

It should not be forgotten that there is also the Overseas Visual Aids Centre, sponsored jointly by the Government and the Nuffield Foundation, which was established some four years ago with a grant from the Foundation, and in December 1961 the formation of the Centre for Educational Television Overseas, with matching contribution from the Nuffield Foundation and the Government of £100,000 over five years, and substantial help from the British Broadcasting Corporation, the independent television companies, the Gulbenkian Foundation, industry and commerce, was announced by the Secretary for Technical Co-operation. The main function of this Centre for the next five years is to be a clearing house for requests for programme material, advice and training facilities from any country that wishes to take educational television seriously. The Centre will help to meet these demands by arranging training courses, and by adapting or producing television material which will enable the teacher in the overseas studio to make the most of his own gifts and local knowledge.

The Thomson Foundation contemplates working in this way and over a much wider field. However, it should not be thought that the Foundation is limited to work in the British Commonwealth or even in under-developed countries. It is empowered to concern itself with raising standards of journalism in the Press and on television anywhere in the world. From what Lord Kilmuir has already written, the Foundation is seeking to help existing bodies in Britain to foster high standards of journalism and responsible use of the film and television screen and mass media generally—its scope could range over a the activities covered by the conference on "The Proble of Communication: Science and Industry" arranged April 1961 by the Department of Scientific and Indu trial Research*. If primarily concerned with educatin through informing the general citizen rather than th technologist, the scientist or the industrialist, the problem of communication often have much in common, and muc that was said in the discussions following the papers Dr. M. R. Hopkins on information as an educationa problem, the late Mr. P. Cudlipp on industry, science an the Press, Mr. F. Anstey on films to illuminate an persuade, or Dr. T. Margerison on television, is highl relevant to the work of the new Foundation.

It is well, therefore, that the Trustees of the Thomso Foundation propose to make the fullest possible use o joint effort and to stimulate other developments by othe people. The Foundation is now a pioneer effort thoug it will be working in a field comparatively neglected an undeveloped. Furthermore, little is known how permanent is the impact of educational broadcasting whether by sound or television, and there may be som danger that the urgency of this immediate problem o educational development in the emergent countries ma lead us to use or rely on the mass media to an exten that fuller knowledge will indicate to be unjustified However, this is no reason for rejecting the aid which th mass media can give. It points rather to the vital need fo co-operation with others working in this field and b other means, to the importance of circumspection and above all, to the urgency for further research into ne methods of teaching, their use and impact. If the aim of the Thomson Foundation are to be realized swiftl and fully, much will depend on the scale and urgenc with which educational research, and especially that concerning the use of the mass media, is carried out. Abov all, it should be remembered that high standards of professional conduct and practice are not rapidly achieved They take time to grow. It is not sufficient to propagat the idea of impartial and disinterested news, of tellin the truth in the belief that it will prevail, unless we see simultaneously to foster the climate of opinion in whic high standards of professional conduct are respected an encouraged.

COMPTON LECTURES ON THE UNIVERSE

The Universe

By Dr. Otto Struve. (Karl Taylor Compton Lectures 1959.) Pp. ix+159. (Cambridge, Mass.: The M.I.T Press, 1962.) 4.95 dollars.

SINCE their inception in 1957 the Karl Taylor Compto Lectures in honour of the ninth president of th Massachusetts Institute of Technology have attracted distinguished group of lecturers—Bohr, Struve, Lwof and Rabi. This book is the second series of six lecture delivered in 1959 on "The Universe" by Dr. Otto Struve

The audience must have been thrilled and stimulate by Struve's six talks. They are so beautifully done tha the speaker obviously had a particular interest in hi subjects. Indeed, Struve makes it clear in his preface tha the lectures were not intended to give a complete accoun f astronomical progress, but that the subjects were hosen because the topics were of special interest to him. e begins with the origin and evolution of the solar ystem, then deals with stellar evolution, galaxies, radio stronomy, binary stars and variables, and concludes with talk on man and the universe. The first two of these ctures appear to include the material which Struve ave in the two Condon Lectures in 1958.

Two features exemplify the lectures. They are sprinkled ith elementary calculations of orders of magnitude which nderline the essence of the problems considered, and their utlook is entirely contemporary. Although the book an be read without any particularly deep knowledge of stronomy, it is too specialized in its selection for those ho might expect the broad treatment indicated by the itle. For example, 8 of the 25 pages devoted to radio stronomy are concerned with flare stars of the *UV Ceti* ype and a discussion of the possibility and consequences f detecting radio emission from them, and a further third f the chapter describes the condition of the central region f the galaxy as observed by the Leyden 21-cm work nd the 4-cm observations at Green Bank. Both these opics are of great importance, but readers from other isciplines might well form an odd impression of the alance of the researches of the world community of radio stronomers. This chapter contains the somewhat parochial claim that in his pioneer pre-War observations Reber "was thus first in having discovered discrete radio sources other than the so-called Sagittarius A source. . . ." This can be allowed only as hindsight. Neither Reber nor any other astronomers recognized the significance of the concentration of the radio isophotes in Cygnus and Cassiopeia in terms of the reality of a discrete or localized source, until Hey and his colleagues observed the intensity fluctuations and the Cygnus source was afterwards isolated by Bolton and Stanley in Australia.

The futuristic outlook which Struve displays in the last chapter—and indeed throughout the book—is remarkable in a scientist of his generation. There is no doubt that the pleasure which Struve gave to his audiences will now be communicated to a wide circle through the publication of this book.

A. C. B. Lovell

VEMA OCEANOGRAPHIC RESEARCH SERIES

Abyssal Crustacea

By J. Laurens Barnard, Robert J. Menzies and Mihai C. Bačescu. Pp. ix+223. (New York and London: Columbia University Press, 1962.) 10 dollars; 80*s*.

OVER the past eight years a major part of the Lamont Geological Observatory's research programme has been based on data gathered by the Columbia University research vessel *Vema*. Her seventeen wide-ranging cruises, primarily for the study of marine geophysics and submarine geology, were planned to permit of co-operation with vessels and scientists of other nations; and future expeditions are envisaged. Limited attention was also given to areas of oceanography and marine biology with an application to the main fields of interest. Previously, work done on the *Vema* was reported in standard scientific journals. Now, through the generosity of the Trustees of the Vetlesen Foundation, funds are available for the publication of a new *Vema Research Series* of reports.

It is rather odd, therefore, to find this, the first number of the series, masquerading as a separate book with the misleading title of *Abyssal Crustacea*. It is not a general account of abyssal crustaceans as the unwary might be led to suppose. Indeed, such a work would be premature when much of the material collected on recent deep-sea expeditions still awaits determination. Nor does it deal with more than a fraction of the astonishingly rich *Vema* collections of abyssal amphipods, isopods and cumaceans. This in no way detracts from the merits of these three first reports, each by a competent specialist.

Dr. Laurens Barnard's paper entitled "South Atlantic Abyssal Amphipods collected by *R. V. Vema*" is the first of a series on the extensive amphipod collections from several abyssal areas such as the Caribbean, eastern Pacific, Indian Ocean and Red Sea. He briefly discusses adaptations to abyssal conditions, the food of some abyssal species, endemism in the deep-sea, the relationship of the abyssal to the shallow-water fauna, and lists all previously recorded abyssal species of Amphipoda from depths exceeding 2,000 metres. Nine new genera and thirty-eight new species of Gammaridea are described and fourteen other species are recorded.

Dr. Menzie's "The Isopods of Abyssal Depths in the Atlantic Ocean" covers a wider region and includes Russian data from the Arctic polar basin. A reasonably complete list of previously known abyssal benthic isopods from all oceans is given by region and the "excluded probable pelagic species" are listed separately. Nine new genera and 107 new species are described and 69 other species are included. The ecology, zoogeography and phylogenetic relationships of these isopods will be dealt with in a subsequent report.

Dr. Bačescu's short paper is devoted to a study of the abyssal cumacean genus *Makrokylindrus* Stebbing; five new species are described in detail, and a key to the determination of the twenty-five species at present assigned to this genus is appended.

The price seems reasonable for a bound volume copiously illustrated with excellent line drawings. Other numbers will be awaited with interest.

Isabella Gordon

PROBLEMS AND RESEARCH IN THE HISTORY OF SCIENCE

History of Science

An Annual Review of Literature, Research and Teaching, Vol. 1. Edited by A. C. Crombie and M. A. Hoskin. Pp. vii+133. (Cambridge: W. Heffer and Sons, Ltd., 1962.) 30*s*. net.

THE first volume of this annual review appeared within a few days of the launching of the first issue of the *British Journal for the History of Science*. This coincidence may be welcomed in the light of the increasing interest in the subject throughout Britain. The scope of *History of Science* is revealed in its sub-title: *An Annual Review of Literature, Research and Teaching*. The editors point out that the aim of the *Annual* is to perform a function not systematically carried out by any of the existing journals in this field. "It is intended not to be a competitor to these older journals in publishing original historical articles, but to complement them by systematically providing critical reviews both of problems and materials for research in specific fields and of recent publications."

A study of the first volume shows how ably the editors have achieved their objective. In the first half of the book six articles appear covering a variety of problems: "The Physical Sciences in the First Half of the Nineteenth Century: Problems and Sources" by L. Pearce Williams; "The Expanding World of Newtonian Research" by D. T. Whiteside; "Science and Technology in the Eighteenth Century" by D. S. L. Cardwell; "The History of Medicine in 1960–61" by F. N. L. Poynter; "History and Philosophy of Science at Oxford" by A. C. Crombie; "History and Philosophy of Science at Cambridge" by Gerd Buchdahl. An example of the critical approach, and its value, may be seen in the following quotation from Dr. Whiteside's contribution: "The fallacy of all summaries of the history of ideas by the analysis of Great Books is that the great thinker is made to stand or fall by one expression of his thought, and we see none of the hesitancy, vagueness and quick changes of opinion as his thought develops".

Not least important of these articles are the two dealing with the history and philosophy of science at Oxford and Cambridge respectively. They provide thought-provoking themes especially with regard to the relation of history and philosophy of science to other disciplines. Indeed, they raise questions of fundamental importance in the teaching of students and the training of future instructors.

The remainder of the book is devoted to essay reviews of nine books. Here again the value to the reader is the critical nature of the review, which may extend to as many as ten pages. Shorter reviews of some twenty other books occupy the last few pages of the volume, which also include a note on the importance to historians of science of manuscript records of scientists, a list of doctoral theses in preparation, and of books received.

The book is well—and very legibly—produced, and fills an obvious gap in the record of the history of science.

H. D. ANTHONY

GENETICS AND HUMAN BEINGS

Genetic Mechanisms in Human Disease

Chromosomal Aberrations. Edited by M. F. Ashley Montagu. Pp. xviii+592. (Springfield, Ill.: Charles C. Thomas; Oxford: Blackwell Scientific Publications, 1961.) 156s.

AN explosive burst of fundamental discoveries about abnormal chromosome constitutions in human beings occurred in 1959–60, as a consequence of the new techniques for short-term cell culture (bone marrow, skin and peripheral blood). A collection of these papers has been made by M. F. Montagu, and they make most exciting reading.

Fifty-five papers have been collected from various international journals, and as one might have expected, more than half of these appeared in *The Lancet*. But a few are from less-accessible sources, and one must welcome this effort at bringing these together into one handy volume.

Evidently, the responsibility of the editor is to select the most important and fundamental discoveries, to put them in a sequence for the most coherent reading, to select, if necessary, such additional papers from this field or closely related fields (medicine) which may make the presentation fuller and place the discoveries in their proper relief, and lastly, to see that the selected papers are presented in the best way, technically.

Although the editor of the present volume has collected most of the basic contributions throwing light on the chromosomal origin of a variety of 'diseases' in man, one cannot help feeling that a better collection might have been made. Some papers have been included to the embarrassment of the authors who no longer would subscribe to their suggested interpretations. Other articles discussing topics without sufficient general knowledge of genetics and cytology should not require a repeated publication, while other, more informative discourses, well deserve this repetition.

The papers appear almost chronologically, which tends to destroy the possible cohesion one might have obtained by bringing them into some sectional arrangement. An introductory paper by K. Hirschhorn and H. L. Cooper attempts to give enough basic information so that the uninformed reader may understand the following pages.

It is remarkable that so few of the workers in the field of human cytology have any experience from plants or lower animals in cytology and genetics. This has led to a number of suggestions and interpretations strangely unreal to the cytogeneticist—suggestions which since the papers appeared have been utterly refuted. Similarly, terminology in the non-cytological papers is not always *au pair* with present-day concepts in cytogenetics. Detailed criticism is, however, beyond the scope of this review.

In spite of some lack of critical judgment in selecting the papers, the fundamental contributions are so exciting and outstanding that they override the few less illustrious ones. The discoveries of trisomy in mongolism, the Turner and Klinefelter syndromes explained as sex chromosome aberrations, the superfemale, the chromosome constitutions of true intersexes and of testicular feminization, a new trisomy syndrome (chromosome 18) previously not recognized as a clinical entity, Barr's work on sex chromatin, and finally, the chromosomal basis of chronic myeloid leukaemia—all represent outstanding contributions to our knowledge.

One cannot but welcome this effort of making available in a single volume so many of the original articles, and the type and illustrations surpass in many instances the original presentations.

S. MULDAL

NOT ALL MY EYE

The Eye

Edited by Hugh Davson. Vol. 1: Vegetative Physiology and Biochemistry. Pp. xv+440. 100s. net. Vol. 2: The Visual Processes. Pp. xviii+796. 157s. 6d. Vol. 3: Muscular Mechanisms. Pp. xiv+323. 86s. Vol. 4: Visual Optics and the Optical Space Sense. Pp. xvii+432. 100s. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.)

THE Academic Press assembled a galaxy of stars, planets and satellites and produced this useful source book on the eye. Divided into four volumes covering ocular physiology and biochemistry, vision, intrinsic and extrinsic ocular muscles, and optics and space perception respectively, the book is further subdivided into separate sections, written by eighteen authorities. One rejoices over the splendid section on ocular protection—much neglected in other comparable texts, and happily plods through the lucid pages on optics. The sections on the cornea and intra-ocular pressure show far and away the best balance, with those on electrophysiology and photobiology of the visual pigments as runners-up. The difficult tasks of describing anatomical, embryological and comparative ideas have also been tackled, although one begins to suspect in Volume 1 that collaboration between the sundry authors might have been closer: by the time one has finished with Volume 4 this suspicion has matured to certainty. Excellent though the work is, it is incomplete. The eye has been atomized, and no one has bothered to pick up the pieces. C. P. Snow is fortunate in having only two cultures to worry about. In this text the eighteen authors barely understand one another's language. The reader may be able to overcome these barriers, though when he reaches the discussion by Pirenne and Dartnall respectively on the absorption of light he will be in as many difficulties as when he juxtaposes what Alpern and van Heyningen have to say on the crystalline lens.

Granit's contribution to Volume 2 is magisterial. Here writes not only a research worker but also a teacher. The introduction to the visual system (not referred to in the section on anatomy in Volume 1) is classical, and that to the electrical behaviour of the visual system a model. Anyone unfamiliar with the detailed ideas underlying many of the experiments mentioned will be grateful to the writer for his pains, although his ready acceptance of some criteria—like the amplitude of the *b*-wave when the whole ERG should be scrutinized—may one day necessitate some changes in emphasis.

One is a little uncertain as regards the audience for whom these volumes are destined. This is a common difficulty. Thus the optics section contains ophthalmological applications, and the sections on the lens (the approach to which could be more up to date) and on binocular vision have also much to interest the clinician. If knowledge of the eye is assumed, the section on anatomy and embryology is redundant; if it is not assumed, more information would be helpful—especially on the lateral geniculate body and beyond.

Most of the sections are thoughtful, and the reader is unlikely to find any part dull. He may, however, differ from the authors in opinion or in interpretation, as when Ogle reaches a questionable conclusion from a wholly inadequate theory of the Pulfrich effect. Again, Pirenne, quoting Fick (with a faulty reference), relates chromatic aberration of the eye to visual sensitivity, but fails to note that his argument need not apply to hypermetropes. The section on vision is bedevilled by deference to rather ambiguous results obtained by fundus reflectometry, and unnecessary repetition of the associated fallacious statements. Turning to Volume 3 the reader will readily notice that Alpern soft-pedals acceptance of Fincham's capsular theory of accommodation because we know of no quantitative data on capsular elasticity, yet peddles Gullstrand's theory although we have no quantitative data on the functional size of the ciliary muscle. This is no isolated example of bias, and the reader may well decide that, in this section, the references form the focal point of interest. The volumes reveal several lacunæ: Stark's and Bleichert's important work on the pupil is forgotten, nor is there any mention of Stone's on lens and eye implants, or of Gaze's experiments on optic nerve regeneration. The recent work on the extent to which *in vivo* photochemistry governs the gamut of visual intensity is not discussed, nor is the fact that the number of retinal receptors stimulated is more important than retinal area as shown by Ten Doesschate.

When these points are made, however, all that is adverse has been said. When they have been considered, one may almost find oneself in a position to answer the question: Who will read it? Biochemists will scarcely look at the chapters on biochemistry—of interest to other specialists—but will learn a lot from the other sections. Visual psychologists will (please!) read Volume 2 before embarking on their next experiment. Ophthalmic surgeons will want to browse through Pirenne's chapters before interpreting 'normal' visual fields. In short, there is a bite here for everyone. If the connoisseur gets up from table without the fond illusion that he has been served a meal at the Parisian Savarin, at least he will not feel starved.

R. A. Weale

SUMMIT DISCUSSIONS ON DEOXYRIBONUCLEIC ACID

Deoxyribonucleic Acid, Structure, Synthesis and Function

Proceedings of the 11th Annual Reunion of the Société de Chimie Physique, June 1961. Pp. xi+235. (Oxford, London, New York and Paris: Symposium Publications Division, Pergamon Press, 1962.) 60s.

THE organizers of this very successful conference deserve special credit on two counts: first, for holding their meeting in such an original place, in the bracing mountain air of Haute-Savoie; and secondly, for initially publishing the proceedings (in the *Journal de Chimie Physique*) only a few months after the meeting. On the second count, it is therefore lamentable that the publishers of this bound edition, which differs mainly from the earlier proceedings in having an index, should have taken a further nine months or so to produce it. The interest of the volume will thus be to some readers mainly historical, since the broad field to which it refers has undergone a major convulsion since the papers were presented. There was at that time no public announcement of the dramatic results obtained in the United States on protein synthesis with synthetic polymers as 'messenger molecules'; these results added a great deal of knowledge, and helped to confirm what were previously only hypotheses, about the way in which the genetic code is translated from a sequence of purine and pyrimidine bases along a nucleic acid chain, into a sequence of amino-acids in a protein.

The volume is redeemed from obsolescence by the high quality of the papers it contains. They are written by an exceptionally representative group of authors, and most aspects of DNA are covered. The thorny question of whether DNA molecules contain sub-units is discussed by Sadron, while Levinthal shows that the DNA of bacteriophage *T2* can be isolated in a single giant molecule. Wilkins reviews X-ray diffraction work, and explains why the Watson–Crick scheme for purine–pyrimidine base pairs is preferable to various alternative schemes. Luzzati reports low-angle X-ray diffraction. Theoretical papers deal with the electronic structure of DNA bases, and with their interaction when stacked together in a helix. Hurwitz *et al.* contribute a paper on the biosynthesis of RNA (ribonucleic acid) by DNA—part of an initial trickle of papers, now become a raging torrent, which has confirmed beyond reasonable doubt the first half of the famous central dogma which says that 'DNA makes RNA'. This dogma, first publicized by Crick, has always aroused strong feelings in the breasts of nucleic acid workers, either of enthusiasm or of irritation. The second half of the dogma—'and RNA makes protein'—was really beyond the scope of the conference, but was implicit in much of what was said. Its proof or disproof has absorbed the energies of an increasing number of workers since then.

The ingenious application of physical chemistry to DNA is described in a paper read by Marmur: quite simple techniques have been used to make hybrid molecules of DNA, in which one of the two strands comes from one strain of bacteria and the other from a related strain. The bearing this work has on genetic crossing-over is obvious. In this connexion, Stahl provided what appeared at first to be intelligent light relief by inviting the conference to consider a hypothetical chromosome structure consisting of a series of linked circles. When the amusement had subsided it became clear that nobody could seriously fault the model, and it remains open for further study. Work on many other important topics was also reported, including the biosynthesis of DNA and the action of various external agents on DNA structure. This latter aspect has been studied with a wide variety of techniques, too numerous to list here. The volume contains papers from many workers prominent in this field.

One may reflect while looking down the list of participants in this conference on the remarkable variety of backgrounds which they display. The conclusion seems inevitable that really comprehensive work on nucleic acids and their function cannot be expected to flourish easily in universities where all the research has to be fitted into compartments labelled "Chemistry", "Biology", "Physics" and so on. In Britain, unfortunately, such universities are still very much in the majority.

M. Spencer

MOLECULAR BIOLOGY FOR THE CYTOLOGIST

Organization of Cellular Activity

By Prof. Ch. M. A. Kuyper. Elsevier Monographs: Biochemical Section. Pp. x+272 (135 figures). (Amsterdam and New York: Elsevier Publishing Company, 1962.) D.fl.20.

THE author has made a valuable attempt to bridge the gap between morphological observations and biochemical data, the accent being placed on cell physiology. Prof. Kuyper points out that morphology and biochemistry should supplement each other, and he tries to break down the still existing barriers of mistrust between morphologists and biochemists. He places the emphasis on what is now being called 'molecular biology' rather than on 'classical' biochemistry: little is said about the description of natural substances, except, of course, nucleic acids and proteins. If Prof. Kuyper's book succeeds in breaking down existing barriers between cytologists and molecular biologists, it will have served a most useful purpose. The best way, for molecular biologists, to get the confidence of the cytologists is to show them that the structure of the nucleic acids and their role in the synthesis of specific proteins can be understood without too much effort. Cytologists must realize that the concepts of molecular biology must be transferred from the '*E. coli* ± phage' system to real cells.

The book begins with a general introduction: the main cytochemical methods, the chemical composition of the cells (with the accent placed on nucleic acids and proteins, as already mentioned) and a brief description of the cell are successively examined. Chapter 2 deals with the production and storage of energy: ATP, enzymes, co-enzymes, glycolysis, tricarboxylic acid cycle, oxidative phosphorylation, mitochondria, hexose-monophosphate shunt, photosynthesis and chloroplasts are well presented. Chapter 3 is devoted to the "organization of frontiers": the main topics are, of course, the cell membrane, its permeability, active transport, pinocytosis and related processes. In Chapter 4 the author deals with protein synthesis: the role of nucleic acids and ribosomes, the genetic control, the secretion of proteins—including the possible role of the Golgi apparatus—are discussed. Chapter 5 (the organization of mechanical activity) is devoted to the structure of muscle and the mechanism of its contraction; cilia, flagellæ and the mitotic spindle are compared with muscle cells. The next chapter deals with mitosis and meiosis, chromosomes, DNA structure and reduplication. In Chapter 7, Prof. Kuyper discusses the organization of specificity and diversity: biochemical genetics, transfer of information from the nucleus, the organization of the interphase nucleus, giant and lamp-brush chromosomes, differentiation are presented in little more than 20 pages (excluding the figures). Chapter 8 deals with the organization of regulation (induction of enzymes, regulation of their activity, Pasteur effect, cellular homeostasis, hormonal regulations). The concluding remarks end with the wish that more theoretical chemists and solid-state physicists might become interested in the organization of cellular activity.

The aims of the author are obviously excellent. However, criticisms cannot be avoided: if the presentation of the book (there are many good electron micrographs) is pleasant—despite too many misprints—its reading must often be confusing for beginners, university students in particular: for example, mitochondria, Golgi, periodic acid Schiff Feulgen 'coloration', DNA, RNA, RNase, DNase are mentioned on pages 6 and 12; but one must wait until p. 33 before nucleic acids are discussed and until p. 41 before the general morphology of the cell is described. Another very serious drawback—which is admitted by the author himself—is the almost complete absence of bibliography: references are limited to reviews and books, and the reader is left with a dogmatic impression.

There are very few factual errors; but the lack of quotations makes it almost impossible to check doubtful statements. For example, to which species might belong the gastrula, made of 128 cells only, in which nuclear transplantations were made (p. 242): not the amphibian gastrulæ studied by Briggs, King, Moore and Fischberg, I hope. The attitude of the author towards biological and cytological problems is often over-sceptical: he does not believe much in the virtues of histological fixation or autoradiography with tritium-labelled precursors. Although he does not admit it, Prof. Kuyper obviously retains some sympathy for a "vital force". Therefore, viruses—which are not "known" for certain to be "living" —have been barred from the book. It is true that they are "decidedly not cellular in nature", but . . . they multiply in cells and change the organization of the latter after infection. Unfortunately for the author, the book was written and published a little too early: messenger RNA is barely mentioned, the Monod–Jacob theory of gene regulation is not discussed and the work on coding of Nirenberg and the Ochoa school was not yet known.

But Prof. Kuyper is certainly not to blame, if molecular biology is advancing at full speed, too fast for writers of scientific books. Despite a number of shortcomings, the present book is very welcome and should interest molecular biologists as well as cytologists.

AIRBORNE RADAR AND WEAPONS SYSTEMS

Airborne Radar

By Donald J. Povejsil, Robert S. Raven and Peter Waterman. (Principles of Guided Missile Design.) Pp. xx + 823. (Princeton, N. J.: D. Van Nostrand Company) Inc.; London: D. Van Nostrand Company, Ltd., 1961., 131*s*. 6*d*.

THE books issued in the series *Principles of Guided Missile Design* are, in many respects, successors to the *Radiation Laboratory Series* of the 1948/49 period. In the early series the emphasis was on the techniques of radar and engineering design details were given, but in this present series the emphasis is on the principles of operation. This volume on *Airborne Radar* is an excellent book, which should be of great value to designers of airborne radar systems and to serving officers, giving them a good insight into concepts of weapon systems.

The mathematical treatment is well handled, and the physical significance is clearly brought out in many examples. The volume is most up to date, and it is probable that because only the general principles of the systems and devices are described, security clearance for publication has been given. There is a possibility that attempts have been made to cover too much ground and descriptions are given of many devices, the omission of which would not have lessened the value of the book.

After briefly describing the general characteristics of radar and the types of operation of which they are capable, the importance of considering radar as a major component in an overall weapon system is stressed. In the example dealing with air interception the inter-relationships of the many sub-systems are examined and the requirements of the air interception radar derived.

The range performances of various radar systems are examined, taking into account the propagation factors, including the effect of the atmosphere and the back-scattering effect of the terrain and precipitation. A concise theoretical treatment is given of signal and noise analysis with many examples. The general properties of many different types of radar are given, and their advantages and disadvantages are clearly brought out.

In the following chapters the principles of operation of the radar system are discussed with the topics including: the receiver; automatic gain control; automatic frequency control; angle stabilization during searching and tracking; automatic angle and range tracking; the microwave properties of aerials, radomes and waveguides; power generation using magnetrons and klystrons; the basic features of display systems and their inter-relation with the human operator; the mechanical design and packaging of airborne equipments. Many chapters are concluded with references to new techniques and devices which may have possible future application. In the final chapter, the application of radar and infra-red radiation is described for use in airborne navigation and air to ground surveillance systems.

R. ASPINALL

AN EXPERIMENT IN SCIENTIFIC COMMUNICATION

By Dr. ALMA HOWARD*

British Empire Cancer Campaign, Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, Middx.

THE large number of papers offered at present-day congresses, and the arrangement of the programme so as to make the contributed material widely available, present a major difficulty for the organization of international meetings. At the second International Congress of Radiation Research, held at Harrogate during August 5–11, 1962, an attempt was made to find a means of solving this problem.

The Congress was sponsored by the Association for Radiation Research. The proposal to hold the Congress in Great Britain was first put forward at a meeting of the Association in September 1959. At that meeting a number of members expressed dissatisfaction with the usual arrangement of the scientific programme at large meetings, in which most of the time is devoted to the presentation of numbers of short papers in multiple parallel sessions. Prof. J. Rotblat suggested that the rapporteur method should be used, and described his experience of it at one or two meetings which he had attended. Members were impressed with his enthusiastic endorsement of the method. The Congress Organizing Committee thus began its work with a recommendation from the sponsoring body to try to devise a plan for the programme which would reduce the number of parallel sessions, and to consider the use of the rapporteur method for this purpose.

In its early meetings some of the advantages and difficulties of the rapporteur method were weighed and discussed by the Committee. It was recognized that some time would be saved by the presentation of papers by a rapporteur. Papers read by their authors could be presented at the rate of four an hour; in a rapporteur session this rate could be increased by a factor of two or perhaps more. It was also recognized that the method had particular advantages for topics of widespread interest which would attract large audiences, and therefore that plenary rapporteur sessions would be appropriate. In an attempt to meet the wishes of the Association, to give the rapporteur method a fair trial, and at the same time to exercise caution by retaining a conventional plan for part of the programme, the Committee decided to devote the five mornings of the Congress week to plenary rapporteur sessions, and to arrange the remaining papers in parallel sessions on the four afternoons.

Radiation research workers all over the world were invited to send abstracts of papers describing their recent unpublished work, on the understanding that if their papers were chosen for the rapporteur sessions they would be asked to submit a full version before the Congress. Abstracts were due by January 15, 1962, seven months before the Congress; most of them arrived by January 25. During February 9–14 fifteen members of the Scientific Programme Committee met at a hotel. Each abstract was assigned to 3–6 members for reading and classification under a number of headings. When all the material was classified, groups of abstracts were selected and examined by small sub-committees of two or three members. In these small groups the subject-matter, scope and pattern of sessions and groups of sessions began to emerge, and the substance and arrangement of the rapporteur programme grew out of the new work submitted by the Congress members. Rapporteurs, all of them workers in Great Britain, were suggested and approached, and abstracts were submitted to them. Usually a few more abstracts were sent to a rapporteur than he was expected to cover, giving him the opportunity to refuse particular papers.

The total number of abstracts received (772) was nearly double the number expected, making both possible and desirable an increased number of rapporteur sessions. Nine separate programmes running in parallel were required on each afternoon, and one of these comprised three rapporteur sessions. Altogether twenty-five rapporteur sessions were arranged, containing initially 387 papers. The number of papers reported on by a rapporteur ranged from ten to nineteen. There were three reasons for putting more papers into each rapporteur's list than had been originally planned. One was the pressure of the number of abstracts submitted; a second was the impression that some of the abstracts represented rather slight pieces of work, which would justify no more than a brief reference; and a third was the expectation that a considerable proportion of authors would fail to submit their papers when requested. This last expectation proved to be exaggerated; in fact, of the 383 papers requested, 314 were received in time to be included in the rapporteurs' reports. Moreover, it became clear that the extent and value of a piece of experimental work is not always explicit in its abstract. The result was that some of the rapporteurs had to deal with a greater bulk of material than they felt was desirable, even though at the start each rapporteur consciously accepted, on the basis of the abstracts, all the papers on which he finally had to report.

Abstracts of all papers, arranged in their sessions, were printed and circulated to all Congress members six weeks before the meeting†. Full papers were requested by June 1, 1962; most had been received by June 15. Rapporteurs were asked to produce the manuscripts of their reports by July 20, and most of them did so. Meetings were arranged between authors and rapporteurs so that questions could be raised before the time of the session. By good fortune, all twenty-five rapporteurs were able to attend the Congress, and to deliver their reports in person. All rapporteur sessions were held in the Royal Hall, Harrogate, with a four-language simultaneous translation service in operation. Each report was scheduled to occupy 30 min of a 1-h session. The remaining time was allotted to discussion. The leading authors of the papers included in the report sat on the platform, and in many sessions their comments were given priority in the discussion. A discussion secretary was appointed for each session, with the duty of writing an account of the discussion for publication in the Congress *Proceedings*, in which the rapporteurs' reports, but not the original papers, will also appear‡.

On the fourth and fifth days of the Congress week, members were asked to write down their comments on the suitability of the rapporteur system for large congresses. Owing to an unfortunate accident some of the replies were lost. Of the 214 available for analysis (and believed to be a random sample), 174 (81 per cent) expressed the view that the system was suitable. 21 regarded it as unsuitable, and 19 did not answer the question.

* Present address: Paterson Laboratories, Christie Hospital and Holt Radium Institute, Withington, Manchester 20.

† Abstracts volume, available from the Hon. Secretary, Association for Radiation Research, Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester 20. 10s.

‡ *Radiation Effects in Physics, Chemistry and Biology*, edit. by Ebert, M., and Howard, A. (North Holland Publishing Co., Amsterdam, in the press).

Among those members who were not in favour of the rapporteur method, the most common reason was that an audience would gain more from a review of the field by an expert who was not encumbered by having to report on the papers which were submitted to the Congress. Some members also felt that the lack of contact between audience and the individual authors was an overriding disadvantage of the method. A few thought it intolerable for an author to have his work reported by someone else.

Many of the replies expressing approval of the rapporteur method contained comments and suggestions on how it might be more effectively used. The most common criticism of the Harrogate practice was that the number of papers per session was too large. Many members thought that it should be not more than ten. There was also a large body of opinion in favour of a more rigorous selection of papers with the aim of greater uniformity in material, methods and approach. Some members thought that only the poorer papers should be put into rapporteur sessions; others, only the best.

With regard to the rapporteur himself, almost everyone pointed out the obvious fact that everything depends on his quality, and many expressed their appreciation of the high level of performance attained at the Congress. Rapporteurs had been asked to introduce their subject and to synthesize the results of the several authors. A number of members thought it very important that this should be done; a few were of the opposite opinion. It was suggested that the rapporteur's report should be printed and circulated to all authors in the session, or even to all congress members. Some members would have liked to have had fuller abstracts or pre-prints of the full papers, to read at, or before, the Congress. Some felt that authors should be allotted time to speak in the discussions, and an equal number thought that the authors had been given too much time, and that more of the discussion should involve the audience.

The Harrogate experiment showed clearly that if, as is undoubtedly true, new techniques must be found to solve the problem of communication at congresses where large numbers of papers are offered, a possible and acceptable one is the rapporteur method. As practised at the Second International Congress of Radiation Research, it had the effect of providing up-to-the-minute reviews and discussions on topics chosen because they were shown by the proffered papers to be the growing points of radiation research. For the non-specialized audience interested in keeping abreast of new developments on a broad front, this was of great advantage in a field which covers a very wide range of disciplines. The comments of Congress members showed that as listeners the great majority found the rapporteur sessions valuable. As authors and would-be speakers, they were much less favourably inclined.

For those at least who attend congresses primarily to listen and to learn, the rapporteur method offers an attractive alternative to the multiple parallel sessions arrangement of congress programmes.

INTERACTION OF TECHNOLOGIES*

By L. HOLLIDAY

Research and Development Manager, Shell Chemical Co., Ltd. (Plastics and Rubbers Division), Carrington, Manchester

SPECIALIZATION increases inexorably in the world of technology. In the Stone Age there were no specialists and every man in the tribe was fully trained to carry out the laborious tasks which were necessary to keep him alive. Every man was concerned with the problems of food, of defence, of shelter, and with the straightforward issue of survival. Specialization began at the time of the neolithic revolution in the Middle East, when farming began and urban communities sprang up. This was accompanied by the emergence of craftsmen—of potters, weavers, smiths and farmers. It had taken about one million years for specialization to begin.

Within the space of about ten thousand years, we have reached the stage of specialization in technology at which we operate to-day. We have brick technologists who know nothing about plastics; we have plastics technologists who know nothing about metals; we have metals technologists who know nothing about wood; we have wood technologists who know nothing about textiles, and so it goes on. This is an exaggeration, of course, but it is the pattern which seems to be emerging. Can we therefore look forward to a time when we have specialization in low-density polyethylene of density 0·925, or of polyurethane foams made from polypropylene glycols? If this were to happen, progress would slow down because communication between technologists would be further impeded, and technologists would be trying to solve an increasing number of problems with unsuitable raw materials. Quite apart from this, to attempt to organize the field of technology into broader disciplines represents a fascinating intellectual challenge.

If we step aside and look at the field of science for a moment, the situation is quite different. The human mind has an urge to understand the external world, and to produce order and system out of facts. The scientist wants above all to produce statements and laws of the widest possible validity. A consequence of this is that a coherent and interrelated structure has been built up in the sciences. It is true that, viewed from Olympus, the realm of science would seem to be a continuum, and the branches of physical and biological science would appear to merge into one another and would seem to extend into further fields of knowledge and activity such as mathematics, philosophy, psychology and so on. However, even though the boundaries which exist between the sciences are arbitrary, there is an order and a system in science which is lacking in technology.

Problems of Technology

One of the first problems in technology is a problem in semantics. The word 'technology' is of necessity vague, since it embraces a vast span of interests and activities. If we qualify it in some way, for example, by saying polymer technology, we immediately describe a subject with certain boundaries. These boundaries may then become restrictive and artificial. Technology is, in fact, the science of industry, and comprises the application of science and of scientific method to industry. The classical way in which technology has been subdivided has been to group together industrial activities, using as a key certain commercial and technical interests which they have in common. Thus we talk of space technology, glass technology, petroleum technology and of many others. This is the first stage of evolution of technology, and represents a major step forward, since it stimulates the internal development of each particular technology. It does not necessarily, however, lead to the stimulation of one technology by another, which is the second stage of technological evolution. If technologists are to advance more rapidly as the result of mutual interaction, it is necessary that technology should be subdivided differently and reorganized so that the maximum number of fundamental similarities emerge.

* Substance of a paper read before Section B (Chemistry) of the British Association meeting in Manchester.

This need becomes even more obvious when one examines the list of research associations in receipt of Government grants. This includes the following:

Baking
Brush
Cast Iron
Coke
Cotton
Cutlery
Drop Forging
Electrical
Felt
Files
Flour
Food
Fruit and Vegetable Canning
Furniture
Gelatine and Glue
Glass
Heating
Hosiery
Hydromechanics
Internal Combustion Engines
Iron and Steel
Jute
Lace
Launderers
Leather
Lime
Linen
Motor
Paint
Paper
Printing
Rubber and Plastics
Scientific Instruments
Shipbuilding
Spring
Steel Castings
Tar
Timber
Water
Whiting
Wool

To what extent can one achieve a synthesis with these pieces? If they are part of a jig-saw puzzle, how can one best produce a recognizable picture? We need to-day someone to do for the evolution of technologies what Mendeléeff and Darwin did a hundred years ago for the growth of chemistry and biology. This raises the question: Who is responsible for producing order out of the chaos which exists in the field of technology, and who is to perceive the technological skeins which run through industry?

One approach is to classify technologies in relation to man's needs, in which case we achieve a measure of simplification as shown in Table 1.

Table 1 gives only examples, but serves to show how technologies can be grouped on a more rational basis. Some of these major technologies are already well recognized—for example, mining, food and chemical technologies. Others, such as materials technology and environmental technology, have not attained the same recognition.

  Printing

Materials Technology

Let us take one example—materials technology—and consider it in a little more detail in order to demonstrate that certain fundamental principles can be seen to apply to a number of technologies which at the moment are considered to be quite separate.

This is a field where there should be great possibilities of cross-fertilization and interaction, for example, in the manufacture of intermediate raw materials, such as plastics, glass, metals, bricks or paper. If it can be accepted that this is, in fact, but one large technology, this will already represent an enormous simplification in the technological field. Can this statement be justified?

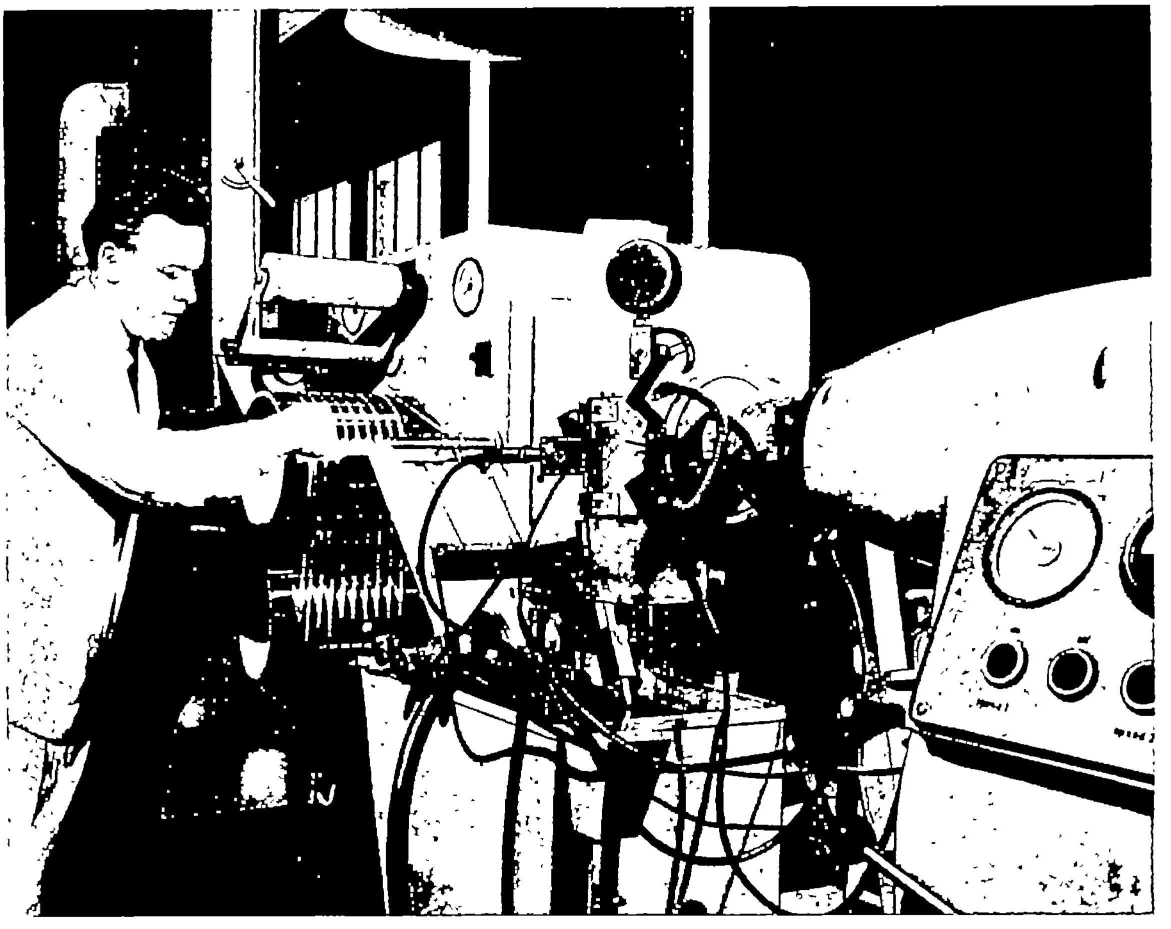

Fig 1. Extrusion of plastic monofilament. This is followed by quenching and hot drawing

There is a unity about simple and complex solid materials which is as fundamental as the unity which exists in the science of chemistry. The unity in chemistry is based on the concept of the atom and the molecule. The unity in materials science is based on the concept of a solid, since all solids by definition have certain features in common with all other solids. These features are the physical properties such as tensile strength, rigidity and hardness which determine whether an object is a solid or not. That there is a fundamental science of materials has only recently been recognized. It is true that there was already a considerable body of knowledge from metallurgy and crystallography which was waiting to be pressed into service, but the subject of materials science had not been investigated in a systematic way.

If materials science is the investigation of the properties of all solid materials, with the view of relating these properties to the ultimate molecular structure, there must also be a subject which we can call materials technology which deals with the fabrication and processing of these materials. Furthermore, since the physical properties of a solid are intimately bound up with the way in which it is made, it will be very difficult to draw a sharp line between materials science and technology. There are clearly two skeins or threads connecting together different branches of materials technology, (*a*) a process skein and (*b*) a product skein. Let us consider the process skein to begin with.

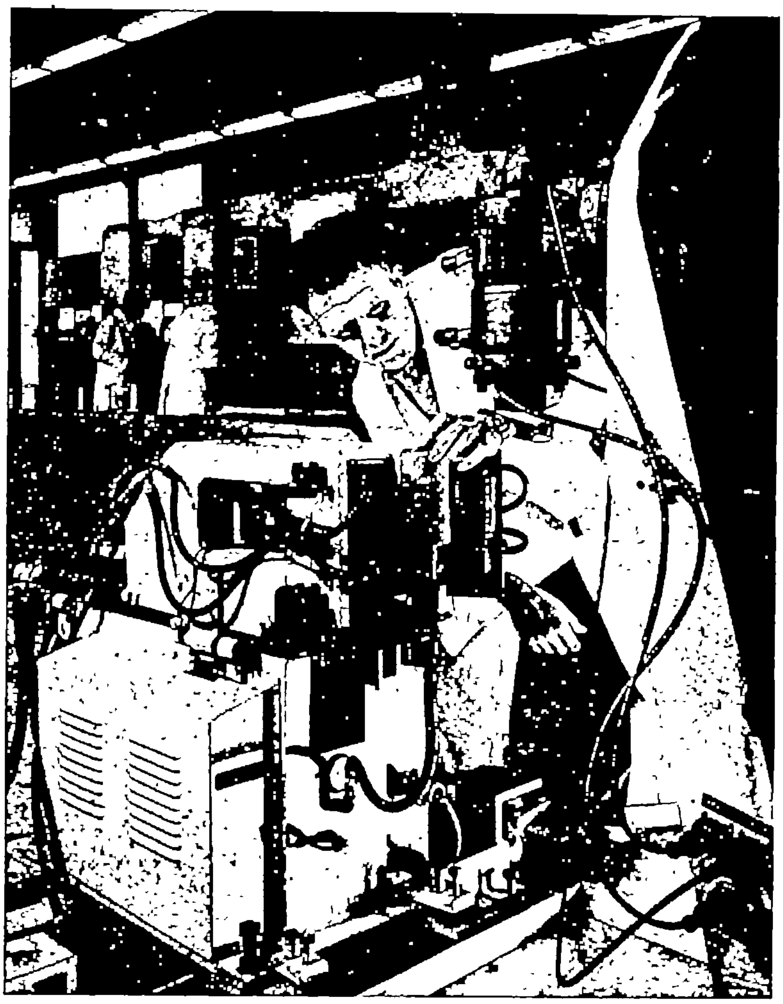

Fig. 2. Blowing of plastic bottles, showing a bottle being removed from the mould. The extruder, which produces a hot 'parison' tube, is shown on the right

Process Skeins—Unit-forming Processes

Ductile materials. A simple starting point is the processing of ductile materials—metals, thermoplastics and inorganic glasses. Inorganic glasses are not ductile at ambient temperatures, but are ductile at, say, 500° C. Metals and thermoplastics are not ductile at very low temperatures, but become ductile in the temperature-range 0–150° C. The property of ductility is, in fact, a function of temperature. Since similar processes are used for fabricating these materials, one can introduce the concept of 'unit forming processes' to describe them. Table 2 shows some processes which are in normal commercial use with these materials, from which it will be seen that similar processes are used, even though the temperature used varies. These processes divide themselves into true geometrical forming processes, and processes which set out to change the micro- or macro-structure of the material.

Although on an atomic or molecular scale the structures of these materials differ—from ordered crystalline lattices containing regions of disorder such as metals, to amorphous structures which show little order such as some polymers—they nevertheless show basic similarities in the ductile stage. In all cases, energy is required in order to change the physical form of the product. This work is required to overcome inter-molecular forces, and in some cases chemical bonds are broken in the process. If the molecules are large, as in the case of thermoplastics, the molecular orientation may be changed. In all cases, stresses may be set up in the product which may affect its physical properties, and these may have to be removed.

It will be seen that processes which have grown up in the older technologies of glasses and metals are being applied in many cases to thermoplastics (this shows the scope for the simplest form of invention—invention by analogy). Fig. 1 shows the manufacture of a thermoplastic monofilament and Fig. 2 the manufacture of plastic bottles. There has been an obvious interaction here, although it is not complete. It is surprising, for example, that three-dimensionally expanded metals (to quote one example) have not yet been developed commercially. There are other new developments in the field of forming processes which have not yet spread to all ductile materials, for example, extrusion accompanied by air blowing, the float glass process, impact extrusion and explosive forming.

Chemosetting materials. It will be seen that there is ample justification for studying unit-forming processes as a class, particularly since the concept of unit-forming processes can be further extended to other materials which at an earlier stage of manufacture will flow like ductile materials. These include bricks, ceramics, many thermosetting resins, rubber, concrete—the list is very long. This class of material is processed at some stage as highly viscous, non-Newtonian liquids which are shaped to the desired form. After they have been shaped, they are usually (but not always) heated in order to cure or set them, after which they are no longer ductile at any temperature. The transition from the liquid to the solid state is the result of a chemical reaction which is in sharp distinction to the class of ductile materials shown in the earlier table. This second class of material can be called 'chemosetting'. Chemosets in the liquid state may be homogeneous (as raw rubbers) or dispersions (as concrete). and the chemical reactions which are responsible for achieving the solid state are diverse—from the formation

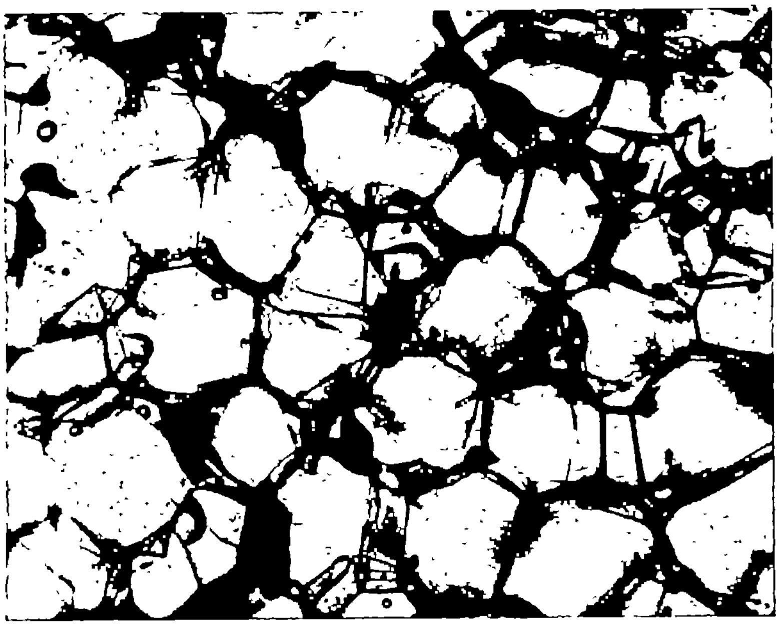

Fig. 3. Photomicrograph of cell structure of expanded polystyrene (× c. 75)

of carbon–sulphur bonds (in the case of rubber) to the formation of aluminates and silicates (in the case of concrete).

It is clear that a large number of unit-forming processes which are utilized for ductile materials can be used for chemosets, and vice versa. However, this analogy between bricks and ceramics on one hand, and metals or glasses on the other, has not been clearly seen. In fact, these have usually been regarded as being completely different classes of materials, which has inhibited the cross-fertilization of ideas which we are looking for. On general grounds it can be claimed that it will repay the brick technologist to study metals processing for example, and vice versa.

Filament processes. Clear analogies also exist in the field of weaving. All the ductile materials shown in Table 2 will form filaments which can be spun or woven. Woven metals, glasses and thermoplastics (like nylon, terylene and polypropylene) are important commercially. There has been very little interest in weaving chemosets, although this could be done. Presumably, the reason has been that woven materials in the great majority of cases are required to be flexible, and chemosets are usually rigid. However, since glass (which is a very rigid material) is woven commercially and rubber (which is a chemoset and very flexible) is also woven, it will be seen that the weaving of chemosets might repay study in special cases.

Matting processes. The formation of a mat or web—made up of fine filaments—is of importance in the manufacture of paper, and of growing importance in the case of non-woven fibres. Cellulose fibres, from which paper is made, are produced from wood by chemical digestions and extractions which remove the non-cellulosic materials, such as lignin. Their approximate dimensions are:

	Length	Width
Softwood	3–5 mm	40μ
Hardwood	1–3 mm	25μ

These fibres are thus very long and thin. The manufacture of paper and board depends on the fact that these fibres can readily be dispersed to form a suspension in water. When this suspension is filtered, a fibrous mat is formed which, on rolling and drying, produces a coherent sheet. This sheet can be built up in layers to produce a thick board of considerable mechanical strength. Superior mechanical properties can be obtained by impregnating this board with thermosetting materials such as urea-formaldehyde resins, which replace the air between the fibres by a rigid plastic.

The binding forces between the fibres in paper occur at the points where the fibres touch. Since the fibres are made up of cellulose, the binding consists of hydrogen bonds between the oxygen atom of a glucose unit in one fibre and a hydrogen atom of a glucose unit in an adjacent fibre. The result is a closely knit network of fibres.

It is apparent that a web or mat can be produced from any fibres of the correct geometry (that is, a high length/diameter ratio) if some self-bonding mechanism exists (as with paper) or some other bonding mechanism can be introduced, for example—the use of an adhesive. The key to using matting processes in a more general way is to recognize that the geometry of the system is not confined to cellulose fibres and the bonding forces are not restricted to hydrogen bonds. This has already been recognized in the case of non-woven fabrics, but the principle should be capable of extension.

Product Skelns

Materials may be simple or complex on a macroscopic scale. The simpler structures like metals, glasses or organic polymers may show either long-term or short-term order on a molecular or atomic scale. It is one task of materials science to relate observed physical properties to molecular structure, and good progress has been made in the past twenty years in the fields of metals and glasses.

There are, on the other hand, a large number of solids which are complex on a macroscopic scale. A typical example is expanded polystyrene (Fig. 3). Table 3 gives a few examples of such materials.

Table 3. Some Complex Solids which consist of Two or More Phases

	Continuous phase	Disperse phase
Concrete	Cement	Sand and gravel
Bitumen aggregates	Bitumen	Stone and air
Filled thermoplastics	Linear polymer	Inorganic filler
Reinforced rubbers	Cross-linked polymer	Carbon black, silica
Asbestos cement	Cement	Asbestos fibres
Laminates	Two continuous phases	
Glass fibre/resin systems	Cross-linked polymer	Glass fibres

One of the important features of these complex materials is their geometry, and phase relationship. They usually comprise a continuous phase and one or more disperse phases. Examples of complex materials with more than one continuous phase are rare, although they do exist (an open polyurethane foam has a continuous gas phase and a continuous polymer phase—expanded polystyrene, which has a closed pore structure, has a disperse gas phase and a continuous polymer phase).

Principle of geometrical similitudes. In understanding the properties of complex materials it is important to consider those aspects which are affected by the geometry of the system. This point can be illustrated by taking a particular example, although the approach is a general one. Let us consider a filled thermoplastic in which a thermoplastic material like polyethylene constitutes the continuous phase, and a filler like chalk or carbon black constitutes the disperse phase. The geometry is defined by such factors as particle size and shape, volume fraction of the disperse phase, size and concentration distribution, orientation if the particles are non-spherical, etc. The geometrical parameters are the same in a concrete road or a bitumen aggregate. If z_s is any physical property of the complex material, then:

$$z_s = f(z_a, z_b, z_{ab}, z_{bb}, c_b)$$

where z_a = physical property of continuous phase a; z_b = physical property of disperse phase b; z_{ab} = interaction term between the disperse and continuous phase; z_{bb} = interaction term between the particles of the disperse phase; c_b = concentration of disperse phase.

We can now enunciate some principles of geometrical similitude for complex materials: (1) the properties of complex materials are closely bound up with their geometry; (2) any complex material may exist theoretically in any geometry; (3) the effect of geometry is broadly similar in different systems.

Returning to the general equation, there are one or two physical properties which depend scarcely at all on interaction terms—for example, density and softening point. Nevertheless, it is the interaction terms which make complex materials so interesting.

Interaction term z_{ab}—between continuous and disperse phase. The magnitude of the interaction term z_{ab} depends on the particle size and concentration of the disperse phase, on the particle shape and surface area, and on the intermolecular forces at the interface between the particles and the continuous phase. In general, it increases as the particle size becomes smaller. It will be evident that not only are there a number of degrees of freedom which enable one to change the physical properties of the system by modifying the geometry but, in addition, it is possible to change the intermolecular forces at the interface by coating the particles before incorporating them into the matrix. This is done in such different fields as thermoplastics and bitumen aggregates.

Interaction term z_{bb}—between particles of the disperse phase. This interaction term is very dependent on particle size and concentration. It is therefore only significant in special cases. A typical example is in the reinforcement of rubber with carbon black or silica, where the particle size is below 1 micron. At below 10 per cent by volume, each particle is operating independently and only z_{ab} is important. As the volume concentration is increased, the particles begin to form filament-like aggregates and the term z_{bb} begins to play a part. This change in geometry shows up in the increased electrical conductivity of the system and in the elastic properties of the rubber.

Conclusions

These illustrations drawn from the field of materials technology illustrate the thesis—that benefits accrue from searching for the fundamental principles in individual technologies and for the relationships between them. This can only come from adopting a more analytical approach to technology as a whole, and by encouraging technologists to look beyond their individual specialities. What can be done to improve the situation?

(1) We should first look to the universities which have technological departments, and to the colleges of advanced technology, to bring together their technological departments into the largest possible units. As an example, instead of having in one university twenty professors of technological subjects each the head of an independent department, one should have a few large departments of technology, each with a number of professors. This is the way in which the Manchester College of Science and Technology is evolving. The department which now looks after textile chemistry and paper technology will in the future include polymer technology. We also need some professors of technology who are not concerned with narrow specialist fields, but who are concerned with industrial research and development as a whole, and with the philosophy of industrial research and development.

(2) There are too many technological societies and institutions, and too many technological journals. Some of these should be amalgamated.

(3) There is, in addition, a great need to cut down the number of industrial research associations and to bring them together into larger units. At the moment these research associations are scattered all over Britain in splinter groups. To have too many individual research associations means that the basic and fundamental research is frequently being carried out by teams which are too small to be really effective. The Department of Scientific and Industrial Research is aware of this fact, but will have a formidable task to improve the present situation. The situation in Holland, with its Toegepast Natuurwetenschappelijk Onderzoek Institutes, represents a pattern which Britain might follow. Most of the Toegepast Natuurwetenschappelijk Onderzoek Institutes are grouped together in one large laboratory complex, and this laboratory complex is situated on the campus of the technical university at Delft. Thus not only do the devotees of specialist technologies rub shoulders with each other but they also rub shoulders with the university scientists.

The Department of Scientific and Industrial Research, as a major spender of public research funds, has probably the key responsibility to promote the interaction of technologies. It is keenly aware of these responsibilities; but it will have to work hard even to stay abreast of a situation which daily becomes more complex.

RICHARD TOWNELEY AND BOYLE'S LAW

By C. WEBSTER

City Grammar School, Sheffield

THE year 1962 was the tercentenary of the publication of one of the best-known laws of science, Boyle's law, which stated that the volume of an enclosed gas was inversely proportional to the pressure applied to it[1]. As originally verified, the law only applied to air, which was at that time not understood to be a mixture of gases.

The law's establishment has been traditionally considered to be the work of Robert Boyle (1627–91), and it is one of the major researches on which his reputation as a principal scientist of the seventeenth century is based. Modern authorities, when commenting on the gas law, occasionally mention that Richard Towneley (1628–1706-7) has some claim to priority in the discovery of the gas law; but the evidence concerning his role has not been critically examined.

Both Boyle and Robert Hooke, his closest associate, referred to the gas law as "Mr. Towneley's hypothesis", and it is clear that it was on Towneley's initiative that they embarked on experiments which confirmed Towneley's suggested law.

Unfortunately, Towneley himself never released a treatise concerning air pressure, although Boyle referred to an incomplete work containing Towneley's views. He did not preserve any letters from Towneley, if, indeed, the latter did communicate with Boyle directly.

The first publication of the gas law occurred in the second edition of *New Experiments Physico-Mechanical Touching the Air* in 1662 [1]. There were no indications in the first edition of 1660 that Boyle was making investigations which would lead to the law, and close scrutiny of the 1662 edition impels the conclusion that the law was introduced as a corollary, rather than as a discovery of major importance. Consideration of the law was confined to Chapters 4 and 5 of Part 2 of the appendix to the work, in which Boyle was concerned with the demolition of Franciscus Linus's arguments or 'funicular hypothesis' disputing Boyle's explanation that the mercury column was supported by the pressure of air[2]. He found Towneley's hypothesis and experiments to be useful material in completing the arguments against Linus.

While writing his defence of the pressure or "spring of air" Boyle had beside him the results of experiments on the same subject by Richard Towneley and Henry Power (1623–68). These investigators had begun experiments using Toricelli tubes in 1653 in the Halifax region, after Power had reach Pecquet's *New Anatomical Experiments* . . .[3] which contained Pascal's views on air pressure as well as the famous observations on the lymphatic system.

Publication of Boyle's work in 1660 created a new impetus to their activities, and they performed a new series of experiments which were completed in April 1661. These were transcribed by Power and forwarded part by part to William Croone, the registrar of the newly formed society meeting in London, which was shortly to become the Royal Society. As was the custom of this group of scientists, the manuscripts were passed on to interested persons, and Croone wrote to Power informing him that Boyle was in possession of the manuscripts concerning the 1660–61 experiments[4]. Further, he informed Power that Boyle was using the information from the experiments using "weather glasses" in preparing his invective against Linus.

The title which Power used for the experiments which particularly interested Boyle was "Additional experiments made at Townley Hall, in the years 1660 and 1661, by the advice and assistance of that Heroick and Worthy Gentleman, Richard Townley, Esqr. and those Ingenious Gentlemen Mr. John, and Mr. Charles Townley, and Mr. George Kemp"[5]. Although the manuscript emanated from Power, it is quite possible that Boyle overlooked Power's part in the work, which would not be easily guessed from the title. Examination of Chapters 4 and 5 of Boyle's appendix show that the author leant heavily on the information from the foregoing manuscripts.

Power himself was mentioned by Boyle, when the latter quoted from a manuscript which he received at a different time from *Additional Experiments* . . .[6]. Boyle quoted a section of "A Confutation of this Funicular Hypothesis of Linus, by Henry Power Mae, Dr."[7].

The above manuscripts shortly became part of the collection of articles which were published as Part 2 of Power's only published work[8].

Because of priority of publication of Boyle's over Power's work, the second part of *Experimental Philosophy* has been neglected, its contents apparently lacking novelty in the light of Boyle's illustrious publication. Even Power's succinct microscopical observations were shortly to be eclipsed by Hooke's rambling *Micrographia*[9].

Towneley and Power's experiments do indicate the main stages which led to the apprehension of the gas law. In 1653 Power introduced into England Pascal's famous experiment in which the decrease in air pressure with increase in altitude could be illustrated by carrying a Torricelli tube up a hill. He measured the fall in the mercury-level with the ascent of Halifax Hill near his home at Elland.

In the same year the authors repeated Pecquet's experiment in which a small volume of air was enclosed above mercury in a Torricelli tube and they noted that it caused a lowering of the mercury column owing to two causes: "Ayr, besides its gravity has a nobler rarefactive faculty, by which it forces the Quicksilver to so considerable a descent, . . ."[10].

On April 27, 1661, they combined the effects of the two previous experiments by enclosing a volume of air above mercury and measuring its change at two atmospheric pressures, either at the foot or apex of Pendle Hill in Lancashire. They repeated the experiment using a tube of different length, and they measured the atmospheric pressure using a simple Torricelli tube containing a 29-in. column of mercury supported in a 42-in. tube.

They compared the pressure exerted on the enclosed air ($p1$) and its consequent volume ($v1$), with the same measurements made at a different pressure ($p2$ $v2$). They called these figures four "proportionals". They examined the relationship between these figures, which was made a little difficult by their use of two different units, either inches or smaller arbitrary divisions of the Torricelli tube. This necessitated conversion of the values into a common unit.

At the end of their experiments they were able to express the rather cryptic conclusion: "So that here is now four Proportionals, and by any three given, you may strike out the fourth, by Conversion, Transposition, and Division of them. So that by these Analogies you may prognosticate the effects, which follow in all Mercurial Experiments, and predemonstrate them, by calculation, before the senses give an Experimental (eviction) thereof"[11].

Thus they consider that if four such proportionals as those mentioned previously are known, they will have the following relationship:

$$p1v1 = p2v2$$

If any one is unknown, then transposition followed by division will enable it to be calculated. For example, if $p1$ is unknown:

$$p1 = \frac{p2v2}{v1}$$

There follow from these equations the common expressions of Boyle's law:

$$pv = K \ (K = \text{constant})$$

$$p = \frac{K}{v}$$

Power and Towneley stated only their experimental results; but they did include sufficient information in their tables and diagrams for the simple calculations to be made. The results shown here are after my conversion of all figures to Power's arbitrary units. It is not possible to convert the figures into inches, using the information given in the experiments. The main barrier in making the calculations was the profuse typographical errors which bedevilled the whole published work.

Locality and barometric height		Pressure (p)	Volume of air (v)	Constant $pv = k$
Exp. 1				
Pendle Hill Beacon (1,800 ft.)	66·58	55·32	84·75	4,687·4
Barlow (800 ft.)	69·01	57·23	83·80	4,795·9
Exp. 2				
Pendle Hill Beacon	32·66	18·60	17·80	334·04
Barlow	33·86	19·49	17·35	337·63
Barlow	33·86	19·66	17·58	345·63

The variation from the constant in these results is small enough to be accounted for by experimental error, and the authors themselves were well aware of frequent fluctuations in barometric height and they considered temperature to be one of its causes[12]. Boyle pointed out that their tubes were liable to be of non-uniform bore[13].

Examination of the evidence summarized here suggests that Richard Towneley and his collaborators played an important part in the postulation and experimental support of Boyle's law, and that Boyle was well justified in expressing his respect for the work of these minor scientific authors. It is overlooked that both Boyle and Hooke utilized the same apparatus, devised by Power and Towneley, in performing their own experiments on the gas law. They modified its use for their laboratory experiments, and obtained satisfactory results with it, although this original apparatus is less well known than the new apparatus which Boyle devised in which air was enclosed beneath mercury, in the short arm of a J tube. While Towneley's apparatus allowed the influence of reduced pressure on the volume of air to be measured, Boyle's J tube enabled the pressure to be increased.

Boyle's role in the establishment of the gas law remains important; his experimental results were accurate and extensive; the apparatus which he devised has become the standard one for illustrating the gas law; most significantly he gave the weight of his great reputation to the law, and published it in a highly influential work. He became the publicist of the gas law, which would have remained unnoticed in Power's work and Towneley's correspondence with Boyle.

However, the process of history has led to a loss of perspective in the examination of the achievements of such major figures as Boyle, leading to their excessive glorification, with the complementary neglect of such authors as Towneley and Power.

COMETARY COLLISIONS AND TEKTITES

By PROF. HAROLD C. UREY, For.Mem.R.S.

University of California, San Diego, La Jolla, California

In a recent communication to *Nature*, Adams and Huffaker[1] have presented arguments purporting to show that tektites cannot originate from the Earth on mechanical grounds. They argue that it is not possible to propel small objects through the atmosphere of the Earth to high altitudes because of the enormous accelerations that are required. They also discussed the question of whether very large objects could be propelled from the Earth's surface through the atmosphere. Such proposals are so obviously impossible that it has seemed to me unnecessary that they should even be discussed, and no proposals that they could occur have appeared in the literature. But since the *Scientific American* has recently accepted these arguments as valid, it may be well to discuss the subject briefly.

I proposed that a cometary collision produced the tektites[2]. It was pointed out that a collision of a comet head with the Earth might be an exceedingly energetic event. It was estimated that one such event could occur every 50 million years. Prof. Z. Kopal (personal communication) pointed out that this was much too low an estimate for the frequency of such events. The qualitative description of this process quite clearly envisaged that the cometary material and the atmosphere would be propelled to a very large distance with high velocities and would probably carry with it some material from the surface of the Earth. No suggestion that small objects would be propelled through the atmosphere was made. It was suggested that a comet head broke up and that the fragments landed at different points resulting in a wide distribution. This suggestion is difficult to reconcile with the very similar compositions of tektites from the widely separated tektite areas as Pinson[3] has shown and as pointed out by him.

Recently, Janet Bainbridge[4] has made numerical calculations in regard to this question and finds that the cometary material would behave approximately as has been assumed. Calculations were made for a cylindrical comet of density 0·01 g/cm^3 approaching an olivine surface in vacuum at velocities appropriate for collisions with the Earth or Moon. Velocities of the colliding object after collisions both in the backward and horizontal directions were found to be nearly equal to the velocities of approach. In the presence of an atmosphere, the behaviour of small comet heads would be quite different but large objects would follow a pattern much like that for the objects in vacuum. The assumptions made above for the cometary object appear to be reasonable.

The proponents of an extraterrestrial origin of the tektites rest their arguments on the fact that the australites are often button-shaped and that these button-like structures have been produced by rapid flight through the atmosphere and on the difficulties encountered in matching the composition of the tektites exactly with that of common terrestrial materials.

Chapman[5] estimated the velocity of entry of the button-shaped australites as about the escape velocity of the Earth and hence reasoned that the tektites came from the Moon. Adams and Huffaker[1] estimate the entry velocity as possibly as low as 6·5 km/sec, and hence postulate a circum-terrestrial orbit which enters the atmosphere at glancing angles. No attempt is made to explain how large objects, that is, 1,700 tons, got from the Moon into such very specialized orbits. A criticism of this suggestion has been made recently[6]. No one has ever questioned that the button-like structures of the australites were made by the passage of these objects through gas at high velocity or at least that high velocity gases flowed over the objects in some way. But there seems to be a complete neglect of all the other evidence in regard to this problem by proponents of the lunar origin. The reader's attention is directed to a recent paper by Taylor[7] on the chemical composition of the australites in which it is concluded that their composition agrees closely with certain materials from the surface of the Earth, which were produced by all the complicated geological processes characteristic of a planet like the Earth. This is a conclusion entirely similar to one that came to my attention quite a number of years ago from the work of O. Joensuu at the University of Chicago in the early fifties. This work was not published but was referred to by me[9]. The large tektites of the Muong-Nong type have been discussed by Barnes and Pitakpaivan[9] recently. They are mixed with a laterite soil which the authors believe has evolved since the objects were produced by fusion of the surface of the Earth. Craters have been discussed by Cohen[10] which might well be the collision sites for cometary objects. The short time that the tektites have been in space has been pointed out by Viste and Anders[11]. The similarity of composition of tektites to certain soils has been discussed by Schwartz[12]. The impossibility of transferring material from the Moon to the Earth with the distributions that are observed was discussed by me in 1955 and again in 1962 [4,8]. The very uniform isotopic composition of the tektites as pointed out by Taylor and Epstein[13], and the very similar compositions of tektites from different areas as shown by Lowman[14] are difficult questions but perhaps not insurmountable for terrestrial origin. The very low nickel content is not easily reconciled with a lunar origin.

In connexion with the cometary collision idea, it is interesting to point out that the recent studies on the Tungussky catastrophe of 1908 are most informative[15]. The evidence is that an object having the energy of 4×10^{23} ergs (10 megatons of TNT equivalent) exploded five or more kilometres above the surface of the Earth. The radiated energy was about 1·1–2·8 times 10^{23} ergs. The estimated energy of the collision is seven times that estimated for the Canyon Diablio crater, yet no crater was observed. Interestingly enough, a forest remained standing directly under the point of explosion. There is considerable uncertainty in regard to the mass and velocity of the object. It apparently arrived at a low angle and Zolotov[15] believes at a low velocity, that is, 3–4 km sec^{-1}. Such a low velocity is not consistent with a high energy unless the energy was internal, that is, chemical energy. Krinov[16] mentions higher velocities. It scarcely could have stopped in the atmosphere if its mass per unit area had been much larger than the mass per unit area of the air through which it passed. But if the object were moving in an initial orbit about the Earth, its velocity would be minimal at 7·9 km sec^{-1}, and thus if its velocity of approach were only half this it must have lost three-quarters of its energy. Its path would have been from the south over some of the most populous regions of the Earth. It is difficult to believe that it would not have been seen by someone at seven o'clock in the morning. The velocity mentioned by Zolotov must be in error for some reason which is not evident from his paper. These uncertainties make it difficult to estimate its physical properties.

It is not possible to estimate the frequency of such collisions from one event. No event of such magnitude could have occurred in civilized regions of the world without some record having come down to us, but such areas have constituted only very small fractions of the Earth's surface. As noted previously[8], several astronomical objects have passed near the Earth during this century, and it is most likely that the inventory is not complete. A rough estimate of the probability of collision with the Earth indicates that this might occur within some millions of years or less. The estimated energy of collision is very much larger than 4×10^{23}, possibly some 10^{28} ergs. An object of this kind, if it had a high density, would pass through the atmosphere almost unobstructed and would produce a large crater. However, comet heads of low density would be stopped to a large degree by the atmosphere and no large deep craters would result. Since large craters are not numerous on the Earth's surface, these objects may well be comet heads of low density.

Suggestions have been made that the Tungussky object was contraterrene matter which is far too extreme a suggestion for serious consideration. This object was a small comet head according to Krinov[16]. If the object had had sufficient mass per unit area, it would have penetrated completely to the surface of the Earth, probably melted the surface of the Earth, and produced a very shallow crater. In other words, the Tungussky collision is an example of precisely the kind of collision that has been discussed in connexion with the origin of tektites, though smaller in mass than those suggested. Larger comet heads are discussed in the astronomical literature and such larger heads may well have produced the craters discussed by Cohen[10]. Both the probable cometary collision of an object only some 200 metres or so in dimension and these larger objects some kilometres in dimension moving near the Earth are consistent with the hypothesis that cometary collisions could be sufficiently frequent and of such character that tektites could be produced in this way. (Cohen at the Third International Space Science Symposium, May 1962, quoted a private communication from W. Gentner, H. J. Lippolt and O. A. Schaeffer to the effect that the potassium–argon age of a glass sample from the Ries crater and a moldavite tektite both have the age within experimental limits of error of 15 million years.)

Many features of tektites are accounted for by the cometary hypothesis. The chemical composition of the tektites is very like that of the more acid terrestrial materials. A mechanism for dispersal to great distances is provided by the cometary collision. High temperatures for rapid and incomplete melting are provided. The decreased estimate for the re-entry velocity, that is, 6·5 km sec^{-1}, makes it possible to account for the second melting of the australites. The types without flanges are those which did not re-enter at high velocities. The Muong-Nong types are residues of the melted pools produced at the collision sites and not scattered to great distances. A comet head collision has been observed in this century. Larger ones should melt the Earth's surface, produce craters and scatter material to great distances. All detailed features of tektites are not immediately explained by this theory, but its successes are so great that it would be well for authors to study possibilities for fitting their data into the general features of this theory. It is evident that a cometary collision is a very complicated event and that it is not possible to describe all its details with certainty.

It is evident that material of approximately tektitic composition is widespread on the Earth, though Taylor and Epstein's[13], Lowman's[14], Pinson's[6] and Taylor's[7] discussions show that only selected samples would account exactly for their composition. However, melting and distribution by a comet head collision would probably be highly selective. Thus, very fluid melts would scarcely remain as objects of the size of tektites in a blast of hot gases, and hence only very acid and viscous materials, that is, tektites and Libyan glass, would survive. Also basic melts would crystallize rapidly and would weather away in short periods of time. Even acidic materials melted at high temperatures would not survive. Only such material which had been barely melted, such as the tektites, would survive the blast of gases and would remain as uncrystallized and unweathered glassy objects after long periods of time. In this way the very selected compositions discussed by Lowman[14] can be understood possibly. Also, it should be noted that the present cometary collision hypothesis assumes that all the tektitic fields of south-east Asia and Australia originated from one site and hence their similarity is naturally explained. The general exclusion of Americanites and the Darwin and Libyan glasses from the classification of tektites make them a more uniform group than they are when these are included. Finally, melting by cometary collisions may be more selective than we are able to deduce from our general estimates in regard to such processes.

The postulate that tektites come from the Moon has never been discussed in an objective way. Varsavsky[17] tried to show that South Australia could be covered by objects from the Moon while North Australia did not receive such objects. He did not account for the other tektite areas nor for objects which missed the Earth on the first pass. O'Keefe has postulated objects moving in spiral orbits from the Moon and in no way considers the high probability, and in fact, certainty that many objects released from the lunar surface by some violent processes would move in very different orbits and arrive at all points of the Earth's surface. It is difficult indeed to recall any proposal discussed in the scientific literature in recent years which is so enmeshed in special pleading for nearly miraculous events as this proposal for the lunar-origin of tektites. Criticisms of these arguments have been made previously[18].

If comet heads collide with the Earth, they must also collide with the Moon, and some of the lunar craters must have been produced in this way. The central peaks with their apparent volcanic craters and the general "scooped out" shape are not inconsistent with qualitative ideas of the results of a gaseous collision such as that studied by Mrs. Bainbridge. These calculations indicate that a mild 'bounce' of the lunar surface at the collision point is possible. Such a rebound might explain the craters in the tops of many central peaks. The propellent and non-penetrating character of high-velocity gases and low-density solids rather than the more 'detonating' and penetrating character of high density silicate and metal objects might well account for some of the lunar craters. It is not evident that there are two classes of lunar craters. At present this suggestion is scarcely more than an intuitive estimate in regard to these phenomena.

I thank Drs. Albert and Celeste Engel for discussions of this subject, and Dr. Herbert York for discussion on the Tungussky collision.

OLD MORTALITY

By Prof. LANCELOT HOGBEN, F.R.S.

DURING the early 'thirties, R. R. Kuczynski introduced then young research workers of Great Britain to the uses of the Actuarial Life Table (A.L.T.) as a substitute for standardized rates hitherto used for interpretation of vital statistics in the best sense of the term. Since the end of the Second World War there has been an agonizing reappraisal, largely due to the use of *cohort analysis* for the study of mortality and morbidity by R. A. M. Case[1] and for that of fertility by W. Taylor[2] and by P. K. Whelpton[3]. Thus the issue of a monograph by Dr. Case *et al.* on the Cohort Life Table (C.L.T.) from the Chester Beatty Research Institute on the eve of the Royal Society tercentenary celebrations of the publication of the *Observations . . . upon the Bills of Mortality* by John Graunt[4] is a timely event *. It is also greatly to the credit of the Institute. For like other inquiries by its senior author, his work in this field has the hall-mark of perceptive originality.

The A.L.T. is like the composite face which Galton obtained by photographic superposition in pursuit of Quetelet's Average Man. That is to say, it tells us what would be the number of survivors out of 1,000 births in each year of life, if age specific death-rates (mortality in each year of life related to the corresponding population at risk) were to remain constant as at the calendar year which dates the Table. No single C.L.T. is referable to one calendar year in this sense. Each such table pertains to the birth year of a particular cohort, that is, assemblage born in the same calendar year. Whereas each entry in the A.L.T. refers to a different cohort in that sense, successive entries of a C.L.T. thus record the life experience of one and the same assemblage, except in so far as migration distorts the picture. In short, the C.L.T. is as factual a record of a unique observable occurrence as is the photograph of an individual face.

Needless to say, the C.L.T., and cohort analysis in general, has two limitations. At the time of writing, one can know nothing about mortality of 14-year-old children born in 1950, and standards of diagnosis may well have changed drastically during the life experience of the now-extinct 1860 cohort. None the less, the outcome of focusing attention on the life experience of the cohort as a unit of study is salutary from a medical point of view, if only because it compels us to take stock of hitherto insufficiently recognized shortcomings of the A.L.T. and of its applications.

Consider first a type of situation characteristic of Western Europe throughout the past half-century, during which mortality in all age-groups has diminished, or at worst remained static at the tail-end of life. Thus the younger age-groups now alive have suffered exposure to less health hazards than corresponding age-groups of the parental generation. In such a set-up, we may expect what this monograph clearly discloses: for nearly all (if not all) age-groups, the A.L.T. for the calendar year X will cite a lower proportion of survivors than the C.L.T. referable to birth-date X. In a uniformly improving situation, use of the A.L.T. to estimate the risk of death before 60 of persons thirty years old at the calendar date to which its figures refer therefore discloses an unduly pessimistic prospect. If, as some people idly imagine, the current A.L.T. actually dictated the premium policy of an Insurance Corporation, circumstances would be prejudicial to the candidate for a life policy and, *ceteris paribus* (that is, with no change of the cost of living), favourable to the purchaser of an annuity.

Alternatively, consider a situation in which risk of contracting a particular killing disease is increasing *pari passu* with net diminution of death risk from all so-called causes. This is indeed what some claim to be true of lung carcinoma with due allowance for changing diagnostic standards. In this *milieu*, cohort analysis exposes what should rightly go into the text-books as the "Robert Case Illusion". Briefly stated it is this: a plot of case incidence in each year of life, expressed as a ratio referable to the corresponding population at risk in one and the same calendar year, may (and often does) disclose a peak followed by a fall suggestive of declining liability in later age-groups. This conclusion is inescapable only if we assume that the risk of onset (or death, as the case may be) does not depend on the duration of the exposure to harmful circumstances or that the latter remain constant throughout the life-time of an individual. By following out the life-story of a cohort, as Case[1] has done elsewhere, it may be possible to show that neither assumption is permissible. Comparison of data yielded by successive cohorts may then divulge that a peak is a non-existent nose of a composite face.

* Chester Beatty Research Institute Serial Abridged Life Tables, England and Wales, 1841–1960. Part 1: Tables, Preface and Notes. Compiled by R. A. M. Case, Christine Coghill, Joyce L. Harley and Joan T. Pearson. Pp. xxvi+87. (London: The Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, 1962.)

Foregoing considerations put the spotlight on how much gamesmanship the actuarial mystique with its insistence on arbitrarily painstaking interpolations conceals from public scrutiny. The belief that laborious refinements prescribed by A.L.T. priestcraft are essential to extraction of whatever useful information the A.L.T. can convey may account for a prevalent reluctance to construct home-made up-to-date tables without the *nihil obstat et imprimatur* of the Registrar-General. It is therefore worthy of comment that educational authorities (including the University Grants Committee) were relying a few years back on estimates of the *bulge* based on what was then the last official table—at that date several decades behind the times.

For some years, a few of us have known or at least suspected that life-tables of the sort Case calls conventional computed from age specific mortality rates in the *Annual Review* of the Registrar-General by the light of common sense (so-called "Greville's Method"), and at the expenditure of half a working day with a machine, differ very little from those computed the hard way. Dr. Case and his collaborators have exhibited in tabular form relevant facts which fully confirm this conviction. As he himself rightly comments: "A consideration of the large discrepancies between the results of conventional methods and actuality . . . and the trivial differences between simply constructed abridged tables and the meticulously graduated official English Life Tables makes one wonder what purpose is really fulfilled by such a display of actuarial expertise !"

SEQUENTIAL ENZYME INDUCTION: A NEW APPROACH TO THE STRUCTURE OF COMPLEX MUCOPROTEINS

By DR. S. A. BARKER, MRS. GRACE I. PARDOE and PROF. M. STACEY, F.R.S.
Chemistry Department
AND
DR. J. W. HOPTON
Microbiology Department, University of Birmingham

SINCE Monod's[1] classical work on the utilization of sugar mixtures by micro-organisms, many examples of sequential utilization of substrate components have been reported. For a particular organism, the sequence is predictable, and it is now well established that the enzyme system required to initiate the attack of a component is not elaborated until other components are preferentially exhausted.

We have been able to show that if the complex mucoprotein, orosomucoid, is included in a medium which will support growth of *Rhodopseudomonas palustris*, development of the culture is accompanied by a sequential release (Fig. 1) of constituent sugars of the polysaccharide moiety of the muco-protein. At any one time, only one enzyme system is operative, and in this respect, there is an obvious similarity to that behaviour of individual substrate specific enzymes which characterizes multiphasic growth. Orosomucoid can be conceived as a composite inducer for enzymes which cleave links between sugar constituents of the polysaccharide. However, the products of the enzyme actions cannot be utilized by the organism (orosomucoid will not serve as sole source of carbon for growth of the organism) and accumulate in the medium. Hence, from the results of qualitative and quantitative analyses of the products of this stepwise degradation, precise conclusions concerning the arrangement of sugar residues in the molecule can be drawn. Furthermore, it has been possible to deduce the configuration and mode of linkage of certain of the sugar residues in the carbohydrate moiety from the specificity of the induced enzymes and the response of cells to inducers of known configuration.

Sequential release can be observed in a single culture over a period of a week, but normal logarithmic growth is certainly not proceeding throughout the whole of this period. Indeed, it is likely that for most of this time, the behaviour of the culture is analogous to that of a resting cell suspension. However, if orosomucoid 'cores' left at the termination of release of a constituent are recovered by dialysis of the centrifuged culture, and incorporated in a fresh culture, the sequential effect can be reproduced and the overall process accelerated.

The electrophoretically and immunologically pure orosomucoid used in this investigation was isolated[2] from nephrotic urine and contained 10·8 per cent *N*-acetyl neuraminic acid (thiobarbituric acid—periodate assay[3]), 1·2 per cent L-fucose (cysteine hydrochloride–sulphuric acid assay[4]), 6·5 per cent D-galactose (D-galactose oxidase[5]), 16·6 per cent *N*-acetyl glucosamine (*p*-dimethylaminobenzaldehyde[6]) and 6·9 per cent mannose (by difference between total hexoses assayed with orcinol[7] and the galactose content[5]).

Washed succinate-cultured[8] cells of *R. palustris* 3574 were re-suspended in sterile fresh medium (5 ml., *p*H 7 adjusted with KOH) containing per litre succinic acid (6 g), $(NH_4)_2SO_4$ (0·015 mole), $MgSO_4$ (0·001 mole) and K_2HPO_4 (0·02 mole) and added to orosomucoid (5 mg) in a sterile flask (25 ml.). The culture was incubated and shaken at 35°. Paper chromatographic analysis of aliquots taken at intervals showed that *N*-acetyl neuraminic acid, *N*-acetyl mannosamine, galactose and oligosaccharides with R_{glucose} 0·18 and 0·27 in pyridine–*n*-pentyl alcohol–water (1 : 1 : 1) appeared successively in the culture medium. Any fucose liberated was below the level of detection.

Quantitative assays[3–10] of the sugars were made as appropriate on the whole culture, on the dialysable sugars and on the non-dialysable mucoprotein 'cores'

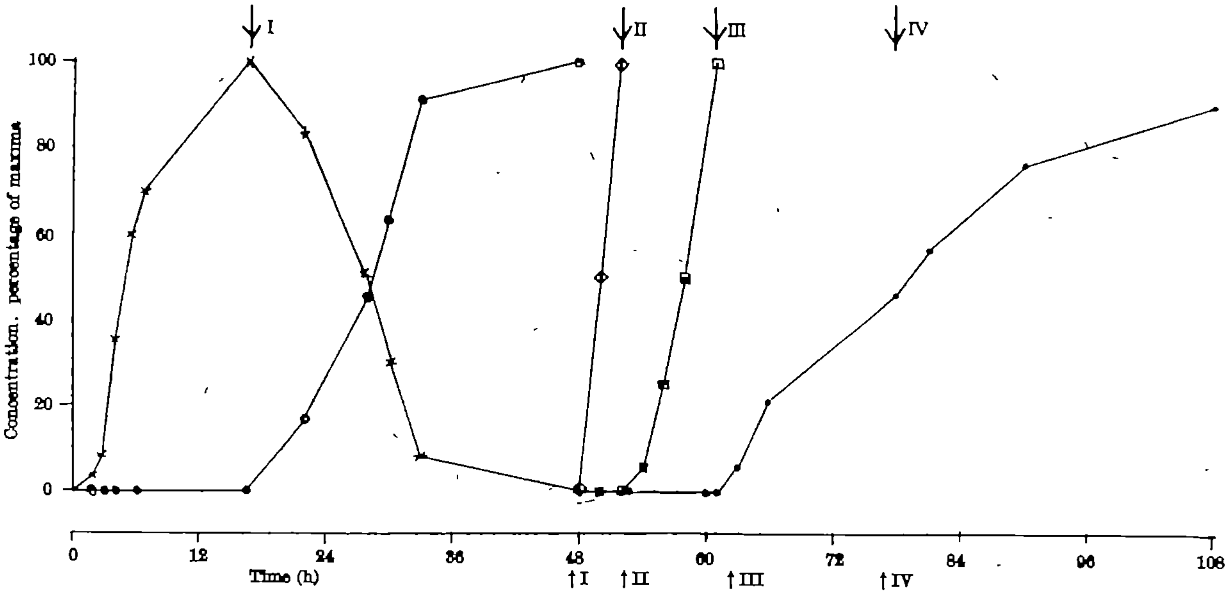

Fig. 1. Sequential cleavage of sugars from orosomucoid by successive enzyme induction. ×, *N*-acetyl neuraminic acid; ○, *N*-acetyl mannosamine; ◇, L-fucose; □, D-galactose; ●, oligosaccharides containing mannose and *N*-acetyl glucosamine. ↓ I, etc., indicates times at which appropriate non-dialysable cores were taken. ↑ I, etc., indicates times at which inductions were made with appropriate non-dialysable cores.

after removal of the cells. Corrections were applied in the analysis of the dialysable fractions for the effect of the constituents of the culture medium and for the presence of other sugars. To eliminate the effect of *N*-acetyl mannosamine, a neuraminic acid-free 'core' was used as an inducer for the later stages of degradation. The results were plotted (Fig. 1) as a percentage of the maximum content of each constituent sugar in the orosomucoid. The time-scale shown was an accelerated one achieved by the use of appropriate mucoprotein 'cores' dissolved in a fresh suspension of cells at the times indicated.

All the *N*-acetyl neuraminic acid (NANA) originally present in the orosomucoid is rapidly released by neuraminidase, the first induced enzyme. This shows that this sugar exists either as isolated end-groups or as a repetitive sequence of NANA residues at the extremities of the chains. Since periodate oxidation[11] of orosomucoid yields one mole of formaldehyde for each mole of NANA the former possibility is more likely. The released NANA (10·6 per cent) was converted to an equimolar amount of *N*-acetyl mannosamine (7·5 per cent) presumably by an aldolase action.

The total amount of L-fucose present in the orosomucoid was next released. Induction experiments with methyl α- and β-L-fucopyranosides showed that only an α-L-fucopyranosidase can be induced in *R. palustris*. Furthermore, this enzyme cleaved at least four-fifths of the fucose in orosomucoid while the NANA remained untouched. We can therefore conclude that NANA and fucose exist as separate end groups and, again, the α-L-fucopyranoside residues can exist as isolated end groups or as a repetitive sequence of fucose residues. Linkage through the 3-position is excluded because the fucose is destroyed by periodate oxidation of orosomucoid[11].

Orosomucoid itself does not cross-react with anti-Type XIV *Pneumococcus* sera which are known[12] to have a pronounced immunological specificity for β-D-galactopyranose end groups. However, after cleavage of the NANA and fucose the residual orosomucoid 'core' did show a cross-reaction with anti-Type XIV which disappeared concomitantly with the removal of all the galactose by the next induced enzyme (Fig. 1) in the sequence. This enzyme had the specificity of a β-D-galacto-pyranosidase since it could cleave lactose but not melibiose. Galactose oxidase is known[9] to react with bound galactose present as non-reducing end groups. Orosomucoid itself showed no reaction with galactose oxidase, a slight reaction after selective removal of fucose, and a strong reaction after removal of neuraminic acid. No reaction was given by a mucoprotein core from which all the galactose had been removed. The foregoing evidence suggested that β-D-galactopyranosyl end groups had been uncovered by the NANA cleavage, and that this residue was the next sugar along the chain.

The final stage of carbohydrate disruption was the liberation of two oligosaccharides. When used as an inducer, the first oligosaccharide R_{glucose} 0·18 gave the trisaccharide R_{glucose} 0·27 which contains two molecules of *N*-acetyl glucosamine and one of mannose. One of the *N*-acetyl glucosamine residues carries the reducing group in the trisaccharide since periodate oxidation followed by acid hydrolysis gave glucosamine before but not after sodium borohydride reduction. The mannose residue was always destroyed by periodate oxidation. The enzyme induced was therefore a glucosaminidase. Subsequent use of the trisaccharide as an inducer gave *N*-acetyl glucosamine and a component with the mobility (R_{glucose} 0·65) of a disaccharide. No free mannose was ever detected in the culture medium. The foregoing evidence, together with analyses of the dialysable oligosaccharide mixtures which consistently showed two *N*-acetyl glucosamine residues for each mannose residue, suggests that the oligosaccharide R_{glucose} 0·18 is a hexasaccharide—the dimer of the trisaccharide.

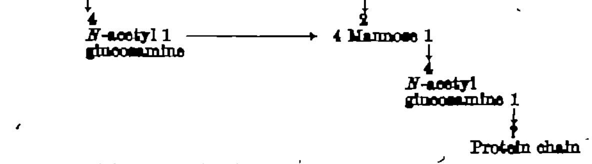

Fig. 2. Partial structure of α_1-glycoprotein

Urinary orosomucoid has been found[13] to be immunologically identical with serum acid α_1-glycoprotein and both show similar sugar analyses. The structure of part of the carbohydrate moiety of α_1-glycoprotein has recently been reported[14] and is shown in Fig. 2. All the foregoing evidence obtained from sequential enzyme induction is consistent with this structure although more details have yet to be established. The powerful tool now at our disposal allows us to stop the degradation at any stage in order to simplify the application of classical techniques of structural determination, and in order that the important relations between structure and biological activities of the complex molecules can be determined. Whether the method is applicable to other macromolecules has yet to be determined.

We thank the Medical Research Council for financial support and the award of a scholarship to one of us (G. L. P.). The culture used was obtained through the kindness of Dr. A. M. Torriani.

Division of Reactors of the International Atomic Energy Agency: Dr. F. T. Miles

Dr. Francis T. Miles, who was until recently deputy chairman of the Nuclear Engineering Department of the Brookhaven National Laboratory, has been appointed director of the Division of Reactors of the International Atomic Energy Agency in succession to Dr. C. Sánchez del Río. He took up his duties at the Agency's headquarters in Vienna on December 27. Born in Princeton, New Jersey, in 1909, Dr. Miles studied at Princeton University, where he gained his A.M. in 1932 and his Ph.D. in organic chemistry in 1936. He also studied at the University of Basle during 1934–35. From 1936 until 1943, Dr. Miles was a research chemist with a chemical firm in Alabama, and then joined Columbia University, where he worked with Dr. W. F. Libby on the gaseous diffusion process for isotope separation. In 1946 he joined Clinton Laboratory (now Oak Ridge National Laboratory) as a group leader supervising research on the extraction of uranium-235 from irradiated reactor fuel, and in 1948 went to Brookhaven to supervise research on the separation of uranium-233 by neutron irradiation of thorium. Later he became deputy chairman of the Nuclear Engineering Department of this Laboratory. Apart from isotope separation processes connected with nuclear energy applications, Dr. Miles has been actively interested in several other aspects of reactor technology. From 1959 until 1962 he was a member of the Board of Directors of the American Nuclear Society. For some years he was also an associate editor of *Nuclear Science and Engineering*.

Experimental Fluid Mechanics at the College of Aeronautics, Cranfield: Prof. G. M. Lilley

A chair of experimental fluid mechanics has been established at the College of Aeronautics, Cranfield, in the Department of Aerodynamics. Mr. G. M. Lilley has been appointed to be the first professor of experimental fluid mechanics, with effect from January 1. The new chair will enable the experimental facilities available in the Department of Aerodynamics at Cranfield to be fully utilized in a developing programme of research. Prof. Lilley, a graduate of the University of London, has been a resident member of the teaching staff at Cranfield since 1946. First appointed as a lecturer in the Department of Aerodynamics, he was promoted to senior lecturer in 1950 and to deputy head of the Department in 1955. He has played a major part in the development of the Aerodynamics Laboratory and its research activities. Prof. Lilley is a recognized authority on turbulent flow and its relationship to aerodynamic noise. He is a member of a number of committees of the Aeronautical Research Council.

The Royal Society of London: Annual Report

The report of the Council of the Royal Society for the year ended September 30, 1962, indicates that the Council expects to make the first two appointments to the new research professorships which the Government is enabling the Society to create early in 1963 (Pp. 53. London: The Royal Society, 1962). An *ad hoc* committee has been appointed to consider the nomination procedure and the methods of selection of candidates for the fellowship, as well as the procedure for the election of foreign members. After taking legal advice and consulting the Charity Commission, which ruled that Rutherford scholarships can no longer be awarded to students from South Africa now that South Africa has ceased to be a member of the British Commonwealth, the Council has altered the regulations accordingly and also to exclude students from Eire. Discussions are still proceeding with Government departments and others regarding accommodation for the Society, and meanwhile members of the Society's staff dealing with geophysical and space research work and the international secretariat for the International Year of the Quiet Sun are being housed in rooms at Cornwall Terrace, Regent's Park. The Council has also agreed to co-operate with the Leverhulme Trust Fund in a scheme to establish Royal Society Leverhulme professorships to enable distinguished scientists to visit India. Of Parliamentary grants-in-aid administered by the Society during the year amounting to £162,640, £87,500 was spent on research, £63,000 on international research and scientific congresses and £7,500 on scientific publications. Besides some notes in the report itself on antarctic research, oceanic research, space research and geophysical research, reports are appended from the twenty-four research professors and research Fellows directly supported by the Society describing some of the results achieved, mostly with lists of publications.

Vice-presidents

THE president of the Royal Society, Sir Howard Florey, has appointed the following vice-presidents for the year ending November 30, 1963: Lord Fleck, treasurer of the Royal Society, formerly chairman of Imperial Chemical Industries, Ltd.; Sir Lindor Brown, biological secretary of the Royal Society, Waynflete professor of physiology in the University of Oxford; Sir William Hodge, physical secretary of the Royal Society, Lowndean professor of astronomy and geometry in the University of Cambridge; Sir Patrick Linstead, foreign secretary of the Royal Society, rector of the Imperial College of Science and Technology, London; Prof. W. T. J. Morgan, deputy director of the Lister Institute and professor of biochemistry in the University of London; Sir Gordon Sutherland, director of the National Physical Laboratory.

The International Calcium Silicate Products Research Organization

THE production of calcium silicate bonded bricks and other building products has developed rapidly in recent years. Yet production of sand-lime and flint-lime bricks, the most well-known form in Britain, still only amounts to about 3 per cent of the total brick output, but as a result of research a high proportion of these are now of specially high strength or of facing qualities. In Germany, Holland and Russia they constitute a major proportion of the brick and block output. The process of manufacture, which is comparable in cost with that of clay bricks, has advantages as quality can be closely controlled and bricks of any required strength can be made from the same raw materials by simple adjustment of various factors in the process. At a meeting held in Amsterdam in December, agreement was reached between the Chalk Lime and Allied Industries Research Association, Welwyn, Herts, and the Associations concerned with research for the Calcium Silicate Brick and Block Industry in West Germany (the Hauptverband Kalksandsteinindustrie e.V.) and in Holland (Stichting Kalkzandsteen-Laboratorium), on the formation of a joint research organization to be known as the International Calcium Silicate Products Research Organization. For the first two years the Secretariat of the Organization will be provided by the Chalk Lime and Allied Industries Research Association at Welwyn.

Building Research at the Manchester College of Science and Technology

WORK has now started at the Manchester College of Science and Technology on a three-year study of the structure and economy of the building industry. First announced in September 1962, this project is being carried out for the Department of Scientific and Industrial Research at a cost of £48,000. The Council of the College has appointed Mr. Gordon Bayley as research director of the project. Mr. Bayley, who is forty, is a graduate of Manchester, and has been area secretary of the Eastern Federation of Building Trade Employers covering Essex and East Suffolk for some years.

A steering committee has been set up to control the general policy of the project and to advise the research director and his team. The committee is composed of the following members: Mr. A. P. H. Aitken, Textile Machinery Makers, Ltd. (chairman); Prof. D. Harper, professor of building, University of Manchester, and director of project; Mr. M. W. Bennitt, Ministry of Public Building and Works; Mr. R. Brech, Economics and Statistics Department, Unilever, Ltd.; Prof. C. F. Carter, professor of economics, University of Manchester, and vice-chancellor elect of the University of Lancaster; Mr. E. J. Cook, Richard Costain, Ltd.; Mr. E. D. France, Industrial Labour Officer, National Federation of Building Trades Operatives; Miss P. K. Piercy, Department of Scientific and Industrial Research; Prof. R. W. Revans, professor of industrial administration, University of Manchester; Mr. R. T. Walters, deputy director research and development, Ministry of Public Building and Works; Dr. J. C. Weston, deputy chief scientific officer, Department of Scientific and Industrial Research, Building Research Station.

The Wellcome Laboratory, Pirbright: Foot and Mouth Disease Vaccines

THE completion has recently been announced of the new Wellcome Laboratory erected within the perimeter of the Research Institute (Animal Virus Diseases), Pirbright. In accordance with the arrangements announced by the Parliamentary Secretary for Science in May 1961, the Laboratory will undertake the large-scale production of living foot and mouth disease vaccines. Research at Pirbright has been particularly directed towards the attenuation of strains of foot and mouth disease virus and the pilot-scale production of living attenuated vaccines. A series of trials in South and East Africa led to increasing demands for these vaccines, and the Wellcome Foundation, Ltd., was invited to set up a production unit at Pirbright so that the Institute could continue to devote its resources and facilities to research. Large quantities of two different living vaccines have already been produced in temporary accommodation at Pirbright and supplied to Government authorities in Africa and elsewhere. Special emphasis has been placed on the production of a vaccine suitable for combating the epidemic of African-type foot and mouth disease which has been raging in the Middle East during the past six months. The vaccine will not, however, be used for the prevention of foot and mouth disease in Britain, where slaughter of infected and in-contact animals is the tried and approved method of controlling periodic outbreaks.

Government Wage Policies in the Public Sector

IN Broadsheet No. 467 (November 19, 1962) issued by Political and Economic Planning as part of a three-year study of Trade Unions in a Changing Society, B. Donoughue reviews wage policies in the public sector (*Planning*, 28, 19 November, 1962. Pp. 363–402. London: Political and Economic Planning, 1962. 4*s*.). The public services contain the fastest growing areas of public employment and also present the most complex difficulties to wage negotiators. Since the Second World War the most persistent problem for the unions in these services has been to maintain income-levels comparable with those in equivalent private employment where bonus payments substantially increase the earnings taken home. For the Government the major problem has been the reconciliation of its role as an employer with its wider responsibilities not to allow wage increases for its own employees which might be detrimental to the nation's economy. The growing acceptance in negotiating and arbitration procedures of the principle of comparability and the application of 'fair comparisons' formulæ largely solved the unions' difficulty. However, this was called into question by the Government's insistence that Britain's economic difficulties would not be solved unless wage increases were restricted to what the country could afford, and that wages must not increase on average faster than the average increase in national productivity. Pointing out that the public sector could play an important part in a national wages policy, Mr. Donoughue notes also that three specific questions will arise: how to ensure that public servants do not suffer a pay disadvantage compared with production workers; the role, if any, of arbitration; and the fixing of wages for loss-making public industries, such as the railways.

The Supply of Science Teachers

In replying to a debate on science and mathematics teachers in the House of Commons on December 21, opened by Mr. A. Skeffington, the Parliamentary Secretary to the Ministry of Education, Mr. C. Chataway, said that in March 1961 there were 7,321 mathematics graduates and 12,734 science graduates in grant-aided schools and establishments, increases of nearly 10 per cent and nearly 15 per cent, respectively, in two years; in the maintained secondary schools the figures were 5,077 and 8,528, increases of 7·8 per cent and 13·2 per cent, respectively. The numbers of mathematics and science graduates entering university departments of education to train as teachers had risen from 715 in 1957–58 to 965 in 1961–62 and 1,110 in 1962–63. While the growth in numbers entering the schools had kept pace with the general increase in the graduate teaching force, men teachers had been leaving the schools more rapidly than normally expected, in consequence of the ending of deferment under National Service, and further education and the training colleges had been gradually increasing their demands for mathematics and science graduates as part of their expansion programme. Physics teachers were far harder to come by than teachers of biology, and the general situation for girls was worse than for boys. The Ministry's Curriculum Study Group had embarked on a study of typical curricula patterns for schools of different types in relation to the demand and supply of teachers of particular subjects. Closer links were being formed with university appointments officers and a small steering committee had been established on the supply of mathematics teachers, bringing together schools, universities and the Ministry. The three-year course had given the training colleges the opportunity to broaden and deepen the training given to non-graduate teachers of science and mathematics. For mathematics there were about 240 lecturers and another 60 were teaching mathematics part-time or in combination with another subject. Science lecturers were limited to about 45 colleges. An encouraging expansion of teaching on television was proceeding and agreement had been reached between the British Broadcasting Corporation, the Independent Television Authority and the Postmaster-General on adult education and the expansion of the time allocated to it.

Standardization of International Non-Proprietary Names for Drugs

The World Health Organization has long been conscious of the need for standardizing non-proprietary names for drugs and seeking to gain their international recognition. In far too many cases the proposed international non-proprietary name (for example, thalidomide) has not appeared on the package in addition to the proprietary name, and this has complicated the problem of preventing, if necessary, any further use of the drug. Since 1953, lists have been published at intervals in the *WHO Chronicle* of proposed international non-proprietary names, and their adoption by national authorities for use in official texts, regulations, national pharmacopœias and other collections of specifications is becoming increasingly common. The first eleven lists of proposed international non-proprietary names have now been collected together under the title of *International Non-proprietary Names for Pharmaceutical Preparations: Cumulative List 1962*, giving the non-proprietary names in Latin and English, accompanied by the chemical names or descriptions in English (Pp. 52. Geneva: World Health Organization; London: H.M.S.O., 1962. 3 Swiss francs; 5s.; 1 dollar). The procedure for the selection of international non-proprietary names and the general principles for devising such names are appended at the end of the list. This publication should be of considerable assistance to national control authorities and pharmaceutical manufacturers, as well as to pharmacists, doctors and editors of scientific literature.

The O.E.C.D. Observer

The first issue of *The O.E.C.D. Observer* (November 15, 1962), published bi-monthly by the Organization for Economic Co-operation and Development, includes an article by T. Kristensen, the secretary-general, describing the purpose of this new periodical and an article by Prof. I. Svennilson on the role of research and education in the growth of an economy. The issue contains an article by G. Rehn on manpower, adaptability and economic growth, and some account of the Organization's structure for aiding development, including technical and educational assistance to newly developing countries. Also presented is a supplement which describes the aims, structure and work of the Organization, including an organization chart which indicates the place of the Committees of Scientific Research, Scientific and Technical Personnel, the Directorates for Scientific Affairs and for Manpower and Social Affairs, and the European Nuclear Energy Agency. Copies of *The O.E.C.D. Observer* are obtainable from O.E.C.D. Information Service, Château de la Muette, Paris 16e.

The Geology of Edinburgh

Just more than a century ago, the Geological Survey of Scotland published the first edition of its memoir on *The Geology of the Neighbourhood of Edinburgh*. Fifty years later a second edition appeared, and now after another half-century a third edition has been published (Pp. xii + 159 + 4 plates. Edinburgh: H.M.S.O., 1962. 35s. net). Probably no city in the world has made as great a contribution to geological thought and theory as has the Scottish capital, and it is a measure of the continuation of this tradition that this latest work, compiled by Dr. G. H. Mitchell and Mr. W. Mykura, is almost wholly concerned with information acquired by the Geological Survey since 1910. Not a mention of Hutton and his associates is to be found in its pages! In one respect alone does the new memoir compare unfavourably with its predecessors: although half the length of the 1910 edition (which had a coloured map), it is nearly five times its price. Not long ago the Edinburgh Geological Society sponsored a model guide for geological tourists (*Edinburgh Geology: An Excursion Guide*. Pp. xv + 222 + 8 plates: Edinburgh, Oliver and Boyd Ltd., 1960. 12s. 6d. net); and the juxtaposition of these two new books brings little credit to the costing methods of H.M.S.O., which result in the publications of the British Geological Survey being more expensive than those of most comparable official organizations overseas.

Research on Food Preservation in Australia, 1961–62

Readers of *Food Preservation Quarterly* will doubtless be aware of the stream of useful work which has emanated from the Food Preservation Division of the Commonwealth Scientific and Industrial Research Organization, Sydney, Australia. The wide scope of the scientific work carried out, together with its practical applications, is reflected in the Division's annual report for 1961–62, which includes sections on physics, food chemistry, microbiology, muscle biochemistry, meat, fish, eggs, plant physiology, fruits, vegetables and canned and dried foods (Pp. iii + 36. Sydney, Melbourne and Canberra: Commonwealth Scientific and Industrial Research Organization, 1962). Theories relating to heat and mass transfer when a fluid flows at a high velocity over the surface 'wall' have been the subject of further investigations. Work on beef showed that the pasteurization of hindquarters using hot water (65°–70° C) caused the destruction of 90–99 per cent of psychrophilic organisms without serious effect on the appearance of the tissues. The storage and quality of fruit has been considered from a number of points of view, including investigation of the prevention of scald and post-harvest treatment against infestation due to the Queensland fruit-fly. Considerable attention has been devoted to the radiation sensitivity of the eggs and larvæ of the fly. Better control of the radiation dose has resulted from the use of a small underwater fuel element irradiator and cobalt-60 source. Future projects will include the use of gas chromatography and infra-red spectrophotometry for the study of the volatile flavouring constituents of foods. Also the radioactive isotopes carbon-14, sulphur-35, calcium-45 and tritium are to be used in a study of the chemical and biochemical changes which take place in animal products.

Science and the Human Condition: Public Lectures at Hatfield College

For the third year in succession, and in response to public demand, the Teaching Staff Association of Hatfield College of Technology has organized a series of eight public lectures on scientific and philosophical subjects, taking as its general theme this year "Science and the Human Condition". The lectures are as follows: January 25, Dr. S. Lilley, University of Nottingham, "The Scientific Revolution and Industrial Processes"; February 22, W. J. P. Webber (Transport Salaried Staffs Association), "The Scientific Revolution and Industrial Organisation"; March 15, Prof. John Cohen (University of Manchester), "The Scientific Revolution and Leisure"; May 10, Sir John Rothenstein (Tate Gallery, London), "The Scientific Revolution and the Arts"; May 17, Dr. P. F. R. Venables (College of Advanced Technology, Birmingham), "The Scientific Revolution and Education"; May 24, Prof. Colin Cherry (Imperial College of Science and Technology, London), "The Scientific Revolution and Communication"; June 7, Prof. C. F. Powell (University of Bristol), "The Scientific Revolution and Morals"; June 14, Prof. P. M. S. Blackett (Imperial College of Science and Technology, London), "Technology, Science and Wealth". The inclusive fee for the course is 30*s*. Further information can be obtained from the Secretary, Teaching Staff Association, Hatfield College of Technology, Hatfield, Herts.

The Night Sky in February

Full moon occurs on Feb. 8d. 14h. 52m. U.T. and new moon on Feb. 24d. 02h. 06m. The following conjunctions with the Moon take place: Feb. 8d. 06h., Mars 3° N.; Feb. 20d. 15h., Venus 0·8° N. In addition to these conjunctions with the Moon, Mercury is in conjunction with Saturn on Feb. 28d. 09h., Mercury being 0·8° S. Mercury is a morning star, but is not favourably situated for observation from northern latitudes. Venus is also a morning star, rising at 4h. 45m., 5h. 00m. and 5h. 05m. on Feb. 1, 15 and 28, respectively. Its stellar magnitude is $-3·8$; its distance increases during the month from 69 to 88 million miles, and the visible portion of the apparent disk increases from 0·545 to 0·661. Mars is in opposition on February 4, and is above the horizon all night. It is at a distance of 62 million miles at opposition, when it has an apparent diameter of 14 seconds of arc and its stellar magnitude is $-1·0$; it moves from Leo into Cancer on February 4. Jupiter sets about three hours after the Sun on February 1, and conditions later become unfavourable for observation. Saturn is too close to the Sun for observation. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Feb. 1d. 19h. 39·5m., +11° 445 (*D*); Feb. 3d. 21h. 48·8m., 104 Tau. *m* (*D*); Feb. 4d. 21h. 08·3m., χ^2 Ori. (*D*); Feb. 5d. 22h. 17·5m., ζ Gem. (*D*); Feb. 6d. 19h. 10·2m., 85 Gem. (*D*). *D* refers to disappearance.

Announcements

Mr. C. C. Hentschel, formerly vice-principal of the Chelsea College of Science and Technology and recognized teacher of zoology in the University of London, has been appointed principal, in succession to Mr. N. M. Lightfoot, who died on November 20 (*Nature*, 197, 19; 1963).

The first British pest control conference, organized by the Industrial Pest Control Association, will be held at Lady Margaret Hall, Oxford, during April 1–3. Further information can be obtained from Mr. W. A. Williams, Industrial Pest Control Association, 86 Strand, London, W.C.2.

A general discussion on "The Structure of Electronically Excited Species in the Gas Phase", arranged by the Faraday Society, will be held at Queen's College, Dundee, during April 2–3. Further information can be obtained from the Assistant Secretary, the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

The Chemistry Division at Argonne National Laboratory expects to occupy its new 'hot' laboratory wing early this year. In celebration of this event, it is planned to hold a symposium on "The Transplutonium Elements" at the Laboratory in Argonne, Illinois, during May 15–17. Further information can be obtained from Dr. D. C. Stewart, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois.

A United Nations conference on "Application of Science and Technology for the Benefit of the Less Developed Areas" will be held in Geneva during February 4–20. Further information can be obtained from the United Nations, Geneva, or, concerning the British contribution, from Mr. D. Flook, Press Office, Department of Scientific and Industrial Research, State House, High Holborn, London, W.C.1.

The tenth Easter school in agricultural science will be held at the University of Nottingham School of Agriculture, Sutton Bonington, during April 8–11. The school will be the first of three discussions on crop ecology and will be concerned with the potato crop. Further information can be obtained from Mr. J. D. Ivins, University of Nottingham School of Agriculture, Sutton Bonington, Loughborough.

The sixteenth Laboratory Animals Centre congress will be held in the University of Glasgow during April 2–3. The programme will include: a method for producing hairless mice in large numbers; further observations on the maintenance of a mouse colony for the production of suckling mice; use of inbred strains of mice for feeding trials; the establishment of a beagle colony for experimental purposes; the care of dogs used for research; some observations on the American opossum; the significance of laboratory animals in the toxicity testing of new drugs. Visits have been arranged to the Hannah Dairy Research Station, the Marine Biological Research Institute and the Veterinary Research Farm, Cochno, and the Veterinary School, Garscube. Further information can be obtained from the Laboratory Animals Centre, M.R.C. Laboratories, Woodmansterne Road, Carshalton, Surrey.

TECHNICAL CO-OPERATION IN SOUTH AND SOUTH-EAST ASIA

THE report for 1961–62 of the Council for Technical Co-operation in South and South-East Asia emphasizes that, in moving into its second decade, the Colombo Plan has become truly international, its 22 members including ten non-Commonwealth countries, and, outside the region, Australia, Britain, Canada, Japan, New Zealand and the United States. More than 24,000 persons from the countries of the area have received training in other Colombo Plan countries, and more than 4,000 experts have visited the area. Scientific, technical and training equipment to the value of more than £32 million has been supplied to the area and the total value of technical assistance supplied under the Plan now exceeds £102 million. The proportion of expenditure allocated to experts, trainees and equipment has remained fairly stable during the past few years, but the distinction between the giving and receiving countries has become gradually blurred. An astonishing and inestimable reservoir of goodwill has been created among its makers and constituted one of the most successful post-war ventures in international trust and co-operation.

The United Kingdom provided 656 new training places during the year, bringing the total provided under the Plan to 4,536, compared with 9,335 by the United States, 4,071 by Australia, 1,863 by Canada, and 1,914 by India. The United Kingdom provided 47 new experts during the year, making a total of 493 under the Plan, compared with 1,833 provided by the United States, 488 by Australia, 425 by Japan, 293 by Canada, 446 by India, and 180 by New Zealand. The United Kingdom provided £362,571 worth of equipment during the year, making a total of £2,372,359 out of the £32,643,789 provided under the Plan. Altogether in 1961–62, the United Kingdom provided £1,571,807 on technical assistance under the Plan, making a total of £8,623,240, exclusive of aid given to North Borneo and Sarawak under the Colonial Development and Welfare Acts. The United Nations and its specialized agencies has also supplied 9,149 experts and 6,951 Fellows to the area during the period of the Plan, and of these experts supplied during the year under the Plan, 103 were in general and 27 in technical education, 72 medical and health, 122 food, agriculture and forestry, 194 engineering, 253 transport and communications, 63 administration, 60 industry and trade and 29 social services.

Apart from continuing as a normal function of the Colombo Plan Bureau the survey of training facilities at the technical level in the area provided by the Mills Report, the Bureau has directed the attention of members of the Council to a recommendation of the Sub-committee on Technical Co-operation for a survey of technical assistance needs in the region and has suggested that each country should survey its needs and send the reports to the Bureau for circulation through the Council. The report also stresses the need for the developing countries to think in terms of long-term economic growth based on a rational use of manpower and material resources rather than short-term expediency and for a continuing critical evaluation of the productivity of technical co-operation. The continuing importance of technical co-operation as a means of removing the shortage of the trained manpower needed for an increased tempo of economic development cannot, however, be overemphasized.

Of trends during the year the report notes that about 25 per cent of expenditure was on trainees, nearly 40 per cent on experts and advisers and the remainder on books, films and equipment. There was a marked increase in the number of training places provided by countries within the region and the United States provided almost half the total training awards made during the year. Long-term assignments for experts were increasingly popular but expenditure on all forms of technical co-operation is increasing.

The examples of British contributions to technical co-operation which follow will illustrate the range of effort covered. In agriculture the British Government repeated its offer of training in the technology of stored products, entomology and rodent control and a laboratory assistant from Malaya was accepted for a two-year course at the Central Veterinary Laboratory of the Ministry of Agriculture, Fisheries and Food, while equipment is being supplied for use at the Veterinary Research Laboratory in Burma. Forest officers from Ceylon, Pakistan and Burma have attended the postgraduate course for forestry officers from tropical countries at the Imperial Forestry Institute, Oxford, and Britain is also supplying equipment to the Pakistan Forest Institute at Peshawar.

The Atomic Energy Commission of Pakistan is to establish an Institute of Nuclear Science and Technology and also proposes to establish training centres at graduate and postgraduate level in different fields of nuclear energy. To implement this programme, six trainees are following courses at the University of Manchester. The Government of India has obtained for five years the services of the Deputy Director-General of the National Coal Board of Britain, who will advise the Indian Coal Development Corporation on the development of three underground coal mines at Jaraughdi, Katanka and Swant. Britain has also provided Burma with the services for two years of an expert in jute grading and baling to assist in supervision and training of personnel in the jute production drive of the Agriculture and Rural Development Corporation. In addition to providing eleven experts and training for eighteen officers for the Operations Division of the Ceylon Transport Board, the British Government has now provided two rolling-stock engineers for one year, several short training courses in bus operation and larger courses for engineers and depot managers, etc. A deputy superintendent of police from Pakistan received three months training in Britain with county and city police forces and training was arranged with British Railways for a senior mechanical engineer of the Railway Staff College, Baroda, the works manager, Central Workshops, Mysore, a district mechanical engineer of the South-Eastern Indian Railway and the mechanical engineer (operating) of the Eastern Railway. Training of six-months duration in aircraft maintenance was arranged for three trainees from Indonesia's Civil Aviation Academy at various institutions in Britain, and Britain is providing an expert, training facilities and equipment for the Telecommunications Department of the Federation of Malaya, while three engineers are being trained in transistor technology for the Community Listening Centres of the Government of India, and a technician of the Burma Broadcasting Service is taking a one-year course in electronics at the University of Southampton.

In health services the British Government arranged a two-year course in radiation physics to supply the physicist of the radiotherapy unit at the Cancer Institute, Meheragana, Ceylon, with specialized training and loaned a physiotherapist to the Rangoon General Hospital to re-organize the Physiotherapy Department and train personnel. Training in oral surgery is being provided

at the Institute of Dental Surgery, London, and Mount Vernon Hospital, Middlesex, for the supervisor and instructor of Thailand's School of Dentistry, and an assistant surgeon of the Mandalay General Hospital is taking a three-year postgraduate course in dentistry at the Dental School, Guy's Hospital, while at the request of Thailand a one-year course in applied nutrition and food sciences was arranged at the London School of Hygiene. A health educator and public health inspector from Malaya is studying for a diploma in health education at the Institute of Education, London, and Pakistan has been assisted to start the F.R.C.S. (Primary) course of the Royal College of Surgeons, London, while to meet the shortage of qualified anæsthetists in Burma, a civil assistant surgeon is following a two-year course in anæsthesiology at the Postgraduate Medical School, London.

In education, Britain arranged a two-year course in concrete technology for an assistant professor of the College of Technology, Coinbatore; a librarian from Malaya is following a one-and-a-half year course in librarianship at the North-Western Polytechnic, London; five trainees from Malaya, Indonesia and the Philippines attended a course in tropical agriculture offered by the British Government, and an engineer from Nepal a postgraduate course in chemical engineering at Battersea College of Technology. Seven teachers from Indonesia's Science Teaching Centre, Bandung, are attending two- to three-year courses in teaching science at Sheffield; science laboratory equipment, chemicals and books were supplied to five State high schools in the Shan States of Burma. A postgraduate course for two trainees from the University of Philippines was arranged at the Royal College of Science and Technology, Glasgow, and arrangements made for the senior lecturer of the Physics Department, University of Sind, to undertake nuclear research at Trinity College, Oxford, while a trainee from the Birbal Sahni Institute of Palæobotany is taking a postgraduate course at Queen's University of Belfast. The President of Burma's Shan State Civil Service is being trained in public administration in Britain, while five Laotian trainees attended a six-month course at the Royal Institute of Public Administration.

THE UPPER CRETACEOUS OF CENTRAL EUROPE

THE Palæontological Section of the Geological Society in the German Democratic Republic held a symposium in Dresden during October 2–7, 1962, on "Problems of the Stratigraphy and Palæontology of the Cenomanian to Coniacian Stages in Central Europe". Three days of papers with discussion and three days of excursions in Saxony were organized by Dr. H. Prescher of the Staatliches Museum für Mineralogie und Geologie zu Dresden and Dr. K.-A. Tröger of the Geologisches Institut der Bergakademie Freiberg (Sachs). The meetings were attended by some thirty geologists, mostly from the German Democratic Republic, but also from Czechoslovakia, Hungary, Poland and Great Britain. The eighteen papers read will be published early in 1963 in the *Berichte der Geologischen Gesellschaft in der D.D.R.*

General reviews of the present state of knowledge of the Upper Cretaceous in Bohemia were given by F. Macák and V. Müller and in papers sent in by J. Soukup and J. Dvorák. A useful summary has already been published by Soukup in tabular form with German transliterations of all the Czech localities mentioned[1].

The extensive work by Polish geologists on the flysch-facies of the Carpathians, thrust northwards into southern Poland, has become well known in Britain in recent years, mainly through the work of M. Ksiazkiewicz and his colleagues at Krakow[2,3]. The post-war work on the boreal facies in Poland is, as yet, less well known. A general summary of this recent work was given by S. Cieśliński, who has already published work on the Albian and Cenomanian which has faunal and facies similarities to north-west Europe[4,5]. For the symposium he had prepared a map which showed the Cretaceous basins in Poland and the facies-succession distribution in each basin. The Silesian–north Sudetic Cretaceous, lying to the south-west of the Sudetenrand Fracture, Eule Gneiss and the North Sudetic Schiefergebirge, was discussed in more detail by J. Milewicz, and is distinct from the rest of Poland, being allied to the Saxony–Bohemian region.

Six of the papers were largely or entirely concerned with Saxony itself. Much detailed work has been done here since the comprehensive summary by Seifert[6]. The fresh-water beds, widely developed at the base, have already been studied by Prescher[7] and Barthel[8]. W. Krutzsch (president of the Palæontology Section) gave an account of the micro-flora obtained from a boring at Königstein. Of the marine formations, not only the Unterquader but also the Plenus Zone has commonly been included in the Cenomanian by Saxon geologists; the Czechs have considered the Plenus Zone to be Turonian and this conforms with British usage; some Czech and Saxon geologists now refer to it as a transitional zone between the two stages. In Saxony the Plenus Zone contains *Metoicoceras* spp., which show that it corresponds to the Actinocamax Plenus Zone in England.

Detailed isopachytes for the Unterquader plus Plenus Zone prepared by F. Decker show that Seifert's palæogeographical maps are misleading and must have depended much on guesswork, at least for land–sea distribution. Decker's map shows a general increase of thickness to the north-east of the Elbtalgebiet beneath the south-westerly overthrust Lausitzer granodiorite. The same granodiorite conceals sediments of the North Sudetic Basin as shown by borings near Spremberg reported on by W. Haller. One of these showed some 1,100 m of marly clays and fine sandstones embracing only the Turonian to Lower Campanian. The coring was sufficiently wide to allow recovery of a considerable fauna of ammonites and *Inoceramus* spp.

The considerable thicknesses of detrital shelf sediments in Saxony above the Cenomanian were noticeable in the excursions. In southern Saxony there are more than 500 m of orthoquartzites (the Quadersandstein) in the Turonian alone. The provenance of this sand is still a problem and H.-D. Beeger has found that the non-opaque heavy minerals are almost confined to the stable trio zircon, tourmaline and rutile. Current bedding is often not developed and does not give a consistent pattern. The contrast with north-west Europe is further shown by the scarcity of glauconite and rarity of phosphate.

The next session of the Geological Society in the German Democratic Republic will be in Leipzig during May 13–18, 1963, on the theme "Facies". Further information can be obtained from J. Lamprecht, Wiss. Sekretar der Geologischen Gesellschaft in der D.D.R., Berlin N4, Invalidenstrasse 44, German Democratic Republic.

MANAGEMENT IN ELECTRICITY SUPPLY

MR. C. T. MELLING'S inaugural address as president of the Institution of Electrical Engineers, delivered on October 11, might be said to constitute a study of management related particularly to the electricity supply industry.

Pointing out that electricity has become almost ubiquitous in its application, being nowadays basic to industrial, commercial, domestic and rural life, Mr. Melling observed that the electricity supply industry's future growth would influence powerfully Great Britain's development as a manufacturing nation. It was, he said, an industry characterized by very rapid technological development and a high rate of growth. These in themselves produced financial problems of great magnitude and, over and above, the industry had undergone several drastic changes of organization. The supply industry will have to solve technical, economic and financial problems of great complexity.

In fulfilling its fundamental purpose of supplying electricity to consumers, the industry operates as a business with public service responsibilities. Business management, combined with public service, formed the incentive in building up electricity supply in the various independent organizations, public and private, which, prior to nationalization, constituted in their aggregate the national system. Principles and practices so established duly influenced the terms of the Electricity Act of 1947 which, in creating a single nationalized system, exemplified in some ways the principle that in codifying what is to be done, legislation should incorporate the best of what is already being done.

In summarizing the general duties of a supply authority Mr. Melling distinguishes nine separate areas of activity. The first of these which, in some sense comprehends, by implication, all the others, may be quoted in full: "to ensure within the framework of a sound financial policy that, by forecast planning and construction, there is sufficient but not extravagant, generation transmission and distribution capacity to meet demands as they arise and that, consistent with reliability and good service, there is economy in capital and operating costs".

In other paragraphs are briefly stated the requirements of a sound tariff structure and a vigorous commercial policy together with the important duties of fostering good employer–employee relations and of good public relations. The pursuit of research, the improvement of efficiency, the development of a good consumer service and the achievement of co-ordination, constitute the subjects of the further paragraphs.

As a first example of a general management problem Mr. Melling took that of the organization of an area board following the nationalization of the industry in 1948. Nationalization, abolishing existing undertakings and establishing new bodies, might under one area board incorporate some forty separate undertakings. Any process of re-organization tends to produce, in employees who will be affected, a sense of uncertainty and possibly of apprehension, and such an operation on a national scale might well have been expected to be accompanied by some degree of disorganization. In fact the transition from the old system to the new was effected quite smoothly, a result to be attributed largely to the momentum of existing practices and to the competence and the good spirit of the people in the industry.

Decentralization of the consumer service was the keynote of the organization of the area boards. It was the aim that district managers should be truly responsible managers for their districts who, working within the framework of a sound practical policy, would have confidence and freedom in their day-to-day operations and in the exercise of their judgment in their relations with employees, consumers, local authorities and the public. Of paramount importance was the maintenance of communication and consultation to keep rank-and-file employees properly informed and to gain their active interest and co-operation in the efficient and economical working of the organization. There are, established by statute, organizations for the negotiation between management and employees representatives of wages, salaries and conditions of service and, similarly, for joint consultation on safety, health and welfare, education and training. These measures will, however, be ineffective unless they really 'permeate' the system. That is to say, the requirement is not met by formal compliance with an instruction to meet at specified intervals but only by top management directly and personally informing and consulting middle management which in turn will do the like with lower management. Thereafter, foremen and supervisors must inform and consult the employees under their direct control. Information must be transmitted promptly along the established chain of command, for the 'short circuiting' of authority at any level undermines confidence and engenders disaffection.

Numerous detailed changes were made in the organization of area boards in the years following nationalization. Unduly small districts were combined to form larger distribution units and experiments were made in the arrangements for repair workshops and stores. Operating practices were analysed and work studies undertaken.

By considering the effects of changes on individual employees and by avoiding undue haste, improvements were made more effectively and resulted in real rather than paper economies. Excluding the cost of bulk supplies of electricity the operating costs of area boards (pence per kWh sold) have been reduced in the ten years to March 1962 by about 16 per cent. This, taking into account the diminished value of money in the same period, represents a real saving of some 45 per cent.

The urge for further economies continues and there are new problems arising from developments in technology and new operating techniques and, underlying everyone of these, is the basic problem of human relations. While it is essential that there should be a dynamic and enterprising spirit in relation to improvements, it remains true that large-scale changes in internal organization are just as disturbing to many people as general changes imposed by legislation. It is to be hoped that there can now be a period of stability and consolidation.

Mr. Melling chose in his second example of a general management problem to deal with certain specific issues in commercial development. The provision of the correct generation, transmission and distribution capacity to meet future demand depends on accurate forecasting. The trend from which such forecasts must be made depends on the antecedent period over which the trend is determined and herein lies the matter of judgment. Periods of depression or of industrial recovery are reflected in an oscillation of the rate of growth curve but, of course, each cycle varies from its predecessor. Based on a ten-year trend curve a compound interest factor of 7·6 per cent is obtained, but owing to the more rapid rate of increase in demand during the past few years a figure of 7·9 per cent is at present being utilized.

The industry's annual capital investment is approaching £500 million, which represents some 10 per cent of the nation's total capital investment. While it is clear that the present rate of increase of demand cannot continue indefinitely, it is unlikely that estimates of growth during the next few years are over optimistic. Great Britain still lags considerably behind the United States in the *per* *capita* consumption of electricity. It is, however, interesting to note that if in six years the present forecast should prove to be over-optimistic by, say, 500 MW the additional capital changes would be nearly offset by savings in operating costs as a corresponding amount of the least efficient plant in operation could be taken out of service and scrapped.

Modern statistical techniques and computer studies are utilized on long- and medium-range forecasting. Distribution requirements having essentially a local and to some extent an individual character remain largely matters of judgment on the part of management.

Research is a primary factor in promoting the commercial development of the industry. For engineering research the supply industry has in the past relied largely on manufacturers and the co-operative work of the Electrical Research Association. It has, however, been realized that the industry requires to conduct a considerable research programme of its own and on this an amount of about £6 million is being spent per annum.

It is clear that insufficient national effort has been directed to matters in which the characteristics of the consumer are of importance. Physiological, psychological and economic factors are involved. For example, the use of 'off peak' supplies for domestic and industrial purposes is increasing rapidly. Electric floor warming introduces a number of novel problems. Not least among the problems requiring investigation is that of the economics of such novel types of load. From the point of view of management, judgment and appraisal have to be applied to determining the sums to be allocated to research in its various aspects, and to the weight to be given to scientific and engineering opinion in the wider context of commercial and social implications. Management must, in fact, endeavour to provide conditions in which engineers, physicists, mathematicians, economists and statisticians can co-operate fully and effectively in advancing the practice of electricity supply.

In the matter of tariffs, management has not only the overriding responsibility of ensuring an adequate total revenue but also a considerable power of influencing the development of demand in desirable directions. While there must be no undue preference for or discrimination against any consumer or class of consumer, there are opportunities for devising special tariffs which can be not only related to the special requirements but also can conduce by better distribution of demand to improvements in the overall operation of the system.

Mr. Melling's third example was the most fundamental one—that of ensuring a supply of managers for one or two decades ahead. In the direct exercise of their professions, engineers, physicists, accountants or lawyers might give quite a good indication of their promise within a few years of graduation. The development of the potential manager and the demonstration of his qualities is a slower process. In Mr. Melling's opinion engineering provides, for management, as good a background as any other profession.

The supply industry, in developing its future managers, utilizes techniques common to most progressive industries. Potential managers attend courses in the industry's own residential training establishments, in universities and elsewhere. At the Electricity Council's training centre in Surrey are provided two types of course, one designed to promote general executive development through the medium of tackling unfamiliar problems by the syndicate method. The other studies individual subjects of importance to managers such as communication, organization and finance. The Generating Board and individual area boards organize similar training courses to meet their own needs. The facilities of the Administrative Staff College at Henley are also used.

Within the actual operating organization itself a system of regular appraisal is being used. This is designed to assess the potential of individuals and to formulate a scheme of training appropriate to individual needs. Following appraisal, selected members of staff may be sent on courses, given 'cross-postings' to new types of work, or allocated to specific assignments. The aim is to provide exposure to some type of problem which has not been met before and which will exemplify human, as well as technical and economic, factors.

Many problems in any sphere of activity are necessarily those of the specialist, and management, in exercising judgment, is as often concerned to assess the qualities of the expert as the advice which he offers.

Academic qualifications, experience, and in some measure knowledge and intelligence are susceptible of direct assessment. The assessment of the qualities of the potential manager which relate to character and personality remains one of the most difficult of problems.

Mr. Melling completed his address by reviewing the role of the Institution of Electrical Engineers in fostering, through the Institution's educational requirements, the development of potential managers.

J. Greig

THE *DRAGON* HIGH-TEMPERATURE REACTOR PROJECT

The third annual report of the Organization for European Co-operation and Development High Temperature Reactor Project (*Dragon*), covering the period from April 1, 1961 to March 31, 1962, has been issued by the European Nuclear Energy Agency*. The participants in the Project are the United Kingdom Atomic Energy Authority; the Euratom Commission, consisting of the six countries, Belgium, France, Germany, Italy, Luxembourg and the Netherlands; the Austrian Government; the Danish Atomic Energy Commission; the Norwegian Institut for Atomenergi; *AB* Atomenergi of Sweden; and the Swiss Government. The Project, which is based at Winfrith, Dorset, has as its principal aims the design, construction and operation of a 20-MW high-temperature gas-cooled reactor, and a programme of research and development to explore the practical possibilities of this type of reactor and the technical problems resulting from operation with temperatures close to 1,500° C in the core of the reactor. The *Dragon* reactor is not the only high-temperature reactor under construction. A similar reactor *HGTR* is being built for the Philadelphia Electric Company at Peach Bottom in the United States, and there has been continuous and close collaboration between the members of the United States Atomic Energy Commission and members of the Project concerning materials for the reactor cores, reactor physics and common design problems. The *Dragon* reactor is likely to be the first of the high-temperature reactors to be brought into operation. Fuel loading was expected to commence towards the end of 1962.

For 1961–62 expenditure on the Project is estimated at about £4,000,000 and for 1962–63 about £5,400,000. The total cost of the original five-year programme ending in 1964 is now estimated at about £15,000,000, and a working party has been set up to examine the question of an extension of the five-year agreement. (It has recently been announced that the extension has been approved; *Nature*, 197, 129; 1963.)

---

* Organization for Economic Co-operation and Development: European Nuclear Energy Agency. O.E.C.D. *Dragon* High Temperature Reactor Project—Third Annual Report, 1961–62. Pp. 196. (Paris: Organization for Economic Co-operation and Development: European Nuclear Energy Agency, 1962.)

The annual report is divided into three main sections, dealing with research and development, reactor design and construction, and administration, respectively. In general, the technical predictions on which the project was originally based continue to be confirmed by experience. No significant changes in the basic concept have been necessary, though an important change in the safety principles has been decided on. The inner containment, which consists of a steel shell containing the reactor core, is to be filled with air instead of nitrogen, but the design is such that a return to nitrogen filling, if required, can still be made. The reactor pressure vessel has been successfully pressure and leak tested and delivered to the site. Its erection within the reactor building is proceeding. Steady progress has been made in the design of the fission product and helium purification systems, and a contract for the purification plant is expected to be placed shortly. Construction of the reactor building has advanced rapidly and the control building has been completed.

Theoretical studies during the year have been concentrated on 'burn-up calculations' and power and temperature distributions. The distribution of radioactivity in the *Dragon* system has been estimated. The experimental reactor physics investigations carried out in the *Zenith* reactor continued until July, when the exclusive use of the *Zenith* reactor for the *Dragon* programme came to an end. Several measurements have been made and evaluated. Heat-transfer channel experiments simulating *Dragon* reactor conditions have been carried out at Risø, Denmark. Carbon transfer experiments have emphasized the importance of extremely pure graphite in the core. Barium has been found to have a strong catalytic influence on graphite corrosion while silica acts as an inhibitor. The graphite for the main reactor components other than the fuel elements has been delivered and is in the process of being machined. No firm decision has yet been taken as to whether a fission product emitting fuel or a fission product retaining fuel will be used for the first charge in the *Dragon* reactor, but development work has proceeded on both types and plans for manufacturing either type are in hand.

The report contains many other details of the core and graphite assemblies and control mechanisms together with numerous dimensional diagrams and photographs of the various components. Annexed to the report are charts showing the composition of the staff of the Project; the members of the Board of Management and the General Purposes Committee—the two international committees responsible for the direction of the Project; and a list of all major contracts placed up to March 31, 1962.

S. WEINTROUB

RADIOACTIVITY IN HUMAN DIET

EACH year, as a reminder of the hazards of the atomic age, reports are issued by the Agricultural Research Council Radiobiological Laboratory of levels of radioactivity in human diet. The annual report, 1961–62*, includes a review of research designed to give better understanding of factors which influence the passage of radioactive material from fall-out into plants and animals, both by direct contamination of foliage and via the soil, finally appearing in the mixed diet of the human population. The results of this work range from a demonstration that deposition of strontium-90 in soils may be reliably predicted from figures for annual rainfall, to a final indictment of the Brazil-nut as a concentrator of radium and thorium from the soil on which it is grown; about 1,000 times as much of these isotopes are found in Brazil-nuts as in other nuts and fruits.

The report gives the mean ratio of strontium-90 to calcium in the total mixed diet as 6·2 picocuries per gram of calcium during 1961 as compared with 6·4 in 1960 and 9·0 in 1959, the corresponding values for milk being 5·9, 6·4 and 9·7. It is stressed, however, that the figures obtained so far do not as yet reflect the full effects of the resumption of nuclear testing in 1961, and the most recent measurements support the forecast that the situation in 1962 will not differ greatly from that in 1959 after the tests in 1958.

Reference is made in the report to a 'working level', which is defined as 130 picocuries of strontium-90 per gramme of calcium. Indefinite exposure at this level would induce in bone amounts of strontium-90 of approximately half the maximum permissible specified by the Medical Research Council. In fact, the recommendation of the Medical Research Council's second report, ***The Hazards to Man of Nuclear and Allied Radiations*** (Cmnd. 1225, December 1960), was that "if the concentration of strontium-90 in bone calculated as an average for any age group, including the groups of infants and young children, was found to be rising continuously and to have reached the level of one-half that recommended as the maximum permissible level for the population as a whole, a re-assessment of the situation would be required". The derivation of a 'working level' in the diet, from a maximum permissible level in bone, is not explained in the report from the Agricultural Research Council, and the size of the margin of safety adopted is not given.

In view of this the implications of the term 'working level' are difficult to assess and at best this seems a most unfortunate choice of words.

---

PETROLEUM MULCH

IN arboriculture the word 'mulch' is usually associated with the compost of wet leaves, straw, etc., laid as a protection to the roots of newly planted or young trees, especially on inherently dry soils. Petroleum mulch, however, is a relatively recent product of research in the industry and although in some respects its behaviour and purpose are similar to traditional soil-dressings, its potentialities are probably more far-reaching and durable. In the autumn number of the ***Esso Magazine*** (1962), an informative and well-illustrated account of a petroleum mulch evolved by Esso Research is given. The efficacy of this product is now being tested and proved on a large number of sites in many different countries. Already results are most encouraging and augur well for yet another application of petroleum to the well-being of mankind.

Briefly, this type of mulch is in fact an inexpensive emulsion of petroleum resins, used as an agricultural spray for improving the growth and yield of crops of all kinds. Its function is four-fold: to warm the soil, to reduce evaporation, to protect against soil-erosion, and to retard the dispersal by rain-wash and other agents of

College of Sc

vital mineral and chemical constituents in the soil growth-zones wherever it is used. Most crops are planted in rows and when seeded can be sprayed with this petroleum mulch. The width of these bands may vary from three to ten inches or more, according to the nature of the crops, spacing, and soil conditions. In this way a thin, continuous protective film of the emulsion is formed on the top of the soil, adherent but not deeply penetrating. This film is rain- and wind-proof and remains intact for up to ten weeks. The effect is drastically to reduce the rate of moisture evaporation from the soil involved; also, because of its dark colour, sunlight is absorbed and heat trapped, so that in favourable circumstances soil temperatures can be raised by as much as 20° above normal.

Some significant results are quoted. Tests on cotton plants in Arizona in 1960 revealed that where this mulch was used, twelve days after planting, 121,900 plants per acre had emerged as against 8,710 per acre on the control area. The final yield in bales per acre was 2·2 with mulch and 1·65 without, an increase of 34 per cent. In comparable tests with melons, an increase of 17 per cent was attained, while with vegetables such as carrots, onions, lettuces, turnips and radishes, the increase ranged from 22 per cent to 67 per cent. Similar tests of the reaction of different plants to petroleum mulch under a great variety of climatic conditions, have been carried out in the United States, Europe, and arid and semi-arid areas in North Africa, with equally beneficial results. H. B. MILNER

METALLOGRAPHIC EXAMINATION OF THE PHASE DIAGRAM OF THE GALLIUM–TELLURIUM SYSTEM

By J. R. DALE

Mullard Research Laboratories, Redhill, Surrey

KLEMM and von Vogel[1] obtained a phase diagram for the gallium–tellurium system by means of thermal and qualitative X-ray analysis. Newman, Brice and Wright[2] modified this by investigating the system by differential thermal analysis and by direct observation of the melting-points under controlled tellurium pressures. Since no attempt appears to have been made to check the phase diagram metallographically and no data on the microscopy of the system appear to have been published, a metallographic analysis of the system between 50 and 85 per cent tellurium (all compositions are quoted in atomic percentages) was undertaken.

The samples for microscopic analysis were prepared from 99·999 per cent gallium (from Aluminium Industrie Aktien Gesellschaft) and 99·999 per cent tellurium (from Mining and Chemical Products, Ltd.). The gallium was cleaned by etching in dilute hydrochloric acid before weighing and the tellurium in concentrated hydrochloric acid. After weighing the materials (total weight approximately 2 g) were placed in silica crucibles which were sealed under high vacuum to eliminate loss of tellurium. In general, the samples were reacted for 8 h at 840°–860° C followed by furnace cooling to give a cooling rate of approximately 4°–5° C/min. Some of the samples were vibrated at 50 cycles/sec at low amplitude to give better mixing and more rapid reaction.

To prevent deformation of the relatively soft GaTe and to facilitate sectioning, ingots were mounted in cold setting low-shrinkage epoxide resin blocks ('Bakelite Resin 19019, Hardener Q18814'). In most cases the whole ingot was potted so that a full macroscopic examination could be carried out to determine if any segregation or other inhomogeneities had occurred during the reaction and cooling procedure.

The ingots were prepared for metallographic examination by first lapping successively on 400 mesh, 600 mesh and precision grades of silicon carbide emery polishing papers (Union Glue and Gelatine Co., Ltd.) using paraffin as a lubricant. Intermediate polishing was carried out by lapping on successive grades of diamond paste (L. M. Van Moppes) from 16μ particle size to 0·25μ held on photographic paper pads. A final polish was carried out using a 'Selvyt' cloth pad rotating at 750 r.p.m. and impregnated with a dilute solution of gamma polishing alumina. This long lapping and polishing procedure was found necessary to prevent flowing and deformation of alloys containing less than 58 per cent tellurium, for those having a higher tellurium content the intermediate polishing procedure could be omitted.

Two etches were selected for the determination of the phase diagram by microscopical analysis. The compositions of these etches were:

No. 1 etch: 50 parts glacial acetic acid; 5 parts hydrofluoric acid (40 per cent); 5 parts nitric acid (sp.gr. 1·42).

Samples were etched for 1–2 sec, rapidly transferred to a water bath or quenched and then dipped in concentrated ammonia for a few seconds to remove any slight film formed. The samples were finally washed in de-ionized water and rinsed in ethyl alcohol to prevent staining. No. 1 etch attacked GaTe more rapidly than Ga_2Te_3.

No. 2 etch: 50 parts glacial acetic acid; 5 parts nitric acid (sp.gr. 1·42); 2 parts hydrofluoric acid (40 per cent); 2 parts hydrogen peroxide (100 vol.). This was used as a stain etch to identify the gallium–tellurium compounds in conjunction with No. 1 etch; this caused Ga_2Te_3 to be stained light brown but had very little effect on GaTe.

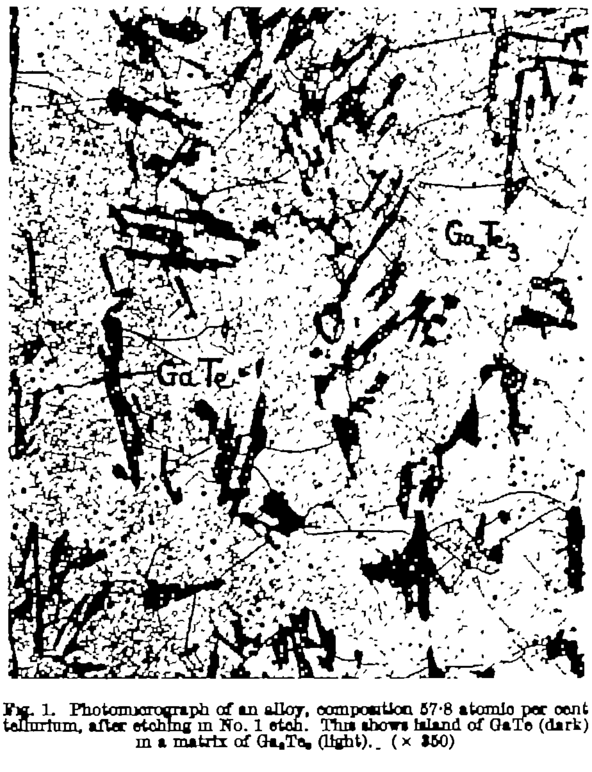

Fig. 1. Photomicrograph of an alloy, composition 57·8 atomic per cent tellurium, after etching in No. 1 etch. This shows island of GaTe (dark) in a matrix of Ga_2Te_3 (light). (× 350)

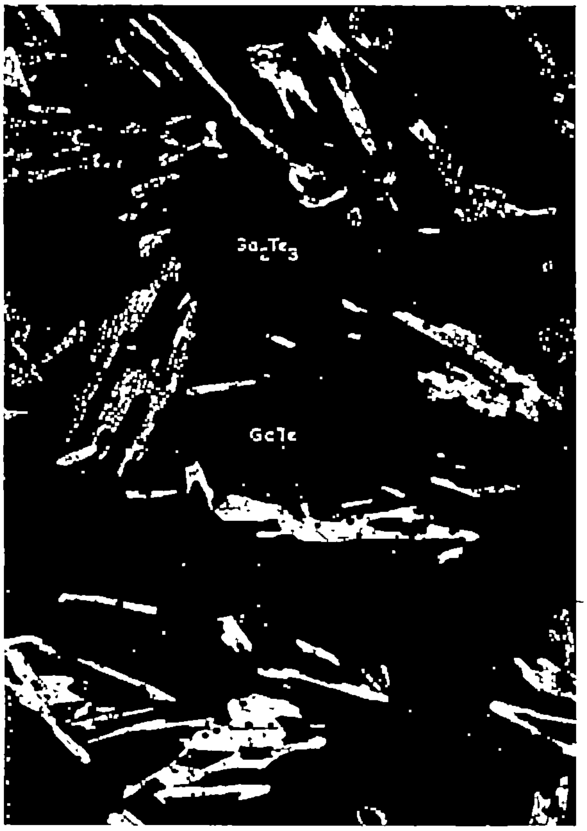

Fig. 2. Photomicrograph of the same section as in Fig. 1 but using etch No. 2. This shows islands of GaTe (light) in a matrix of Ga_2Te_3 (dark). (× 500)

The procedure normally used was to etch for 2–3 sec, wash in de-ionized water and finally rinse in ethyl alcohol.

The effects of these etches on similar sections of an ingot of 57·8 per cent tellurium can be compared in Fig. 1 etch No. 1) and Fig. 2 (etch No. 2). In Fig. 1 dark plates of GaTe can be seen in a light matrix of Ga_2Te_3, in Fig. 2 the matrix of Ga_2Te_3 is stained light brown and the GaTe unattacked.

All the samples examined were highly polycrystalline with a range of grain sizes from a few μ to almost 1 mm. A small number of ingots which showed segregation of the different phases were rejected when assessing the accuracy of the phase diagram. The type of segregation normally observed was that of plates of GaTe accumulating at the top free surface of the ingots with crystals of Ga_2Te_3 at the bottom.

A limited number of horizontally zone refined polycrystalline bars of Ga_2Te_3 grown under controlled tellurium pressures from $7{\cdot}4 \times 10^{-1}$ mm mercury to 5·2 mm mercury were examined for inhomogeneities and microhardness. In most cases when the tellurium pressure was less than approximately 2 mm mercury, free plates of GaTe were found in a matrix of Ga_2Te_3; as would be expected, the higher the tellurium pressure the smaller the concentration of GaTe formed. When only 5–10 per cent GaTe plates (by volume) were present they were found to segregate around the periphery of the bars leaving the centre single phase. When bars were grown under tellurium pressures greater than approximately 2 mm mercury both $GaTe_3$ and $GaTe_3$–Te eutectic were observed along grain boundaries of the Ga_2Te_3, generally near the centre of the bars and not close to the periphery.

Sections of ingots having compositions of 50–55 per cent tellurium showed strained primary plates of GaTe in a matrix of GaTe–Ga_2Te_3 eutectic. This can be seen in Fig. 3, which is a photomicrograph of a section of an alloy containing 54·9 per cent tellurium (loaded composition) after etching (No. 1 etch). In this case the microstructure of the eutectic shows it to be composed of a matrix of Ga_2Te_3 in which are set a large number of fine plates of GaTe.

Fig. 4 is a photomicrograph of an alloy containing 55·8 ± 0·1 per cent tellurium (by chemical analysis) after etching. The microstructure of the alloy shows a slight excess of GaTe from a homogeneous eutectic structure. Fig. 5 shows an alloy of 56·3 per cent tellurium (loaded composition) after a 30-day anneal at 760° C; this appears to have a slight excess of Ga_2Te_3 from a homogeneous eutectic structure.

From the microstructure of these ingots the composition of the GaTe–Ga_2Te_3 eutectic lies between 55·8 and 56·3 per cent tellurium, which is slightly lower than that obtained from differential thermal analysis measurements of Newman *et al.*[3] (they quote 56·5 per cent tellurium eutectic composition); this is not unreasonable since up to 1 or 2 per cent scatter of results was indicated.

Fig. 6 is a photomicrograph of an alloy of 58·4 per cent tellurium after etching. In this alloy the matrix consisted of strained crystals of Ga_2Te_3 surrounded by a large quantity of the GaTe–Ga_2Te_3 eutectic. In alloys having a tellurium content higher than 55–56 per cent, GaTe crystals had a needle-like appearance rather than the broad plates observed in alloys with less than 55 per cent tellurium.

When observed in the polished but unetched condition, GaTe (in alloys having a composition between 50 and 60 per cent tellurium) appeared as a light blue phase polished in relief.

Alloys containing 59·7 ± 0·1 per cent tellurium (by chemical analysis) were observed to consist of fairly large unstrained single-phase grains of Ga_2Te_3. On increasing the tellurium content to 60·0 ± 0·1 per cent (by chemical analysis), a highly strained but single-phase structure of Ga_2Te_3 was formed. This is shown in Fig. 7, where the grain boundaries (*g*) could be identified from mechanical polishing damage (*d*) by the change in orientation of the strain bands at the boundaries.

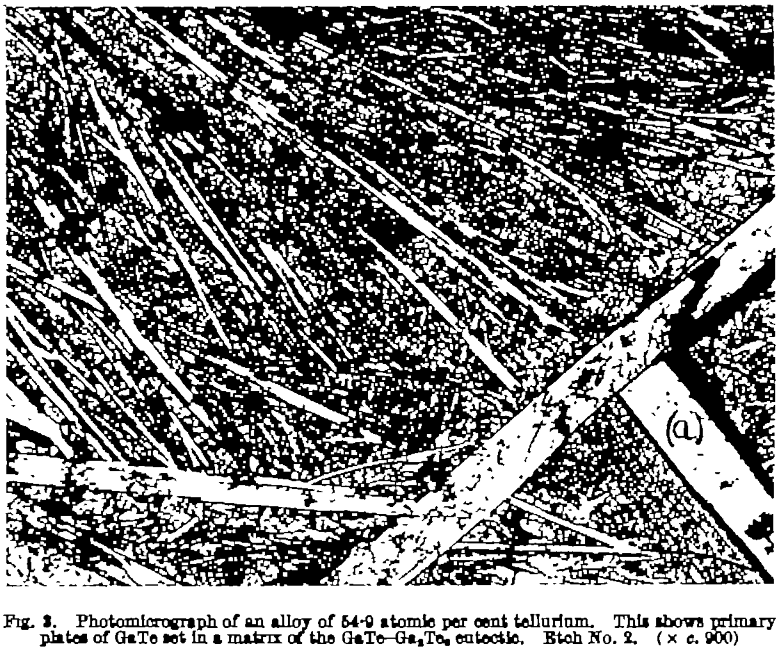

Fig. 3. Photomicrograph of an alloy of 54·9 atomic per cent tellurium. This shows primary plates of GaTe set in a matrix of the GaTe–Ga_2Te_3 eutectic. Etch No. 2. (× *c*. 900)

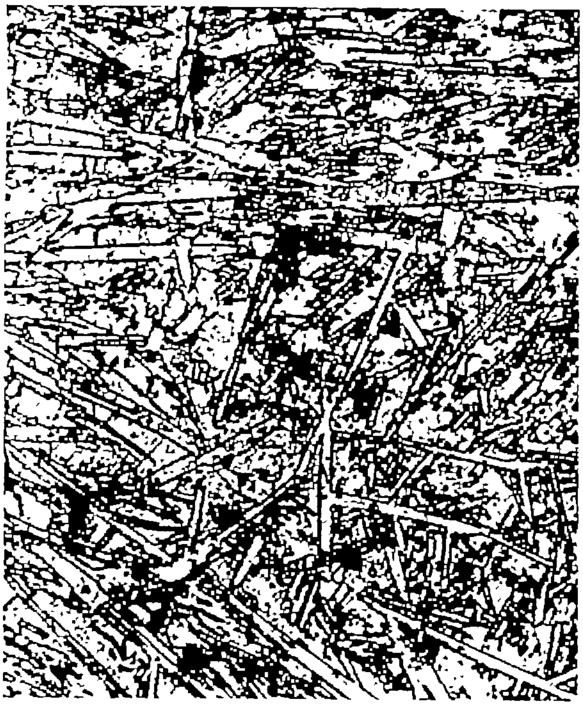

Fig. 4. Photomicrograph of an alloy of 55·8 atomic per cent tellurium. This shows the GaTe–Ga_2Te_3 eutectic. Etch No. 1. (× 180)

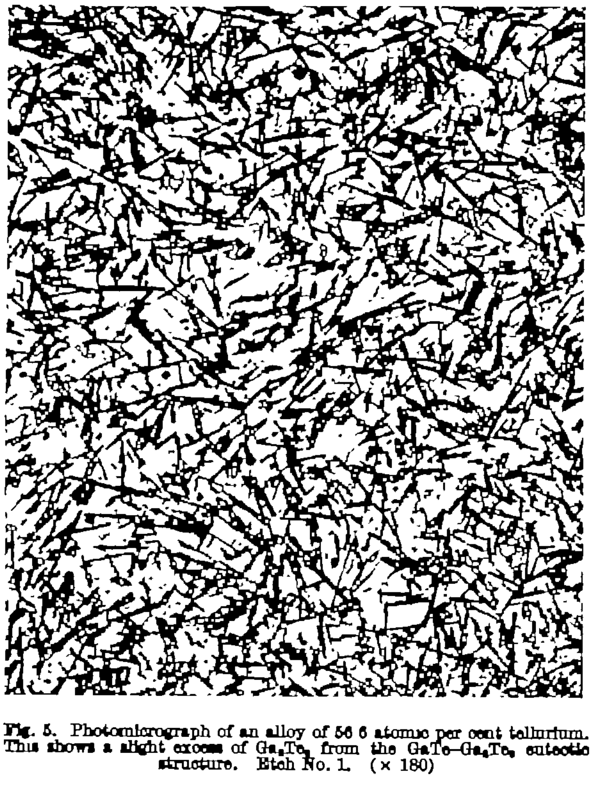

Fig. 5. Photomicrograph of an alloy of 56·6 atomic per cent tellurium. This shows a slight excess of Ga_2Te_3 from the GaTe–Ga_2Te_3 eutectic structure. Etch No. 1. (× 180)

Since these alloys were single phase it must be assumed that the compound Ga_2Te_3 has a finite range of solid solubility which appears to be of the order of at least 0·3 atomic per cent; it seems probable, however, since no strain bands were observed in the 59·7 per cent tellurium alloy, that the solubility range is much greater than 0·3 per cent. This observation of a wide composition range is also supported by the difference in resistivity of single-phase alloys of Ga_2Te_3: simple two-probe measurements showed a change from approximately 20 Ωcm for single-phase tellurium-rich alloys to more than 10^6 Ωcm for single-phase gallium-rich alloys. The wide range of hardness values obtained for the single-phase compound also supports these observations. These results differ from all previous work on the systems, which showed Ga_2Te_3 to exist only as a 'straight line' compound at 60 atomic per cent tellurium.

Fig. 8 is a photomicrograph of an alloy of 75·0 per cent tellurium after reacting at 460° C for 8 h and slow cooling; this indicates that equilibrium conditions have not been approached and show primary crystals of Ga_2Te_3 in a matrix thought to consist of dendrites of $GaTe_3$ and the $GaTe_3$–Te eutectic.

Fig. 9 shows the same alloy at a higher magnification; from the microstructure it can be seen that at 460° C

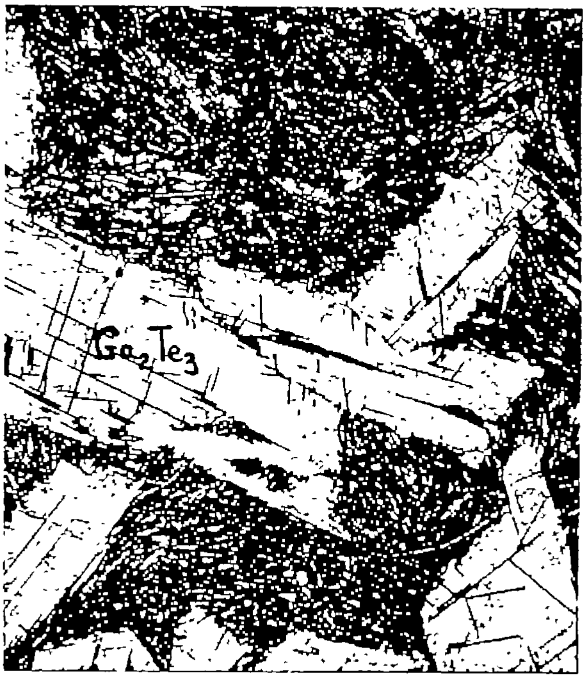

Fig. 6. Photomicrograph of an alloy of 58·4 atomic per cent tellurium This shows strained primary crystals of Ga_2Te_3 in a matrix of GaTe–Ga_2Te_3 eutectic. Etch No. 1. (× 180)

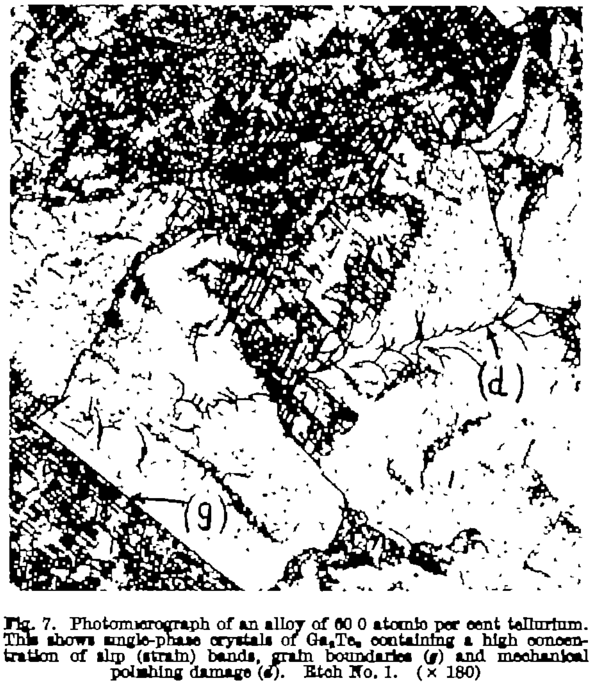

Fig. 7. Photomicrograph of an alloy of 60·0 atomic per cent tellurium. This shows single-phase crystals of Ga_2Te_3 containing a high concentration of slip (strain) bands, grain boundaries (*g*) and mechanical polishing damage (*d*). Etch No. 1. (× 180)

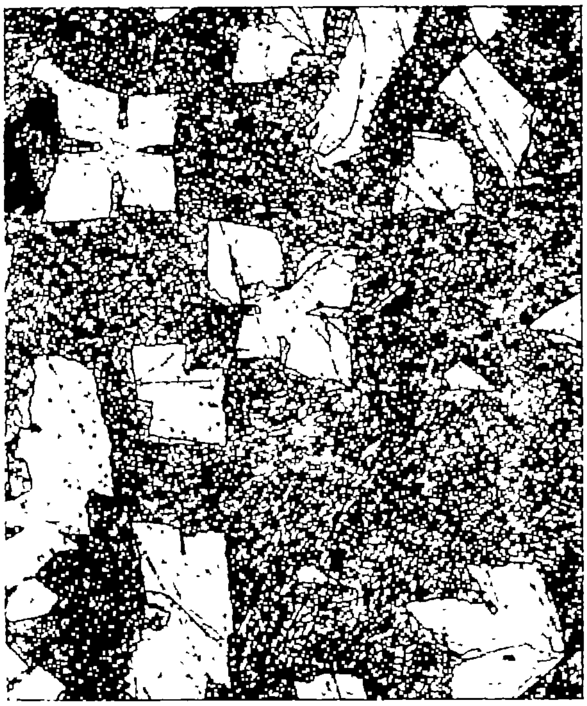

Fig. 8. Photomicrograph of an alloy of 75 atomic per cent tellurium. This shows primary crystals of Ga_2Te_3 in a matrix of $GaTe_3$ dendrites (light) and tellurium (dark). Etch No. 1. (× 100)

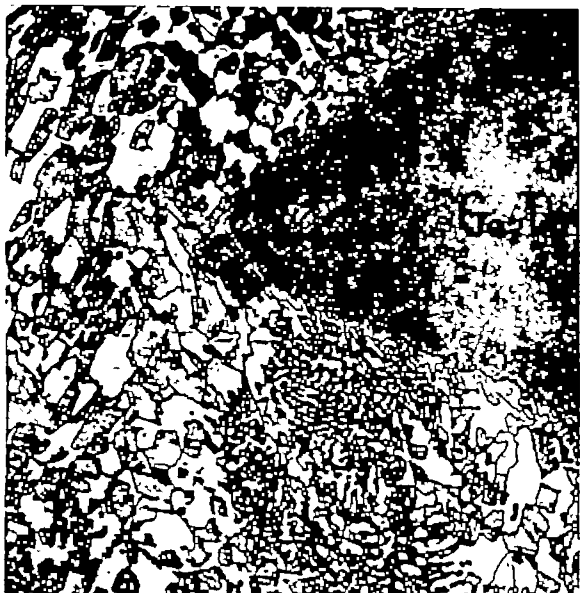

Fig. 9. As for Fig. 8 but showing more clearly the compound $GaTe_3$. (× 750)

crystals of Ga_2Te_3 were deposited, on cooling these reacted with the remaining liquid to form a single-phase component thought to be the compound $GaTe_3$. This peritectic reaction is also confirmed by the irregular edges of the Ga_2Te_3 crystals. The cruciform shape of the primary crystals of Ga_2Te_3 (Fig. 8) is probably due to their dissolution by the remaining liquid along preferred crystallographic planes.

The presence of approximately 20 per cent primary Ga_2Te_3 crystals in the ingot shows that equilibrium was not achieved, since, if the peritectic compound $GaTe_3$ was formed not more than 5 per cent Ga_2Te_3 would be expected. An attempt to obtain equilibrium conditions by reacting at 800° C, slow cooling from 435° C to 420° C at approximately 1° C/day (that is, through peritectic transformation) followed by quenching showed almost no increase in the size and quantity of the $GaTe_3$ crystallites. X-ray 'powder' patterns taken on crystalline and not powdered material proved the existence of the compound $GaTe_3$, which was also shown to be stable at room temperature over a period of almost one year. Powdered samples, however, did not exhibit the diffraction lines of $GaTe_3$, but it could not be established if this was due to a mechanical effect on crushing. This effect probably explains the observations of Newman *et al.*[4], who found $GaTe_3$ to be unstable.

Fig. 10 is a photomicrograph of a lightly etched alloy of 82·0 per cent tellurium; this shows a slight excess of $GaTe_3$ (light-coloured phase) from a homogeneous $GaTe_3$–Te eutectic.

Modifications suggested by these results have been been added to the phase diagram determined by Newman *et al.* This is shown in Fig. 11, where the amendments are indicated by dotted lines.

Microhardness measurements were carried out on a wide range of alloys to give additional information on the nature of the different phases in the system. The samples were prepared for testing in an identical way to those for microscopical analysis and were then given a light etch in No. 1 etch to delineate the different phases. Microhardness values were obtained by using a standard Vickers microhardness tester with loads of between 5 and 50 g, dependent on the nature of the phase being examined.

The values obtained for GaTe were inconsistent because of the high degree of deformation along cleavage and slip planes on application of the indenter. The high elasticity of the material also caused inconsistent results since the recovery of the GaTe after deformation on removal of the indenter load tended to give high values. The range of microhardness values obtained for GaTe was 40–70 Vickers pyramid numbers (V.P.N.), the lower number being probably near the true value.

A range of microhardness measurements were taken on individual crystals of Ga_2Te_3 grown from different melt compositions; these indicated that the higher the gallium

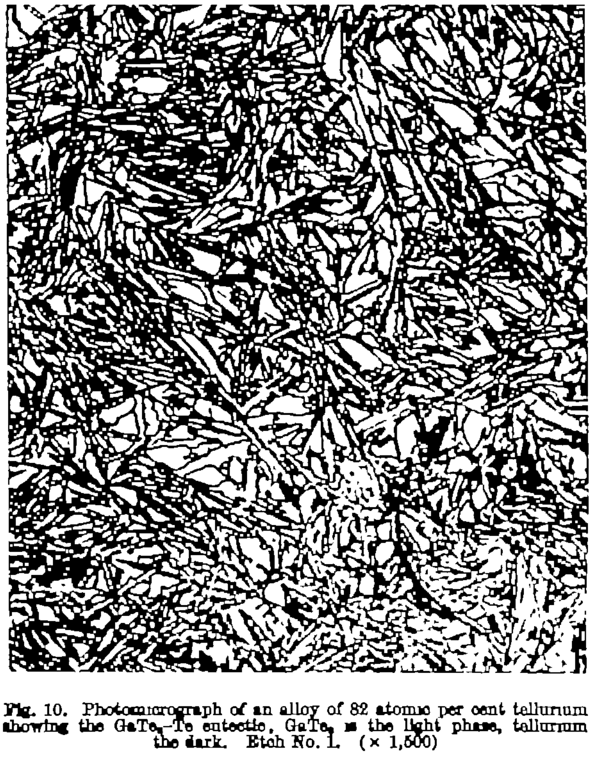

Fig. 10. Photomicrograph of an alloy of 82 atomic per cent tellurium showing the $GaTe_3$–Te eutectic. $GaTe_3$ is the light phase, tellurium the dark. Etch No. 1. (× 1,500)

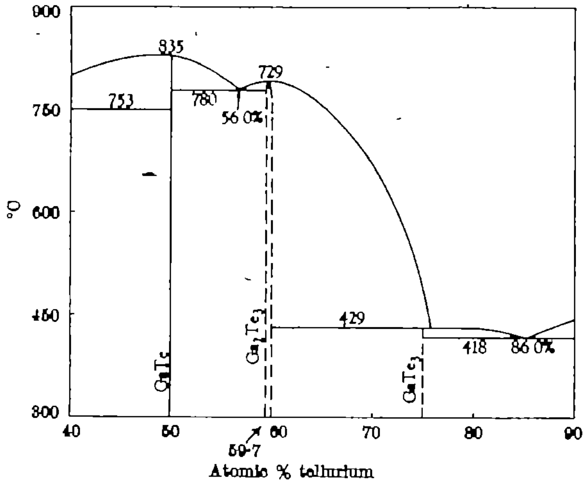

Fig. 11. Phase diagram of the gallium–tellurium system

content the higher the microhardness. Using a 20-g load applied for 15 sec the figures were:

Ga_2Te_3 primary crystals in GaTe–Ga_2Te_3 eutectic (total alloy composition 59 0 atomic per cent tellurium)	234 V.P.N.
Highest resistivity single-phase Ga_2Te_3 examined (not analysed)	198 V.P.N.
59·7 atomic per cent tellurium (single-phase alloy)	185 V.P.N.
60·0 atomic per cent tellurium (single-phase alloy)	174 V.P.N.

All the microhardness values were obtained from an average of at least 10 impressions with scatter of the order of ± 5 per cent.

The increase in microhardness with increasing gallium content was probably due to gallium atoms filling some of the vacant sites in the Ga_2Te_3 (Ga_2Te_3 has zincblende structure with vacancies on one-third of sites available for gallium atoms)[2]. The microhardness of Ga_2Te_3 primary crystals in tellurium rich matrices was measured and gave a range of microhardness figures of 180–200 V.P.N. This variation and relatively high value was thought to be due to the temperature of formation of the crystallites, the higher the temperature of formation the higher the hardness value was indicated. This effect would be expected if the Ga_2Te_3 solidus curved slightly from the maximum-melting point to the peritectic temperature and composition, that is, if the maximum melting-point of the compound is at a lower tellurium content than the stoichiometric composition. From the hardness measurements obtained on the tellurium rich Ga_2Te_3 this would appear to be nearer 59·7 than 60·0 atomic per cent.

This investigation has yielded evidence for modification of the gallium–tellurium phase diagram and has shown that the compound Ga_2Te_3 has a range of at least 0·3 atomic per cent solid solubility. Microhardness measurements on a wide range of alloys have shown that values vary from 40 V.P.N. for GaTe to 234 V.P.N. for Ga_2Te_3.

I thank Miss C. A. Fisher and J. A. Wilkinson for providing the alloys, J. A. Cundall for taking X-ray photographs, and Messrs. H. C. Wright, P. C. Newman and J. C. Brice for helpful discussions.

TITANIUM COLOUR CENTRES IN ROSE QUARTZ

By P. M. WRIGHT
Department of Chemistry, Wheaton College, Illinois
J. A. WEIL
Chemistry Division, Argonne National Laboratory, Illinois
T. BUCH
Department of Physical Chemistry, University of Buenos Aires
AND
J. H. ANDERSON
Department of Physics, University of Pittsburgh, Pennsylvania

ALTHOUGH several studies of the chemical content and the optical properties of rose quartz have appeared, no electron paramagnetic resonance investigations have yet been reported. We wish herein to describe several impurity 'colour' centres found in all the numerous samples studied by us.

We have prepared single, oriented crystals of rose quartz from various geographical locations (Table 1). These crystals in their virgin state do not (except for peaks from iron in some samples) show electron paramagnetic resonance at room temperature. A set of magnetic centres visible at 77° K in all crystals were created by X-irradiation at room temperature; these centres were already present in the virgin state of one sample (Custer) and were enhanced by the irradiation.

Of dominant interest in this article, we wish to report the observation by 3-cm electron paramagnetic resonance of a set $[\equiv A(\mathrm{Ti})]$ of new centres and the identification of their principal constituent as titanium existing substitutionally in silicon sites. These centres, stable at 300° K in the dark, could be bleached with ultra-violet light and restored by X-rays. The spectrum of each centre observed at 77° K consists basically of three primary lines (from equivalent unit cell sites made distinguishable by the magnetic field $\vec{H}$) which reduce to a single line for $\vec{H}$ along the three-fold symmetry axis ($\equiv Z$) and otherwise to two lines when $\vec{H}$ is located in the plane ($\equiv YZ$) perpendicular to any ($\equiv X$) of the three two-fold symmetry axes. The lines of one of the set, to be denoted by $A_{\mathrm{Ti}\text{-}M}$, exhibit four-line anisotropic nuclear hyperfine structure (Fig. 1, upper, and Table 2) indicating that an alkali atom M, most probably lithium, is contained in the centre. A second centre, tentatively denoted by $A_{\mathrm{Ti}\text{-}H}$, is very similar but has lines showing only two-line hyperfine structure which we attribute to interaction of the unpaired electron with a proton. In general, the lines of $A_{\mathrm{Ti}\text{-}M}$ were much more intense than those of $A_{\mathrm{Ti}\text{-}H}$ in the samples examined.

Table 1. Geographical Origin of Rose Quartz Crystals

Rabenstein, Bavaria, Germany (courtesy of Museum of Geology, Princeton University).

Besides these strong primary peaks, we have detected the weak anisotropic hyperfine structure arising from the low-abundance odd titanium isotopes, each line

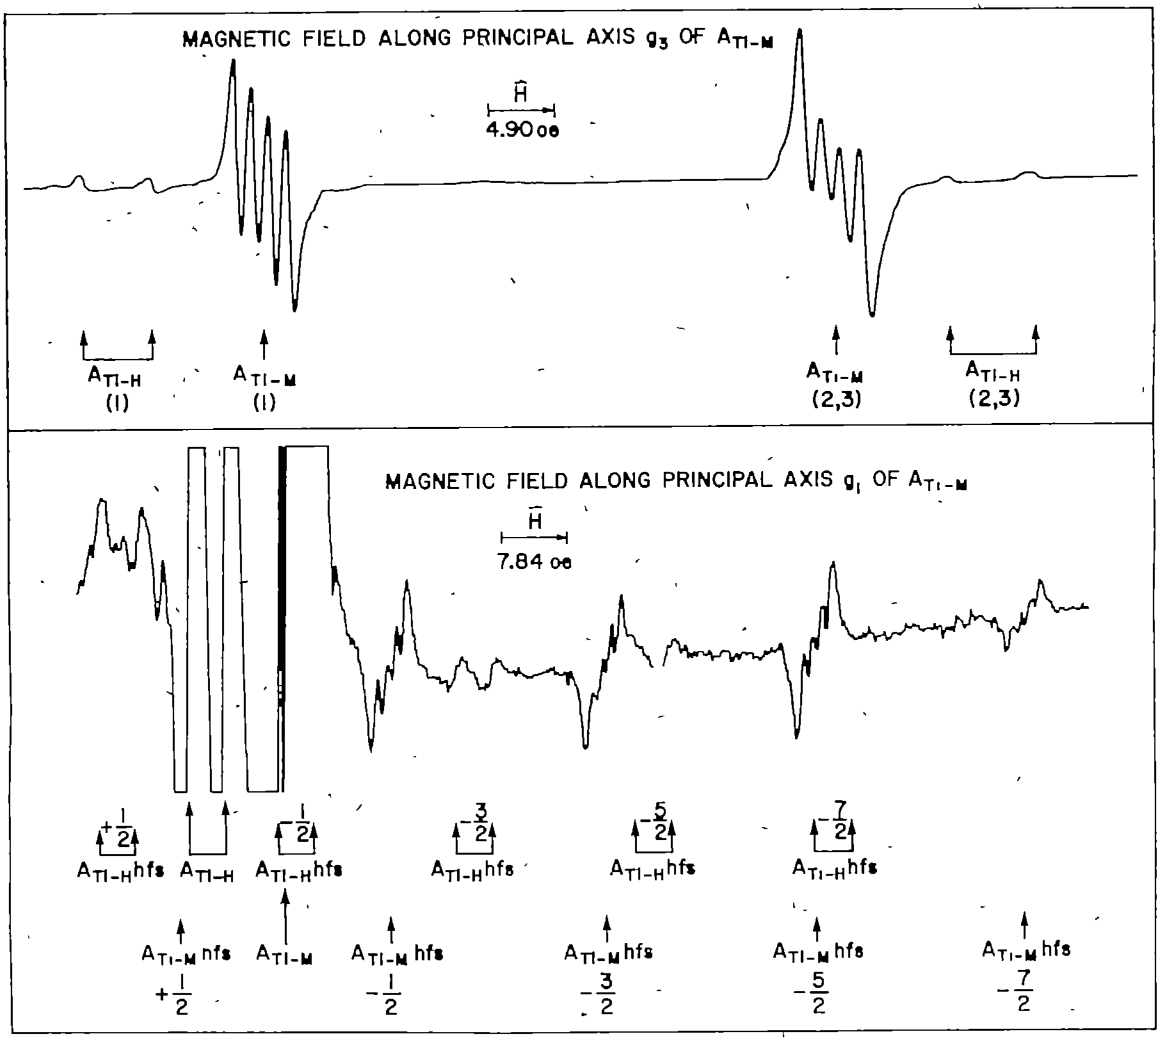

Fig. 1. The paramagnetic resonance spectrum of titanium centres in an X-irradiated rose quartz crystal at 77° K. Upper: The A_{Ti-M} and A_{Ti-H} centres. Lower: A portion of an amplified spectrum showing the weak titanium hyperfine structure

showing the alkali or proton peaks as secondary hyperfine structure. The relevant parameters are listed in Table 2. Because the hyperfine splitting goes as μ/I, which happens to be virtually identical for titanium-47 and titanium-49, the 6 lines of titanium-47 superimpose on the inner 6 of the 8 titanium-49 lines. The observed spectrum (Fig. 1, lower) shows exactly this form, making unequivocal the identification of titanium as the primary component of the centres; the relative intensities of these lines are also quantitatively as predicted. One previous report of titanium hyperfine structure has been made[1].

Elemental analysis by spectrochemical means, as well as by neutron activation and flame photometry, revealed the presence of titanium (5–15 p.p.m.), germanium (0·5–5 p.p.m.), aluminium, lithium and sodium in all the crystals of rose quartz.

The superposition of two of the three lines (Fig. 1, upper) from equivalent sites in the unit cell, when $\vec{H}$ lies in the plane YZ, indicates that one principal axis of the Zeeman splitting tensor $\bar{g}$ lies along the two-fold axis X. Moreover, then, only three lines will be seen at arbitrary orientations of $\vec{H}$, rather than the six expected for more general locations of the principal axes. These tensors, for both A_{Ti-M} and A_{Ti-H}, are given in Table 3, as are some hyperfine splittings along the principal g axes. Determination of the hyperfine tensors is difficult because of the overlapping of the numerous anisotropic lines.

Table 2. ABUNDANCE AND MAGNETIC HYPERFINE PARAMETERS FOR VARIOUS NUCLEI

	Abundance	I	μ (Bohr magnetons)	Relative intensity
^{1}H	99·98	1/2	2·79270	—
^{6}Li	7·43	1	0·82191	—
^{7}Li	92·57	3/2	3·2560	—
^{23}Na	100	3/2	2·2161	—
^{46,48,50}Ti	86·74	0	0	1
^{47}Ti	7·75	5/2	−0·78712	0·0219
^{49}Ti	5·51	7/2	−1·1023	0·00794

Table 3. ZEEMAN SPLITTING TENSOR $\bar{g}$ FOR THE CENTRES A_{Ti-M} AND A_{Ti-H}, AS WELL AS THE HYPERFINE SPLITTINGS AND LINE-WIDTHS (MAX TO MIN.) WHEN $\vec{H}$ IS ALONG THE g_1 OR g_3 AXIS

Centre	g	Hyperfine splitting $M(H)$	Hyperfine splitting Ti	Width
A_{Ti-M}	g_1 = 1·912, 70° from Z	1·16 oe	27·1 oe	0·68 oe
	g_2 = 1·930, X	—	—	—
	g_3 = 1·979, 20° from Z	1·35	—	0·67
A_{Ti-H}	g_1 = 1·916, 62° from Z	4·43	22·8	1·15
	g_2 = 1·936, X	—	—	—
	g_3 = 1·984, 28° from Z	5·0	—	1·11

The identification of lithium, rather than sodium, as the cation seen in A_{Ti-M} depends on the predominance of the former in the crystals, as given by the elemental analyses, and by analogy to the germanium centres (see following) in which lithium seems to form the more stable centres. Only one alkali centre is seen despite the presence of both lithium and sodium in the samples. Similarly, the correlation of the doublets with protons rests on the magnitude of the splitting and on the known presence of hydrogen in quartz crystals[2]. Experiments are under way to confirm these identifications.

Since the spectra of A(Ti) exhibit the point group symmetry (D_3) consistent with the quartz structure, it is clear that the titanium observed is not in the form of rutile needles (symmetry D_{4h}) embedded in the crystal. The orientation of the principal g axes, taken together with knowledge that titanium will form tetrahedral compounds, strongly suggests that the titanium atoms have replaced silicon atoms in their positions on the two-fold axes. In the solution studies of Ti^{3+} complexes[1], the electron paramagnetic resonance absorption was not observable at room temperature, but was strong at 228° K, with $g \simeq 1·95$ and titanium hyperfine splitting of 18·2 oe. Thus these spectra are very similar to ours and serve in the identification of the trivalent state for the titanium in the A(Ti) centres.

We have observed other colour centres, previously examined in other quartzes, in our samples of rose quartz. However, no manganese resonance was detected in any sample. The aluminium centres reported by Griffiths, Owen and Ward[3] were seen (at 77° K) in several virgin and all irradiated samples. All crystals, after irradiation, showed (at 77° and 300°) the germanium centres previously seen in germanium-doped synthetic quartz; three such centres ($A_{Ge\text{-}M}$, B_{Ge}, $C_{Ge\text{-}M}$) are obtained on irradiation at room temperature[4], whereas others occur after low-temperature irradiation[5]. A and C differ in the position of the alkali and are known with either sodium or lithium, but not with hydrogen; B is unstable and may be just a GeO_4^- site not stabilized by a positive ion.

A model suitable for the A(Ti) centres appears to be exactly analogous to that proposed by two of us for the germanium centre[4a,c]. We believe that an electron, dislodged from a source such as the aluminium–alkali sites[3], settles on the titanium central atom situated within the quartet of neighbouring oxygen atoms (which form a somewhat distorted tetrahedron in α-quartz). The alkali or hydrogen ion acts as charge compensator and is located in a nearby open space such as one of the c-axis channels. The small magnitude of the alkali and proton splitting indicates that the unpaired electron spends only a very small fraction of its time on the atom. Despite this, the alkali may have an important role in stabilizing the centre by interacting with the two nearest members of the oxygen quartet.

It seems likely that ions other than titanium and germanium, such as zirconium, tin, hafnium and lead will tend to form centres of the same type in quartz, although size limitations may become important.

The colour of rose quartz is still not completely understood. Since the early studies and the summary of the subject by Holden[6], who attributed the rose colour to traces of manganese, several investigations have been made which produced evidence that titanium is the important factor. Small rutile (TiO_2) needles have been shown to be present in all rose quartz, and give rise to light-scattering and absorption[7] in the ultra-violet. In addition, an absorption peak at 495·7 mμ is present and produces the colour. Our investigations show that substitutional titanium is present in addition to the colloidal rutile. However, its diamagnetic, tetravalent form will not cause the colour, and the paramagnetic trivalent titanium of the A(Ti) centres is destroyed by ultra-violet bleaching or heating without affecting the rose colour. It seems probable, as has also been suggested elsewhere[7b], that the colour is caused by a centre offering a more complex situation than titanium by itself, such as aluminium and titanium occurring as nearest neighbours in the lattice.

We are making detailed investigations of the action of ultra-violet light and X-rays on the concentration of the A(Ti) centres, of replacement of the alkali ions by electrodiffusion (as was done for the germanium centres[4c]), and of the hyperfine tensors. These results should lead to a more detailed quantum-mechanical model for the centres, and will be presented elsewhere.

This work was carried out under the auspices of the U.S. Atomic Energy Commission, and was presented at the 1962 Conference on Radiation Effects on Glass and Quartz, Rochester, New York. One of us (J. H. A.) was partially supported by the U.S. Air Force through the Air Force Office of Scientific Research of the Air Research and Development Command.

POLYCARBOXYLIC AND PHOSPHONITRILIC ACIDS AS RADIOPROTECTORS: EFFECTIVENESS OF PYROMELLITIC ACID

By J. H. BARNES and J. St. L. PHILPOT

Medical Research Council Radiobiological Research Unit, Harwell, Didcot

THE ability, previously reported by us[1], of inorganic condensed phosphates to protect mice against X-ray lethality when injected before irradiation has prompted us to test for this property other compounds having multiple acidic groups associated with a ring or short open-chain structure. In this work female mice of R stock weighing 20–25 g were used at the age of 14 weeks. The doses of the compounds administered in the radioprotection experiments were determined by their toxicity. After preliminary trials with single mice, increasing doses of each compound were given intraperitoneally to groups of 5 mice, which were observed for at least one week, until a dose resulting in at least one toxicity death in a group was reached. The next lower dose (Table 1, third col.) served as a guide to the dosage of the compound that could be used in irradiation experiments. This or a slightly lower dose was generally used at the outset. In these experiments, such doses frequently resulted in deaths during or shortly after irradiation: these were due to toxicity, as deaths from the dose of X-rays given do not occur before the fifth day. Some toxicity deaths would be expected statistically, especially since larger groups of animals were being used; however, enhancement of toxicity by X-rays is suspected though statistical proof is lacking. Where deaths occurred before the fifth day, these were avoided in subsequent experiments by using a lower dose of the compound.

Test acids were given intraperitoneally, as neutral aqueous solutions of the sodium salts, 10 min before exposing the mice in partitioned boxes to 1,025-r. X-rays under the following conditions of irradiation: 250 kV, 15 m.amp, half value layer 1·2 mm copper, distance to underside of box 60 cm, average dose-rate 73·6 r./min. The experiments were on the pattern previously described with internal controls[1], corresponding experimental and control groups being equal in size. 1,025 r. X-rays gave 100 per cent mortality in controls (injected with saline) during the course of these experiments, but gave 98 per cent mortality during one year. Survival at 30 days was taken as the measure of protective effect. The results are given in Table 1.

Table 1. PROTECTIVE EFFECTS OF POLYBASIC ACIDS (AS Na^+ SALTS) WHEN GIVEN 10 MIN BEFORE 1,025-R. X-RAYS

Acid	Basicity	Max. non-lethal dose in sample (m.moles/kg)	Dose used (m.moles/kg)	No of mice surviving/No. used

† One toxicity death occurred before fifth day.

‡ Significant (ref. 2) by 2 × 2 contingency test using internal controls ($P < 0·02$).

§ Significant ($P < 10^{-4}$).

The structures of tri- and tetra-phosphonitrilates differ from those of cyclic metaphosphates only in that the ring O atoms are replaced by —NH—. This change alters the pharmacological properties, as shown by the marked effects on toxicity. Sodium tetraphosphonitrilate lacks radioprotective effect but the non-toxic triphosphonitrilate, in very high dosage, shows indication of effect which, however, is not significant by the severe test for significance used[2]. Evidently, in this group of substances the cyclic arrangement of anionic groups is not the sole requirement for radioprotective ability.

Of the polycarboxylic acids listed significant protective effect is shown only by naphthalene-1 : 4 : 5 : 8-tetracarboxylic and pyromellitic acids. In the former case the effect is shown only at a dose-level where marked toxic effects are also evident, resulting in one death due to toxicity in the irradiated group. The protective effect of pyromellitic acid is highly significant ($P < 10^{-4}$) at a dose-level of 9 m. moles/kg (conc. 0·3 M), when only a mild depressant effect is observable, which is not modified by exposure to X-rays, and the dose is substantially less than the maximum tolerated. It is of interest that this dose-level is optimal: the protective effect at 9 m.moles/kg is significantly greater ($P < 0·02$) than that at 12 m.moles/kg when the depressant effect is more marked. This indicates that the radioprotective effect is not merely a manifestation of toxicity. Pyromellitic acid is ineffective when given as long as 30 min before irradiation and has no influence on mortality when given immediately after 1,025 r.

No structure-activity relationships in the benzenepolycarboxylic acid series are discernible since any protective effects of the acids listed, other than pyromellitic, are non-significant with the numbers of mice used. Nor does radioprotective action appear to be related to the observed pharmacological effects in this series; thus, both mellophanic and trimesic acids share with pyromellitic acid a depressant property. Phthalic and hemimellitic acids produce enhanced irritability and seizures resembling the tetany due to calcium-complexing agents such as linear polyphosphates and ethylenediaminetetraacetic acid. We have as yet no evidence as to the mechanism of the protective action of pyromellitic acid.

Experiments with the hexabasic mellitic acid have been complicated by the fact that samples from different sources have shown different toxicities; however, a sample of low toxicity has shown significant radioprotective effect. Mellitic, benzenepentacarboxylic and related acids are at present being investigated.

We thank Mrs. D. M. R. Lowman for assistance, Mr. M. J. Corp for irradiations and Dr. D. R. Peck, of Albright and Wilson, Ltd., for gifts of sodium tri- and tetra-phosphonitrilates.

AFFINITY OF STEROIDS FOR ELECTRONS WITH THERMAL ENERGIES

By J. E. LOVELOCK, P. G. SIMMONDS and W. J. A. VANDENHEUVEL

Baylor University, Texas Medical Centre, Houston

THE vapours of most organic compounds are transparent to the passage of electrons with thermal energies; those few substances which absorb electrons strongly are frequently associated with the biological process of oxidative metabolism. Thus the alternate intermediates and coenzymes of the Krebs's cycle have unusually large coefficients for the absorption of thermal electrons and so do substances toxic to this system[1]. The possession of a high affinity for thermal electrons appears also to be a necessary molecular property of substances active in the hormonal control of metabolism, for example, the thyroid hormones. The steroid hormones are active in the control of metabolism; the measurement of their electron absorption was therefore potentially interesting to theories of the mechanism of their action. Recent advances in the analysis of steroids by gas chromatography[2,3] have made possible the presentation of the pure dilute vapour samples necessary for the measurement of electron attachment to steroid molecules in the vapour phase. Using these new techniques, the absorption coefficients for thermal electrons of steroids were measured and are reported here. The substances tested included members of the various hormone classes and the possible significance of the measurements in the chemistry and in the biological function of the steroids is discussed.

The technique used to measure electron absorption was closely similar to that previously described[1,4]. Briefly the test compound was vaporized in a stream of argon containing 5 per cent of methane at 250° C; the dilute vapour was passed through a 12-ft. chromatograph column containing a solid support coated with 1 per cent '*SE*-30' silicone stationary phase according to the method described[3] and then into an ionization chamber for the measurement of electron absorption. The chromatograph column served to separate from the test substances traces of electron absorbing contaminants. The ionization chamber contained a source of soft β radiation (tritium occluded in titanium foil) which set free from the carrier gas 8×10^{10} e/sec. At intervals of 50 μsec the concentration of free electrons in the chamber was sampled by the application of a pulse of potential to the chamber electrodes. This sampling pulse was 0·5 μsec in duration and 30 V in amplitude; it was sufficient to collect all the electrons present but too weak and brief to raise the electron energy appreciably above that of thermal equilibrium with the gas in the chamber. The presence of

5 per cent of methane in the argon carrier gas ensured the rapid removal of any excess energy gained by the electrons from the sampling pulse. In the presence of test vapour some of the electrons are removed to form negative molecular ions; these are too slow moving for collection during the brief sampling pulse and so the decrease in electron flow is a measure of the absorption of electrons by the test vapour. At the high temperatures needed to maintain the steroids in the vapour phase some loss by thermal decomposition or by irreversible absorption on the chromatographic column could take place.

To avoid possible errors in the calculation of absorption coefficients, the quantity of steroid surviving passage through the chromatograph column was measured directly by replacing the electron absorption chamber with a cross-section ionization detector[5,6]. This detector is precise and impartial in its response to the vapours of different substances. It was not possible to use this detector simultaneously with the measurement of electron absorption since it requires hydrogen or helium as the carrier gas, and neither of these is suitable for the measurement of electron absorption. As a further precaution against error, a reference standard substance, pyrene, was always included with each steroid tested and appeared as a separate peak on the chromatogram.

The absorption coefficients for thermal electrons of the steroids tested were calculated as follows: the total number of electrons attached to a known quantity of steroid was compared with the total number attached to a known quantity of the reference standard, pyrene. The numbers of electrons attached were calculated directly from the peak areas of the chromatograms under conditions where not more than 10 per cent of the free electrons were absorbed. In the interests of consistency with previous measurements, the reference standard, pyrene, was given an absorption coefficient of 6·0 in arbitrary units; an absorption coefficient of 1·0 on this scale corresponds approximately to a molecular cross-section for electron absorption of 10^{-16} cm^2. The probable error of the method was estimated by calibration with a single test steroid 4-androstene-3,17-dione and found to be ± 17 per cent. This lack of precision is less serious than it might at first appear to be. Electron absorption coefficients cover a range of at least 10^7 and ± 17 per cent error rarely affects the significance of comparisons between the absorption coefficients of different substances.

Table 1 lists the absorption coefficients of the steroids tested and also those of comparable substances from previous investigations. The absorption coefficients cover a range of at least 10^5 with the hydrocarbon steroids transparent to electrons and the unsaturated triketo steroids the most strongly absorbing.

A marked electron absorption in the steroids tested is found only with those possessing the structure $.CO.CH:CR_1R_2$; from previous measurements[1] it is known that this structure confers electron absorption provided that there is in the molecule an opportunity for further electronic interaction. For example, methyl vinyl ketone, 2-*cyclo*hexenone, and ethyl acrylate absorb free electrons weakly; whereas cinnamaldehyde, and fumarate esters absorb intensely. In the last two compounds the additional phenyl, and carbonyl components have respectively provided the necessary further 'conjugation' for a high degree of electron absorption.

It is not yet known experimentally what is the minimum requirement of the groups (R_1R_2) in the α β unsaturated keto structure above, for marked electron absorption; the results in Table 1, however, show that within the saturated part of the steroid framework these requirements are met. For example, 4-cholestene-3-one has an absorption coefficient of 11. Table 1 also indicates the relationship between structure and electron absorption in the saturated and unsaturated keto steroids. The presence of even three isolated keto groups in a saturated steroid confers little more absorption than the slight amount expected of a simple ketone, thus the absorption coefficients of androstane-3,17-dione and of allopregnane-3,11,20-trione are both less than 1. The introduction of a double bond at the 1 position in androstane-3,17-dione, although introducing the α β unsaturated keto structure, does not appreciably increase the electron absorption; a double bond at the 4 position in androstane-3,17-dione, however, increases the absorption 200-fold. Some of this large increase would appear to be attributable to interaction between the 4-ene 3-one system and the remote 17 keto group, for in cholestene 3-one and in testosterone where the 17 position is substituted respectively with an alkyl chain or a hydroxy group the absorption is three times less. The exact location of the remote keto group on the *cyclo*pentane ring does not appear to be important since the absorptions of progesterone, 4-androstene-3,17- and 3,16-diones are all similar. However, a keto group at the 11 position greatly enhances absorption, as in 4-pregnene-3,11,20-trione and 4-androstene-3,11,17-trione; these compounds absorb 2,500 times more strongly than does androstane-3,17-dione.

Table 1. ELECTRON ABSORPTION COEFFICIENTS OF THE STEROIDS AND OF RELATED COMPOUNDS

Compound class	Compound	Absorption coefficient
Hydrocarbons	Androstane	0·01
	Cholestane	0·01
Sterols	Cholesterol	0·03
Saturated ketones	Androstane-3,17-dione	0·10
	Allopregnane-3,11,20-trione	0·50
	i Cholestane-6-one	5·8
Unsaturated ketones	4-Cholestene-3-one	11·3
	Testosterone	8·4
	19-Nortestosterone	9 1
	3,5-Cholestadiene-7-one	96·5
	17β-Hydroxy-1,4,6-androstatriene-3-one	85·0
	1-Androstene-3,17-dione	0·21
	1,4-Androstadiene-3,17-dione	4·5
	4-Androstene-3,17-dione	23·5
	4-Androstene-3,16-dione	19 2
	Progesterone	22·2
	4-Androstene-11-ol-3,17-dione	76·0
	1,4,6-Androstatriene-3,17-dione	167
	Cortisone band	63·5
	6-Keto progesterone	143
	4-Androstene-3,11,17-trione	248
	4-Pregnene-3,11,20-trione	250
	1,4-Androstadiene-3,11,17-trione	535
	25-Keto-norcholesterol	0 03
	4,4′-Dimethyl-5-cholestene-3-one	0·03
	Oestrone	0·03
Comparable compounds	Methyl vinyl ketone	1·1
	Cinnamaldehyde	310
	Dimethyl fumarate	1,500
	Dinitrophenol	1,500
	Diiodobenzene	1,300

All values are relative to the absorption coefficient of chlorobenzene which is taken as unity and are for electrons with thermal energy.

Steroids containing the 1,4-diene-3-one system also provide interesting comparisons; 1,4-androstadiene-3,17-dione absorbs to only one-fifth the extent of 4-androstene-3,17-dione. When the 1,4-diene-3-one system accompanies a keto group at the 11 position, a vast increase in absorption is found; 1,4-androstadiene-3,11,17-trione with a coefficient of 535 is the most strongly absorbing of the steroids tested. The ene- and diene-one systems in other locations of the steroid framework may show electron absorption, for example, 3,5-cholestadiene-7-one; perhaps less expected is the absorption coefficient of 5·8 found for *i*-cholestane-6-one, which suggests an interaction between the 6 keto group and the *cyclo*propane bridged-ring. In general, electron absorption appears to be a sensitive indicator of electronic interaction between, for example, the orbitals of the 4-ene-3-one system and those of other keto or unsaturated systems elsewhere in the steroid molecule.

It may be significant that the highest absorption coefficients are found with compounds which are either steroid hormones or at least compounds having a substantial part of the structure of a hormone. The steroid hormones with the highest affinity for free electrons would appear to be the adrenocortical hormones; the androgens and progestogens, as exemplified by testosterone and progesterone respectively, absorb electrons moderately but the œstrogens represented by œstrone have no appreciable affinity for thermal electrons. The adrenocortical hormones themselves are unstable at high temperatures and tend to lose the side-chain attached to the 17 position[6]; it was not possible, therefore, to measure their absorption directly except with the chemically protected derivative *bis* methylene dioxy cortisone. This compound, with one less keto group than cortisone, nevertheless had an absorption coefficient of 72. The absorption coefficient of the thermal decomposition product of cortisone, 4-androstene-3,11,17-trione and also that of 4-pregnene-3,11,20-trione are both 250; and probably more truly representative of the absorption of cortisone itself. If 1 : 4-androstadiene-3,11,17-trione, the thermal decomposition product of prednisone, is representative of prednisone, then this substance is among the most intensely absorbing of the steroids tested.

So far the measurement of the absorption of electrons by organic substances has indicated that a marked degree of absorption (a coefficient greater than 10) is rare. Those naturally occurring substances which do react readily with thermal electrons are usually, however, directly or indirectly associated with the biological process of oxidative metabolism. The measurements reported here with the steroids are no exception to this rule.

It was previously suggested[1] that the presence of so many of the few simple carbon, hydrogen and oxygen compounds with a high affinity for free electrons among the intermediates of the process of oxidative metabolism was more than coincidental; and that this process required for its function the presence of an ordered sequence of reversible electron traps. If this idea is accepted, then it is possible to speculate further that the control of metabolic activity by the thyroid and some of the steroid hormones is directly connected with their undoubted capacity to function as electron traps. The fact that the œstrogens do not absorb electrons is not necessarily contradictory to this notion since their activity could be regarded as antagonistic to that of other steroid hormones and the œstrogens could possibly function by the competitive displacement of the electron-trapping steroids from their site of action.

We thank Dr. E. C. Horning for his advice.

CHROMOSOME labelling with tritiated thymidine has been shown to be a useful tool for discriminating between similar but non-homologous chromosomes in man[1]. The only example of significant difference in isotope incorporation between homologous chromosomes is in the *X*-chromosome pair in females[1-3]. At the end of synthesis of DNA (late-*S*) flash-labelling renders one of the *X*-chromosomes heavily labelled indicating not only a late synthesis but also a faster rate of synthesis than any other chromosome in the complement. We have previously suggested that this 'hot' *X*-chromosome is identical with the *X*-chromosome forming the Barr body (female sex chromatin) in interphase[1].

We have labelled leucocyte cultures from the young *XXXXY* male with 49 chromosomes previously described by three of us[4-6]. Prevalence of Barr bodies in smears of buccal mucosa from this patient was:

No. Barr bodies per nucleus	0	1	2	3	4	unclassified	Total
No. of nuclei	6	18	82	148	14	32	300

Blood cultures and their tritiated thymidine labelling were performed in Stockholm, and slides afterwards taken to Manchester for further processing and analysis. The autoradiographs show clear evidence of three 'hot' chromosomes in group III (Fig. 1) in virtually all cells examined.

Table 1. NUMBER OF AUTORADIOGRAPHIC GRAINS

Over all chromosomes	Over the three 'hot' chromosomes ('hot' *X*'s)			Total grains of three 'hot' *X*-chromosomes
43	11	9	5	25

3,361	496	389	309	1,194

Mean label grains over all chromosomes : 153
Mean percentage of grains over the three 'hot' *X*'s = 35·5
Mean percentage of grains over one 'hot' *X* = 11·84.

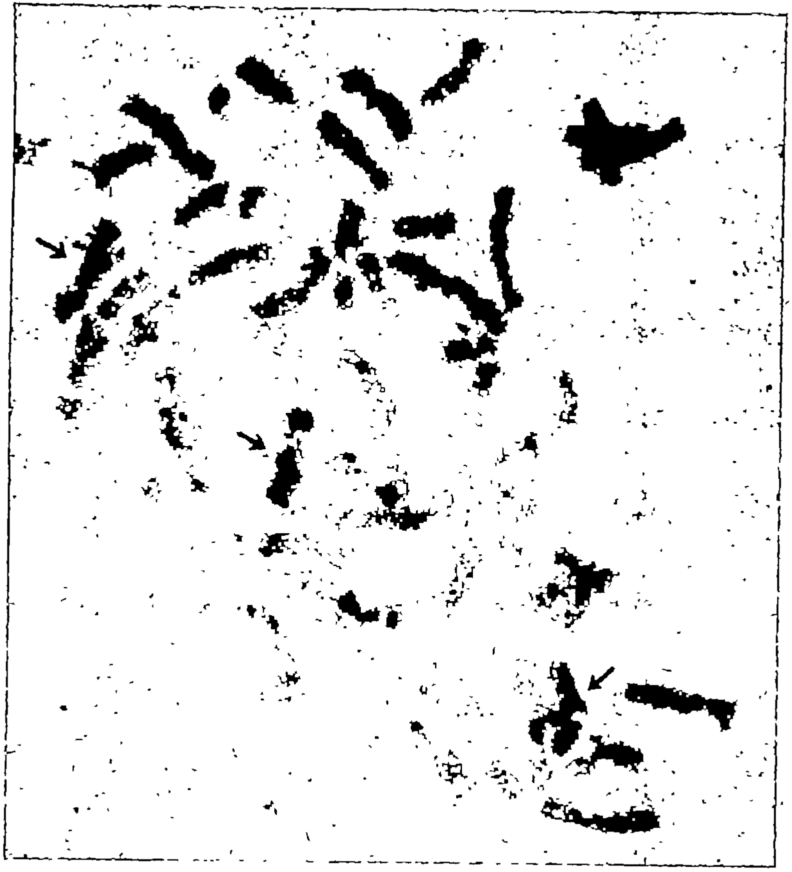

Fig. 1. Autoradiograph of end of *S* labelling (−3 h) of a typical cell from the *XXXXY* patient

The results of the grain counts for 22 cells of the *XXXXY* male are shown in Table 1. A detailed statistical analysis shows that the variation of the number of grains between the three 'hot' *X*-chromosomes in each cell is no more than that to be expected from the random nature of the formation of grains. We therefore conclude that all three 'hot' *X*-chromosomes in this cell synthesize in synchronism. The three 'hot' *X*-chromosomes account for 35·5 per cent of all the grains, or 11·8 per cent per 'hot' *X*. This value, however, cannot be directly compared with the 14·4 per cent on the 'hot' *X* in a normal female previously reported, as in that case there was only one 'hot' chromosome[1] while in this case there are three. If we assume that each 'hot' *X* and all the other chromosomes synthesize independently of each other then the ratio of the grains on one 'hot' *X* to the total grains over all other chromosomes excluding 'hot' *X*'s should be comparable. (The grains over the *Y* should also be excluded if complete identification of chromosomes is made.) This ratio for the *XXXXY* cells is 0·18 and for the *XX* cells 0·17.

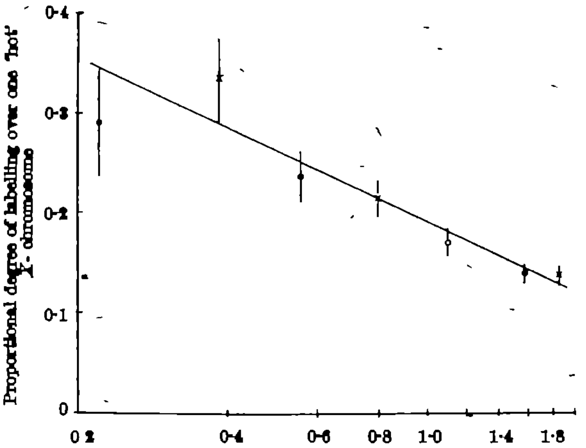

Fig. 2. Comparison of the 'hot' *X*-chromosomes in an *XX* and an *XXXXY* cell after flash labelling with tritiated thymidine at the end of *S*. Ordinate, the ratio of the autoradiographic grains over one 'hot' *X* to the total number of grains over all chromosomes except 'hot' *X*'s; abscissa, proportional to the number of grains over all chromosomes excepting the 'hot' *X*'s, the mean for each preparation being 1·0. The vertical lines indicate the estimated standard errors. (○, normal *XX* female; ×, *XXXXY* male (the three points correspond to the means of the three groups of cells in Table 1)

A further comparison can be made between the 'hot' *X* in these two cell types. It has previously been shown that the relative amount of labelling of the 'hot' *X* is dependent on the degree of labelling of the cell. This dependence for the *XXXXY* cells together with a replot of the previous data for the normal *XX* female cells is shown in Fig. 2. The abscissa is proportional to the grains over all chromosomes, excepting the 'hot' *X*'s, of the cells. This is chosen rather than the total number of grains because this is the set of chromosomes which is common to both types of cells and would be expected to serve as a better yardstick for the comparison of timing of the end of the *S* period. The constant of proportionality is chosen for each preparation to bring its overall average to the common point 1·0. The choice of a log scale is arbitrary, but has an important advantage that the dependence of the absolute number of grains per cell in irrelevant circumstances (for example, exposure time of the autoradiographs, specific activity of label, etc.) will only result in a lateral shift of the curve. A minor advantage is that the results are an approximate fit to a straight line on this plot. It will be seen that there is a remarkably close fit between the results from the two cell types. The slight displacement between the two sets of points is not really significant and could be either due to the *XXXXY* cells being slightly nearer the end of the *S* period, or, if the lateness in *S* period is the same for the two cell lines, due to an increased rate of synthesis of the 'hot' *X* in the *XXXXY* cell.

The overall conclusion is that there is a remarkable similarity of the pattern of synthesis of the 'hot' *X* chromosome at the end of the *S* period in such different material as a normal *XX* female, containing one 'hot' *X* chromosome and an abnormal *XXXXY* male containing three.

It appears that the late labelling (late-*S*) of chromosomes—by showing 'hot' chromosomes—is more informative about the nature of extra chromosomes than the mere determination of the number of Barr bodies, however, these two assessments should be used in conjunction whenever possible.

It has been reported previously[1] that the 'hot' *X*-chromosome represents a relatively inactive chromosome. The observation in this case of three 'hot' *X*-chromosomes may provide an explanation why supernumerary *X*-chromosomes have relatively little effect compared with extra autosomes.

PROPERTIES OF THE SEPARATED CHAINS OF HUMAN γ-GLOBULIN

By Dr. S. COHEN

Department of Immunology, St. Mary's Hospital Medical School, London, W.2

ANTIBODIES in man and many animals are associated with a complex group of proteins known collectively as γ-globulin. This fraction was originally defined as the component which moves most slowly during electrophoresis of serum at alkaline *p*H. Serum proteins with the electrophoretic mobility of γ-globulin have certain common physico-chemical and immunological characteristics but are heterogeneous according to several criteria. In all species investigated the main component of γ-globulin has a molecular weight of about 150,000 and is usually referred to as *7S* γ-globulin; the heterogeneity of this fraction is shown by its wide range of electrophoretic mobility and diffuse spread on ion exchange chromatography as well as by the multiplicity of antibodies which it contains. About 5–10 per cent of γ-globulin consists of protein having a molecular weight of about 1,000,000 and referred to as 19*S* γ-globulin; this fraction can be identified by immunoelectrophoresis, when it is usually referred to as β_2M- or γ_1M-globulin. Immunoelectrophoresis has also led to the identification of a third type of γ-globulin known as γ_1A- or β_2A-globulin, which is mainly of similar molecular size to *7S* γ-globulin, but like the 19*S* fraction has a relatively high carbohydrate content. In multiple myelomatosis and certain related conditions in man, abnormal γ-globulins distinguished by their relative homogeneity are found in the serum; these pathological proteins may belong to any of the three main γ-globulin types.

Methods which have recently been used in the study of antibody structure provide a means for investigating the relationships between the three types of γ-globulin and the differences between normal and pathological γ-globulins. These methods involve a preliminary splitting of the protein by enzymatic digestion[1] or reduction of disulphide bonds[2]. When human *7S* γ-globulin is reduced in the presence of 6 M urea approximately 15 disulphide bonds are split and the molecular weight falls from about 150,000 to 50,000; the products of reduction are separable by chromatography but are biologically inactive and insoluble in aqueous solutions[3]. Reduction of γ-globulin in neutral aqueous solution splits a maximum of five disulphide bonds and subsequent dialysis against acetic or propionic acid dissociates two fractions which have been called *A* and *B* (ref. 4); these can be separated on 'Sephadex *G75*' columns and appear to correspond to the chains referred to as *H* and *L* (ref. 5) which are obtained after more extensive reduction. Fleischman, Pain and Porter[4] have shown that in human, horse and rabbit γ-globulin *B* chains comprise about 25 per cent of the total protein and have molecular weights of about 20,000.

Fig. 1. Electrophoresis in 8 M urea-formic acid starch gel of human *7S* γ-globulin (*U*), reduced human γ-globulin (*R*) and the *A* and *B* chains separated in 1 N acetic acid on a 'Sephadex *G75*' column

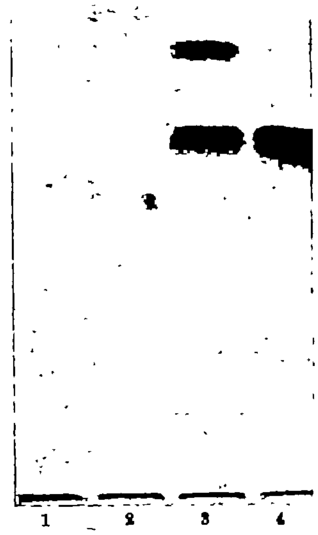

Fig. 2. Electrophoresis in 8 M urea-formic acid starch gel of reduced *7S* γ-globulin (4), *7S* myeloma globulin (3), pathological γ_1M-globulin (2) and γ_1A-myeloma globulin (1)

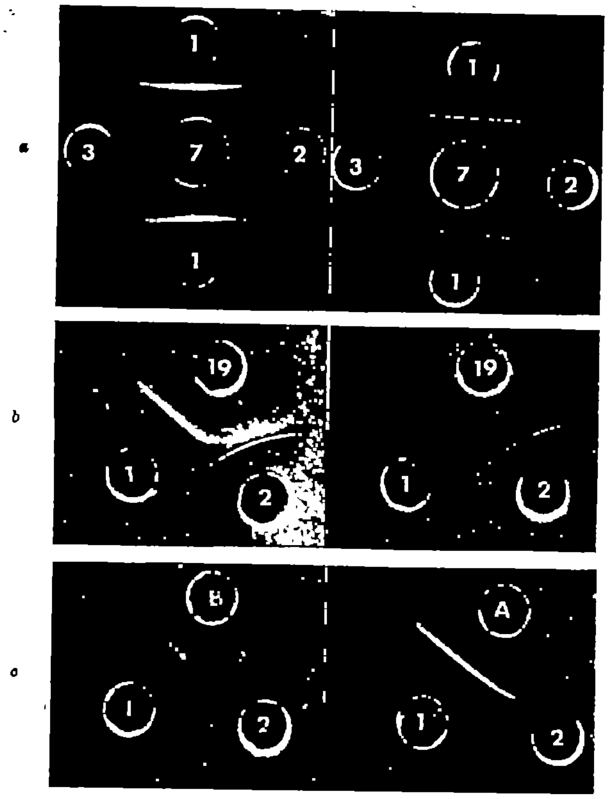

Fig. 3. *a*, Left, reaction of human $7S$ γ- (1), γ_1M- (2) and γ_1A-globulins (3) with rabbit anti-$7S$ serum (7), and right, with the same antiserum after absorption with $7S$ *B* chain. *b*, Left, reaction of normal human $7S$ γ- (1) and γ_1M-globulins (2) with rabbit anti-$19S$ serum (19), and right, with the same antiserum after absorption with $7S$ *B* chain. *c*, Left, reaction of normal human $7S$ γ- (1) and γ_1M-globulins (2) with rabbit anti-$7S$ *B* chain, and right, with anti-$7S$ *A* chain

The *A* chain which tends to precipitate at neutral *p*H comprises three-quarters of the original γ-globulin and has a maximum molecular weight of about 110,000. Some further properties of the *A* and *B* chains from various types of normal and pathological γ-globulins have been investigated. The results indicate that *B* chains carry those properties which are common to all γ-globulins while *A* chains are specific for each type.

Separation of A and B chains. Normal and pathological $7S$ γ-globulins were prepared by chromatography on diethylaminoethyl (DEAE) cellulose or by zone electrophoresis, and γ_1M-globulins by chromatography first on DEAE cellulose and then on 'Sephadex *G*200' columns. *A* and *B* chains were separated by the method of Fleischman *et al.*[4]. The yield of *B* from normal $7S$ and from pathological $7S$ and γ_1A-globulins was 24–29 per cent of the total protein.

Electrophoresis. The electrophoretic behaviour on a urea-formic acid starch gel of normal human $7S$ γ-globulin and the sub-fractions obtained after reduction is shown in Fig. 1. The *B* chains from all types of pathological γ-globulins differ from normal in their relative homogeneity[6], but all migrate within the range of normal $7S$ *B* on electrophoresis at acid *p*H (Fig. 2) or in alkaline buffers. The *A* chains of normal and pathological $7S$-globulins appear to be identical in urea-formic acid starch gels, but *A* chains from γ_1A- and γ_1M-globulins have slower electrophoretic mobilities (Fig. 2).

When *A* and *B* chains were prepared from γ_1 and γ_2 sub-fractions of $7S$-γ-globulin or from fast- and slow-moving pathological γ-globulins, it was found that the relative heterogeneity and mobility of the *A* chain at alkaline *p*H corresponded with that of the protein fraction from which it was derived. The mobility of the *B* chain, however, bore no relation to that of the molecule from which it was prepared.

Antigenic properties. *A* and *B* chains of $7S$ γ-globulin are antigenically distinct as judged by their reaction with rabbit anti-human $7S$ γ-globulin. Rabbit anti-$7S$ sera absorbed with $7S$ *B* chain do not react with γ_1A- and γ_1M-globulins (Fig. 3*a*). Similarly, anti-$19S$ sera absorbed with $7S$ *B* chain are specific for normal γ_1M-globulin (Fig. 3*b*). Antisera obtained by immunization of rabbits with human $7S$ *B* chain give a reaction of identity with normal $7S$ and γ_1M-globulins while antisera against the *A* chain react only with $7S$ γ-globulin (Fig. 3*c*). Similarly, *B* chains from pathological $7S$, γ_1A- and γ_1M-globulins give a reaction of complete or partial identity with normal $7S$ *B* when reacted with an antiserum to $7S$ *B* chain; antisera against $7S$ *A* chain, on the other hand, react only with *A* chains from abnormal $7S$ proteins and not with the *A*'s from pathological γ_1A- and γ_1M-globulins. These findings indicate that in both normal and pathological γ-globulins *B* chains carry antigenic determinants common to the three main types of γ-globulin while determinants specific for each are associated with their respective *A* chains.

Genotypic specificity. Recent investigations have established the presence within a single species of individual variants of γ-globulin which are antigenically distinct[7]. Variants of human γ-globulin have been distinguished from one another by differences in their ability to inhibit the agglutination of sensitized cells by selected sera containing substances serologically related to rheuma-

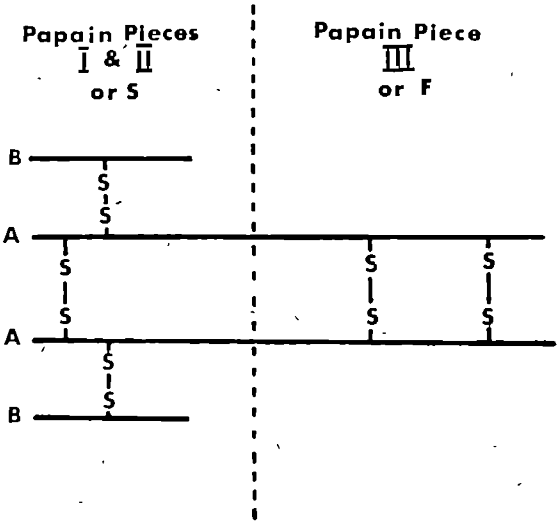

Fig. 4. Possible configuration of $7S$ γ-globulin The protein is shown made up of two *A* and two *B* chains. The dotted line indicates the probable site of papain cleavage which separates human γ-globulin into *S* and *F* fragments (ref. 12)

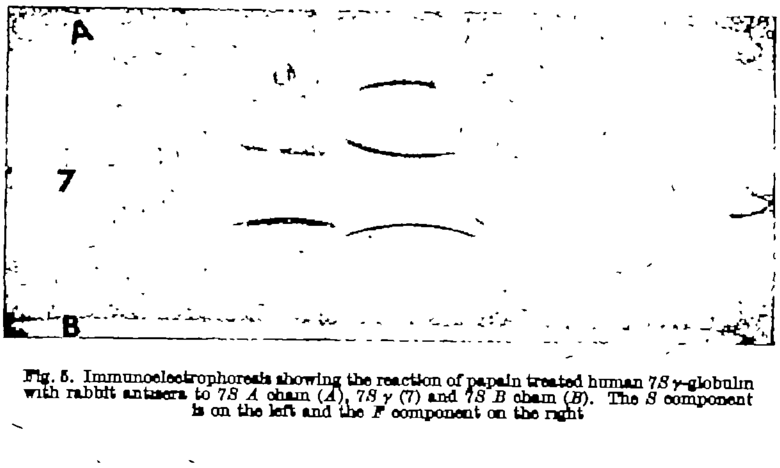

Fig. 5. Immunoelectrophoresis showing the reaction of papain treated human $7S$ γ-globulin with rabbit antisera to $7S$ *A* chain (*A*), $7S$ γ (7) and $7S$ *B* chain (*B*). The *S* component is on the left and the *F* component on the right

toid factors. Since the introduction of this technique[8] several genetically determined types of γ-globulin have been described. In Caucasians there are two independently segregating loci (Gm and Inv) which control the production of six well-defined γ-globulin variants. Gm activity is associated only with *7S* γ-globulin while the Inv factors are found on *7S*-, γ_1A and γ_1M-globulins[9,10].

A preparation of human *7S* γ-globulin from a Gm (a+b+) Inv (a+) individual was reduced and the *A* and *B* chains separated on 'Sephadex *G*200' in 1 N acetic acid; the *A* fraction prepared in this way is free of unreduced γ-globulin as judged by starch-gel electrophoresis. After separation of the chains Gm(a) and Gm(b) factors were detectable only on the *A* chain while Inv(a) activity was associated only with the *B* chain[11].

Relationship of γ-globulin chains to enzymatic pieces. Porter[1] has shown that papain activated by cysteine splits γ-globulin into three fragments separable by chromatography. One fragment (III in the rabbit, *F* in human) contains no antibody activity, while the other two (I and II in the rabbit, *S* fragments in human) each contain a single antibody combining site. Fleischman *et al.*[4] investigated the relationship between the papain pieces of rabbit γ-globulin and the chains separated by reduction. The *A* chain was found to react with antisera to piece I and piece III, while the *B* chain reacted only with anti-piece I. These findings indicated that pieces I and II contain the *B* chain and a portion of *A* chain, while fragment III contains only *A* chain, and this led Porter[12] to propose that *7S* γ-globulin has the general configuration shown in Fig. 4. The papain fragments of human γ-globulin have been studied by immunoelectrophoresis using rabbit antisera to *7S* *A* and *B* chains. The *S* fragment reacted only with anti-*B* and the *F* fragment only with anti-*A* (Fig. 5). Similarly, *S* purified by chromatography on diethylaminoethyl cellulose reacted with anti-*B*, but not with anti-*A* on gel diffusion. Since the *S* fragments comprise about two-thirds of the molecule and the *B* chains less than one-third, it appears that *S* must contain part of the *A* chain, but it has not been possible to demonstrate this with two different rabbit anti-*A* sera or with anti-*7S* sera absorbed with *B*; this suggests that the portion of the *A* chain included in the *S* fragment may be antigenically inactive in human γ-globulin.

Conclusion. Despite their diversity, all human γ-globulins have a basically similar structure and can be split by reduction into large *A* and smaller *B* chains. It is therefore logical to call the three main components of the system *7S*, γ_1A- and γ_1M-globulins and not to refer to the latter two as β-globulins.

The *B* chain of γ-globulin carries those antigenic and genotypic determinants which are common to *7S*, γ_1A- and γ_1M-globulins; *B* chain has been demonstrated in the papain fragment *S*, which is associated with the same common antigenic[13,14] and genotypic[9,10] factors (Table 1). These findings indicate that the three main types of γ-globulin contain *B* chains of similar structure.

Table 1. PROPERTIES OF THE SEPARATED CHAINS OF HUMAN *7S* γ-GLOBULIN

	A chain	*B* chain
Synonyms (ref. 5)	*H*	*L*
Total (per cent)	71–76	24–29
Max. mol. wt.	110,000	40,000
Elect. mobility (pH 8·8)	Related to original γ	Not related to original γ
Antigenic determinants		
Common to γ_1A and γ_1M	0	+
Specific for *7S*	+	0
Genotypic specificity		
Gm	+	0
Inv	0	+
Presence in papain pieces		
S	?	+
F	+	0
Myeloma proteins	Relatively homogeneous	Homogeneous

The *A* chains of *7S*, γ_1A- and γ_1M-globulins differ in electrophoretic behaviour and carry the antigenic determinants which are specific for each type of γ-globulin. Gml specificity, which is associated only with *7S* γ-globulin, is present on the *7S* *A* chain. The papain fragment, *F*, which is associated with the specific antigenic determinants of *7S* γ-globulin[13,14] and with Gm specificity[9,10], consists only of *A* chain. It appears therefore that the three main types of γ-globulin have different *A* chains; all the carbohydrate of the molecule is present in the *A* chains[4] and this may contribute to the differences which have been observed.

I thank Prof. R. R. Porter for his advice and Prof. N. H. Martin of St. George's Hospital and colleagues at St. Mary's Hospital for samples of pathological sera. The facilities for this work were provided by grants from the U.S. National Science Foundation, the U.S. Public Health Service, the Wellcome Trust and the Medical Research Council, London.

NEUROCHEMICAL DIFFERENCES BETWEEN TWO STRAINS OF MICE

By DR. JAMES W. MAAS

Section on Psychosomatic Medicine, Adult Psychiatry Branch, Clinical Investigations, National Institute of Mental Health,
Bethesda, 14, Maryland

PREVIOUS investigators[1-5] interested in genetic factors in behaviour have rather consistently found differences in behavioural measures between two strains of mice, the *BALB/cJ* and *C57BL/10J*. Briefly, these differences are as follows. The *BALB/cJ* mice are more fearful, as measured by the Hall open field test[6], show less exploratory activity, and are generally less active than the *C57BL/10J* strain. Caspari[7] noted a difference in total brain serotonin between these two strains (serotonin and 5-HT will hereafter be used interchangeably). My later work[8] indicated that these two strains were significantly differentiated by the 5-HT content of a dissected portion of brain consisting of pons, mesencephalon, and diencephalon, whereas the norepinephrine content of this dissected portion was the same for both strains. Specifically, the *BALB/cJ* mice had 1·34 μg of serotonin/g of dissected brain tissue and the *C57BL/10J* 1·07 μg/g ($P = < 0·01$) while the values for norepinephrine were 0·73 μg/g and 0·70 μg/g respectively ($P = > 0·25$). This article presents further work as to the nature of this strain difference in serotonin-levels.

All mice used in these experiments were from the Jackson Memorial Laboratories in Bar Harbor, Maine, all were males, and were 8–11 weeks of age at the time of death. All experiments were designed so that a given mouse from one strain was always paired with a mouse from the opposite strain which had been reared and housed under similar conditions and was of course of the same age. The method used for 5-HT determinations was basically that of Bogdanski[9] with the modifications suggested by Kuntzman[10] being used for microanalytical procedures. The mice were decapitated without premedication. The dissected portion of brain referred to frequently in this article was prepared as follows. The medulla, cerebellum, cerebral lobes, all tissue anterior to the optic chiasm and lateral to the optic tracts were dissected away and the portion left thus consisted of pons, mesencephalon, and diencephalon.

Although there was no reason to suspect that the mice from the Jackson Laboratories were behaviourally different from those previously reported, the two strains were tested, with the sample consisting of fifteen mice from each group, as to 'fear' response using a modified Hall open field apparatus[8]. It was found that following one two-minute trial in the field 95 per cent of the *BALB/cJ*'s and 25 per cent of the *C57BL/10J*'s had defæcated whereas the respective incidences of urination was 62 per cent and 0 per cent. Another group was tested by measuring the number of 5 in. × 5 in. squares crossed by the mouse while in the 'open field'. Here twenty mice from each strain were used. The mean number of 5 in. × 5 in. squares crossed was 32·4 for the *BALB/cJ*'s and 80·8 for the *C57BL/10J*'s. This difference is statistically significant ($P = < 0·01$). These results agree favourably with those of other investigators and suggest that the mice presently being obtained from the Jackson Laboratories have retained the earlier noted behavioural differences.

Table 1

	Strain *BALB/cJ*	Significance of difference	Strain *C57BL/10J*
Serotonin in total brain ± S.E.	0·807 ± 0·013 μg/g (*N* = 9 determinations on a total of 50 brains)	N.S.	0·783 ± 0·018 μg/g (*N* = 6 determinations on a total of 20 brains)
Mean weight of total brain ± *S.E.*	474·63 ± 0·0067 mg (*N* = 50 brains)	*P* = < 0·05	452·42 ± 0·0066 mg (*N* = 20 brains)
Serotonin in dissected portion of brain ± *S.E.* (ref. 8)	1·34 ± 0·046 μg/g (*N* = 19 brains and 19 determinations)	*P* = < 0·01	1·07 ± 0·037 μg/g (*N* = 19 brains and 19 determinations)
Mean weight of dissected portion of brain ± *S.E.* (ref. 8)	146·4 ± 1·56 mg (*N* = 45 dissections)	*P* = < 0·01	140·7 ± 1·60 m (*N* = 45 dissections)
Total* serotonin in portion of brain remaining after dissection ± *S.E.*	0·1578 ± 0·0033 μg (*N* = 4 determinations on 8 brains)	N.S.	0·1535 ± 0·0061 μg (*N* = 4 determinations on 8 brains)

* Serotonin values are expressed as total amount present rather than as μg/g because those structures rich in serotonin in this portion of brain constitute a relatively small fraction of the total weight.

Serotonin values (see Table 1) for total, that is, non-dissected, brain were found not to differ significantly for the two strains. This is in contradiction to the earlier noted finding of significant differences in 5-HT levels using a dissected portion of brain[8]. This disparity immediately suggested that the earlier observed difference is not a function of a general increase in serotonin in all those structures known to be rich in this amine but rather that the greater serotonin noted in the *BALB/cJ* strain is to be found specifically in that portion of the brain which had been dissected out. Experimental evidence supporting this was found when determinations of the serotonin present in that portion of the brain remaining following the formerly described dissection indicated no strain difference (Table 1). From this it is concluded that the earlier noted difference in serotonin content for the two strains is not generalized but rather is found only in that portion of brain consisting of pons, mesencephalon, and diencephalon. Further investigations may be of use in more accurate localization as to specific structures which may account for the difference found.

In order further to understand the biochemistry of the noted difference in the two strains a potent monoamine oxidase inhibitor, 'Parnate', was injected intraperitoneally at 5 mg/kg. 1 h and 5 h after injections, the animals were killed and serotonin determined on the earlier described dissected portion of brain. For the 1-h experiment five animals from each strain and for the 5-h experiment ten animals from each strain were used. Results obtained are presented in Fig. 1. Although the differences between the two strains are still significantly different at the 1-h and 5-h point, it is noted that the characteristic 125–130 per cent greater serotonin-levels found in the *BALB/cJ* animals has decreased to 115–116 per cent at the 1-h and 5-h points. These results suggest that the observed differences between the two strains cannot be explained solely on the basis of a differential in the rate of transfer of 5-hydroxytryptophan to brain nor to some impairment of decarboxylation of this precursor of serotonin. (The presence of equal amounts of norepinephrine found in earlier work[8] also suggests that the serotonin difference is not due to different activities of 5-hydroxytryptophan decarboxylase as this enzyme seems to be the same as Dopa decarboxylase[10].)

These findings are consistent with the possibility that the *C57BL/10J* strain has more or more active monoamine oxidase and that if 'Parnate' completely inhibits all the monoamine oxidase, there is a slightly more rapid increase of serotonin. However, the fact that a significant difference persists throughout the entire 5-h period suggests that a difference in monoamine oxidase levels or activity could be only a partial explanation. Because of the foregoing, it is concluded that it is possible but unlikely that the observed differences can be explained on the basis of differences in production or catabolism of serotonin.

Although the prime purpose of the injection of 'Parnate' was the examination of changes in serotonin-levels, an observed difference in behaviour between the two strains was noted. Following the drug administration the *BALB/cJ* mice were periodically hyperactive; they assumed an 'alert' stance with the head up when not moving about; and they were most sensitive to any stimuli during periods of non-movement. This behaviour reached its maximum 30–45 min after injection and continued for the 2 h during which they were observed. In contrast the *C57BL/10J* mice while alert remained huddled in the corner of the cage with their heads down and showed only moderate sensitivity to stimuli. At the end of 2 h the differences were still noted but the behaviour of the *C57BL/10J* mice was more like that of the *BALB/cJ* mice, that is, with time the behaviour of the two strains became nearer to being equal. These effects were noted both for animals housed in groups of five following the injections and to a slightly lesser degree when housed singly.

It is well known that serotonin exists in the brain in at least two forms, a bound and a free, and that reserpine

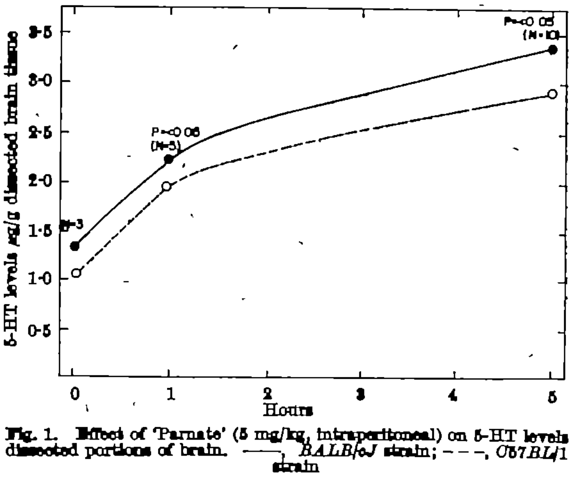

Fig. 1. Effect of 'Parnate' (5 mg/kg, intraperitoneal) on 5-HT levels in dissected portions of brain. ——, *BALB/cJ* strain; – – –, *C57BL/10J* strain

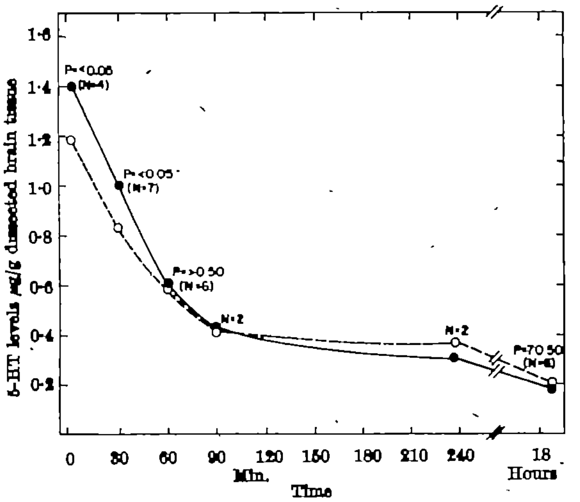

Fig. 2. Rate of serotonin depletion in dissected portion of brain following reserpine injection (2·5 mg/k body-wt. intraperitoneal) ——, *BALB/cJ* strain; – – –, *C57BL/10J* strain

acts on the binding or transport mechanism in some way so as to effect a release of 5-HT and norepinephrine. Furthermore, Potter *et al.*[11] as well as Weil-Malherbe *et al.*[12] have suggested that for norepinephrine the bound form is divided into two components, an easily releasable, and a more tightly bound. It was felt that it would be of some interest to compare 5-HT depletion curves for the two strains following an intraperitoneal injection of 2·5 mg reserpine/kg body-wt. These curves are presented in Fig. 2. Note that by 60 min the two strains have similar values for 5-HT, suggesting a more rapid release in the *BALB/cJ* strain. Parenthetically, these curves offer further evidence that the lower 5-HT levels in the *C57BL/10J* strain are not due to a relative deficit of monoamine oxidase in the *BALB/cJ* strain, for if this were the case the rate of depletion of 5-HT in the *C57BL/10J* would be expected to be greater than for the *BALB/cJ*. These curves do suggest, however, that there may be a difference in the binding mechanisms for the two strains and that this may in some way be responsible for the differential in 5-HT levels found between the two groups. The paucity of basic knowledge about binding and release mechanisms, and cellular partitions, is such that opposite hypotheses could be erected from the data presented. For example, if one assumes three cellular locations for 5-HT as does Brodie[13], that is, a granular, a lipid membrane bound area, and the portion of the cell having free monoamine oxidase, then one could explain the higher 5-HT in the *BALB/cJ* strain by postulating that there is *in vivo* a more rapid release of 5-HT from the granular fraction in the *BALB/cJ* strain with a consequent increase in 5-HT in the portion of the cell having the lipid membrane. Thus, measuring 5-HT in a homogenate would indicate more 5-HT in the *BALB/cJ* even though the granular fraction was less.

On the other hand, an alternative hypothesis is that the 5-HT *in vivo* is released less rapidly from the granular fraction in the *BALB/cJ* strain and thus the observed differential. This hypothesis would hold whether one uses Brodie's concept or the simpler one of a granular and non-granular fraction. This concept might also explain the closer approximation of 5-HT levels after 'Parnate' administration.

It is felt that the use of these inbred strains of mice for further clarification of the found neurochemical differences and their possible relationship to well-established behavioural differences is particularly appealing because the differences are naturalistic, that is, they occur without introducing non-physiological conditions which heretofore have been necessary in order to produce chemical and behavioural changes.

I thank Mr. Harold Landis for assistance, and Dr. Donald Morrison for advice as to statistical methods. Smith, Kline, and French kindly supplied the 'Parnate' used.

SUCCESSFUL DEVELOPMENT OF CHICK EMBRYOS NOURISHED BY YOLK-SAC PERFUSION WITH CALCIUM-LOW MEDIA

By C. R. GRAU, N. E. WALKER, H. I. FRITZ and S. M. PETERS

Department of Poultry Husbandry, University of California, Davis

THE abundant supply of yolk and white in the hen's egg hampers direct study of chick-embryo nutrition. In order to remove yolk nutrients and maintain essentially normal relationships between the embryo, its membranes, and the shell, techniques were devised first to replace the yolk of three-day embryos by the injection of salts solution[1], and later to perfuse the yolk sac with various media[2]. By use of an electrosurgical unit, a canal of coagulated white was formed, thus connecting the yolk sac of three-day embryos with the exterior of the shell. Next, metal connecting tubes were attached, and a salts solution was slowly injected upward into the yolk through a hypodermic needle, so that most of the yolk, being heavier, was displaced by the lighter salts solution. An overflow tube was then attached, and fluids were perfused through the yolk sac.

Since the publication of these preliminary studies efforts have been made to obtain normal development, but without success until recently. A few embryos survived more than 100 h when perfused with 15 ml. of fluid every 8 h, starting at 4 days of incubation, but even these were small and had poor extra-embryonic circulation and little allantoic fluid. Despite failure to obtain normal development, it has been possible to study survival time in relation to salt balance, solute concentration, glucose requirement, and casein or egg-white as components of the medium. When the medium lacked either casein or white, the median death-time was about 30 h; when either one was present, median death-time was sometimes more than 100 h. The effects of white were less remarkable, perhaps, than the observation that the presence of yolk in the perfusion medium was not beneficial; on the

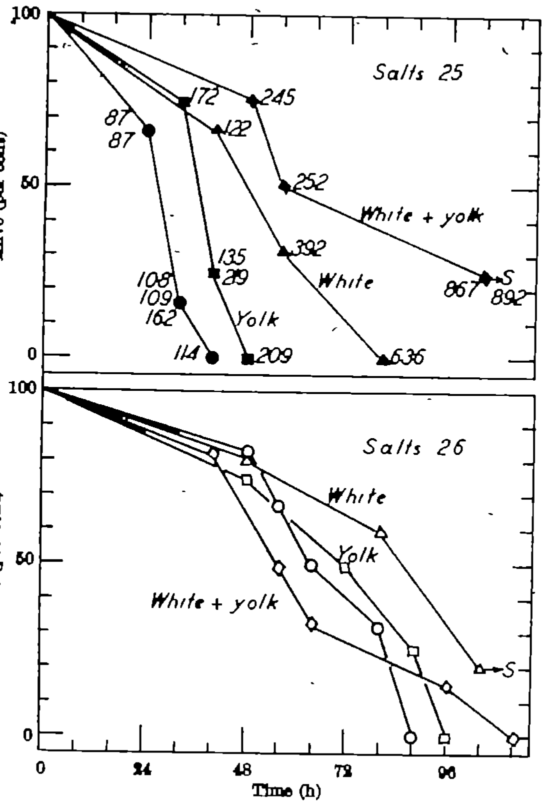

Fig. 1. Survival of embryos perfused with 30 ml. of medium every 8 h, starting after 4 days of incubation. Unmarked curves are for groups perfused with salts 25 or 26 only, compared with yolk (10 ml./l.), white (20 ml./l.), or both. Each curve represents from 3–6 embryos. Embryos marked *S* were killed at 112 h. Upper curves, salts 25. Numbers are the wet weights of embryos that had died. Lower curves, salts 26. The embryo weights are given in Fig. 2

contrary, embryos receiving a medium containing 12 ml. of yolk per litre died earlier than those receiving salts alone. In contrast to the results obtained during perfusion were the findings that embryos left undisturbed after most, but not all, of the yolk had been displaced by the salts solutions survived well and grew essentially normally for several days. After thorough removal of yolk at 4 days, embryo size at 8 or 9 days was found to be influenced by the amount of yolk returned to the yolk sac[3].

The removal and replacement system was then utilized in studies on glucose, magnesium and calcium in relation to survival and development, and to concentrations of these nutrients and of sodium and potassium, in various fluids. Survival was improved by reduction of the calcium chloride level of the salts solution from 200 mg/l., a concentration commonly used in cell and organ culture media, to 20 mg/l. In these investigations, 2 ml. of yolk (containing 0·15 m.equiv. calcium) were injected into the yolk sac; thus, the total concentrations in the 25 ml. volume of yolk sac were increased by the additions of yolk to 9·7 m.equiv./l. from the original level of 3·7. When the calcium-level of the salts solution was 0·37 m.equiv./l., the addition of 2 ml. of yolk raised the calcium-level to 6·4 m.equiv./l. From these and other experiments yet to be published, it appears that the major problem in previous perfusion studies may have been that excess calcium limited survival.

The working hypothesis of the present investigation was as follows: Perfusion removes components of the white which have entered the yolk sac. These soluble materials have, in addition to their value as nutrients, a greater ability to bind calcium than have yolk components. When the embryo is subjected to a level of available calcium in excess of its tolerance, it succumbs. The effective level of calcium in the perfusion medium is related to calcium-levels of yolk, white and the salt solution, and to the calcium-binding capacity of components of yolk and white.

This hypothesis was tested by two experiments in which the effects of yolk and white supplements were studied in relation to the calcium-level of the medium, using embryo survival and weight as criteria. The embryos were prepared for the experiments in essentially the same manner as before[3]. The salts solutions contained the following: sodium chloride, 4·46 g; potassium chloride, 1·70 g; magnesium chloride $(6H_2O)$, 0·34 g; magnesium sulphate $(7H_2O)$, 0·20 g; sodium dihydrogen phosphate (H_2O), 0·28 g; glucose, 5·00 g; sodium bicarbonate, 1·1 g; erythromycin, 0·095 g (as glucoheptonate); dihydrostreptomycin, 0·66 g (as sulphate); and deionized water to make 1 l. of solution. In addition, calcium chloride was present at 0·2 g/l. (salts 25), or 0·02 g/l. (salts 26).

After a total incubation time of 4 days, the canal of each egg was cleared of yolk by a few ml. of fluid, an overflow tube was attached, and the yolk sac was connected through a hypodermic needle to a reservoir from which 30 ml. of fluid were dispensed every 8 h. It required approximately 10 min for each of two 15-ml. volumes to flow through the yolk sac. Death times were noted, and the dead embryos were preserved in 10 per cent formalin for study and for determinations of wet weights.

The salts solutions contained more potassium and magnesium, and less sodium, than solutions ordinarily used for cell and organ culture[4]. Salts 25 contained 3·7 m.equiv. calcium/l.; salts 26, 0·37 m.equiv./l. 10 ml. of fresh yolk contain 0·75 m.equiv. of calcium; 20 ml. of liquid white contain 0·075 m.equiv. (ref. 5).

The results obtained from one experiment are presented in Figs. 1 and 2; the results of the other experiment are consistent with these, but are omitted for brevity. When the basal medium contained the higher level of calcium (Fig. 1, upper curves), death occurred quickly in both the absence and the presence of yolk, but the addition either of white or of both yolk and white prolonged survival. Comparison of the upper and lower curves of Fig. 1 shows that reduction of the calcium-level from 3·7 to 0·37 m.equiv./l. improved survival in the absence of the supplements (unmarked curves) or in the presence of

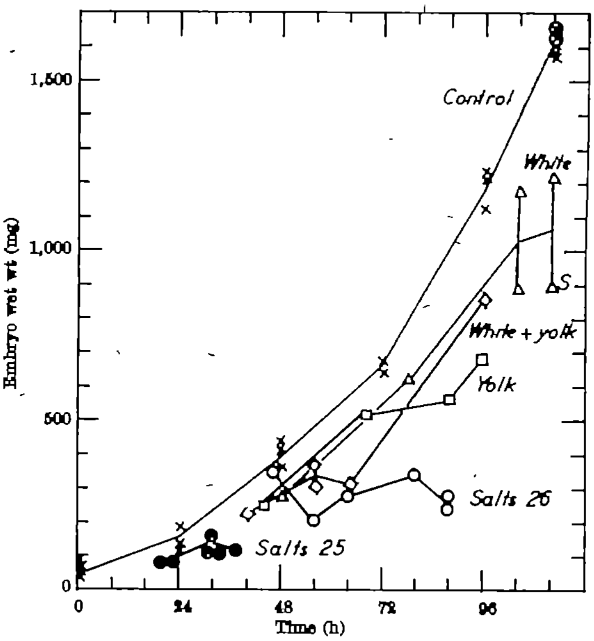

Fig. 2. Wet weights of embryos in relation to time of death. All embryos except controls were perfused with 30 ml. of medium every 8 h. Embryos marked by solid circles were perfused with salts 25 alone; all others received salts 26, plus supplements as shown. Points marked by x in circles were from embryos which had been subjected to the preparative steps, but had not had their yolk displaced

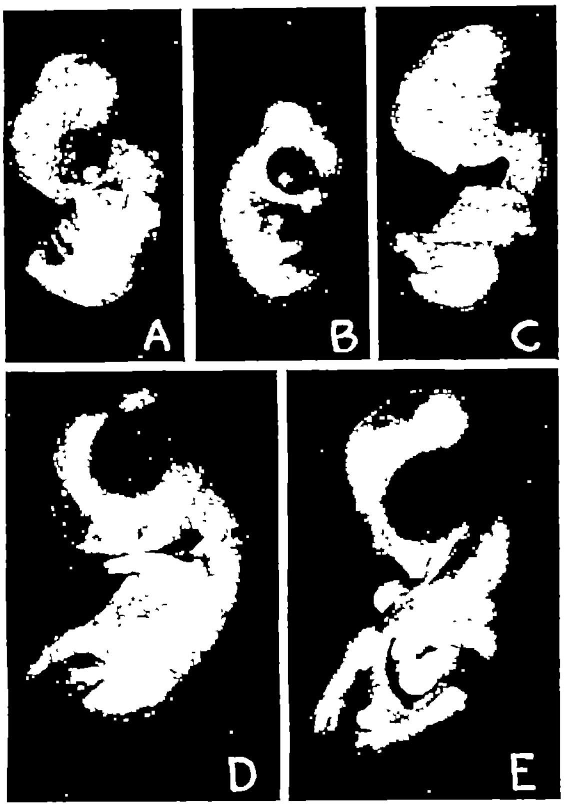

Fig. 3. Effects of media on embryo growth and developmental stage (ref. 6). Embryos *A*, *B*, and *C* died between 78 and 88 h: *A*, salts 26 plus yolk, 560 mg, stage 30; *B*, salts 26 only (no white or yolk), 270 mg, stage 27, *C*, salts 26 plus white, 600 mg, stage 30. Embryos *D* and *E* were examined at 104 h: *D*, salts 26 plus white, 1,190 mg, stage 33; *E*, control embryo, killed, 1,330 mg, stage 34. Embryos *B* and *C* were normal, *A*, *D*, and *E* had beak abnormalities. *D* was slightly edematous

yolk. When white was present, the effect was less marked, and when both yolk and white were present, there was no effect.

The relation of embryo weight to time of death is shown in Fig. 2, from which it is clear that the unsupplemented salts 26 solution permitted only poor growth. This result is in contrast to those with supplemented media: when yolk and white were added to the medium, embryos which died after 80 h weighed twice as much as those perfused with salts alone.

The small embryos were retarded in development, but showed no gross abnormalities. Two embryos perfused with salts 26 supplemented with white were found at autopsy to be edematous, which accounts for their greater weight. In contrast to previous perfusion experiments, the extra-embryonic circulation and allantoic sac volumes were essentially normal in those embryos perfused with salts 26. Some of the embryos which died after 80 h exhibited parrot-beak abnormalities or shortened mandibles, but there was no evidence that any of the treatments was specifically responsible for the abnormalities. When the egg-tooth was present, it was calcified normally.

The control embryos were obtained from eggs of the same group, prepared in the same way as the experimental ones, except that yolk removal was incomplete because of rupture of the canal lining during the first displacement process. Previous trials had shown that such embryos grow normally during this period of incubation. Photographs illustrating some of the size differences in relation to medium content and perfusion time are presented in Fig. 3.

From the results of previous experiments using the replacement system, in which the yolk sac was thoroughly flushed out at 4 days, it was expected that embryos perfused with solutions containing white but no yolk would be smaller than those receiving both white and yolk. In the experiment described here, however, such a thorough washing was not performed, because of the expected effectiveness of subsequent periodic perfusions. The poor growth obtained with salts 26 alone indicated that residual yolk had been effectively removed. When white was present in the medium, however, growth was almost normal. Two possible explanations for this observation are: (1) when white was present in the medium, removal of vestiges of yolk clinging to the entodermal lining of the yolk sac may have been impaired; or (2) when white was present, yolk materials in entodermal cells may have been more effectively utilized than when white was absent.

Questions concerning the relative effectiveness of white and yolk as supplements, the concentrations required, and their possible replacement by other protein sources or by amino-acids in defined media await further investigation. The results reported here show that it is possible to obtain almost normal growth and development through the eighth day of incubation by perfusing through the yolk sac of 4-day chick embryos a salts and glucose solution, supplemented with white and yolk. Compared with the media commonly used for cell and organ culture[4] this medium is characterized by a low sodium-to-potassium ratio and by a very low level of calcium. It is concluded that the proposed hypothesis, namely, that components of the white enter the yolk sac and protect the embryo by combining with calcium from the yolk or salts solution, is still tenable.

SERUM TRANSFERRINS IN CHIMPANZEES

Serum Transferrins in the Orange Park Chimpanzee Colony classified by the Boyer and Young Scheme

BOYER and Young[1] observed seven phenotypes of transferrin on analysing the sera of 25 chimpanzees for iron-binding components by vertical starch-gel electrophoresis[2] and autoradiography[3]. Each serum (pretreated with iron-59) contained after the starch-gel separation either one or two heavily labelled zones of iron-binding protein and 1–3 additional bands of more weakly labelled protein (Fig. 2). In naming these phenotypes it was assumed that if an animal was homozygotic for transferrin only one heavily labelled band would be present; but, if heterozygotic, two such bands would be present. Thus the seven observed phenotypes were designated: AA, AC, AD, BC, CC, CD and DD, the A transferrin having the highest electrophoretic mobility and the D transferrin having the lowest electrophoretic mobility. Buettner-Janusch[4] also used vertical starch-gel electrophoresis and autoradiography to identify transferrin differences in chimpanzees. He analysed 41 sera, 20 obtained originally from animals in the chimpanzee colony of the Yerkes Laboratories of Primate Biology at Orange Park, Florida. In agreement with the findings of Boyer and Young[1], Buettner-Janusch[4] reported that there were multiple bands of transferrin and a pronounced polymorphism of this protein in chimpanzees. However, he did not consider it wise to attempt to distinguish by the system of nomenclature heavily labelled bands from more weakly labelled bands. Nor did his phenotypes correspond in the relative positioning of components to the Boyer and Young phenotypes. In contrast to Buettner-Janusch, Parker and Bearn[5], who analysed 67 sera from animals in the same Orange Park chimpanzee colony, were able to classify the transferrin phenotypes of these sera according to the Boyer and Young scheme. Their paper described the presence of the AC, BC, CC, and CD phenotypes in the Orange Park colony.

Here we present the results of our own analyses performed on 122 sera drawn at various times from 77 of the Orange Park chimpanzees. We thank Dr. Arthur J. Riopelle (director of the Yerkes Laboratories of Primate Biology), who provided us with the sera from these animals. Almost all samples were analysed by two-dimensional starch-gel electrophoresis[6] in the *tris* discontinuous buffer system[7], and the principal transferrin components in several representative sera were identified by immunological examination of the separated β-proteins with unispecific chicken antiserum to human transferrin. The method of immunological examination was that previously utilized to identify transferrin components in the two-dimensional starch-gel electrophoresis patterns of rhesus monkey sera[8]. In addition, the iron binding patterns of 70 sera from 60 of the chimpanzees were determined on samples pretreated with iron-59 by comparative one-dimensional starch-gel electrophoresis and autoradiography.

It was observed in both sets of analyses that the transferrin fraction of chimpanzee serum is comprised predominantly of either one or two electrophoretically distinct molecular species. Furthermore, a consistent pattern of minor transferrin components was demonstrated, the variations of which in the chimpanzee sera were related to the variations of the major transferrin components. In accordance with the scheme of Boyer and Young these major components could be labelled in order of decreasing electrophoretic mobility: A, B, C and D. By two-dimensional starch-gel electrophoresis in the discontinuous buffer system, C and D could usually be distinguished from each other and could always be distinguished from A and B, but A and B could not be readily distinguished from each other. Indeed, even by the method of vertical starch-gel electrophoresis in borate buffer, with its much longer period of separation, repeat analyses were necessary clearly to resolve A from B. (The 70 sera pretreated with iron-59 were first analysed by the more rapid horizontal starch-gel electrophoresis in the *tris* discontinuous buffer system. Then the samples having either A or B transferrin were analysed by vertical starch-gel electrophoresis in borate buffer.) The significance for our study of the method of two-dimensional starch-gel immunoelectrophoresis was that it permitted us to visualize clearly the major transferrin components of chimpanzee serum, since by the iron-binding method (as pointed out in the report of Buettner-Janusch[4]) "the possibility occurs that the degree to which the transferrins are saturated *in vivo* before the blood samples were taken plays a part in the extent to which each band will take up iron-59 *in vitro*". Indeed, cord blood obtained from a new-born chimpanzee (Ball No. 195) failed to show any transferrin by the iron-binding method, but was readily typed as CD by two-dimensional starch-gel immunoelectrophoresis.

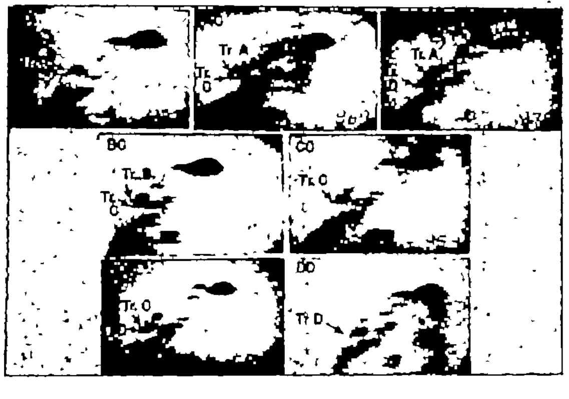

Fig. 1. Two-dimensional starch-gel electrophoretic patterns of chimpanzee sera showing seven phenotypes of transferrin. The distinction between the *A* and *B* transferrins, not evident in the patterns, was established by vertical starch-gel electrophoresis in borate buffer of samples pretreated with iron-59 and by autoradiography

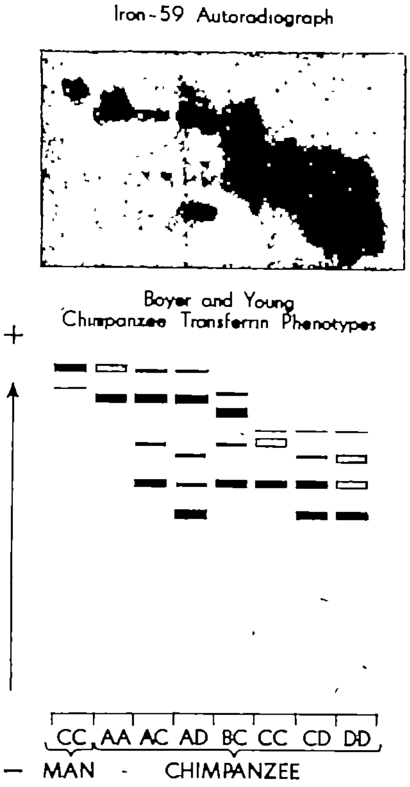

Fig. 2. The photograph presents the results of a vertical starch-gel electrophoresis experiment which compares the transferrins of Orange Park chimpanzees, representing seven phenotypes, with the transferrin of normal human serum (far left). The transferrin bands are indicated by white dots. The diagram below is a representation of the seven chimpanzee transferrin phenotypes discovered by Boyer and Young (ref. 1). The similarity in the relative positioning of major and minor transferrin components can be noted on comparing the photograph with the diagram for each of the seven phenotypes

The results of our analyses are given in Figs. 1 and 2 and Table 1. As can be noted, seven distinct phenotypes of serum transferrin were found in the Orange Park chimpanzee colony. Furthermore, as demonstrated in Fig. 2, these seven phenotypes showed the same relative positioning of minor transferrin bands to major bands as the phenotypes described by Boyer and Young[1]. Thus even though chimpanzee sera were not exchanged with these investigators, we were convinced that our seven phenotypes were the same as theirs. Accordingly, the same system of nomenclature can be used for describing the transferrin phenotypes of the Orange Park chimpanzees.

In recording the distribution of these phenotypes (Table 1) we divided the animals into those which were born in the jungle (birth-date unknown) and those which

Table 1. DISTRIBUTION OF TRANSFERRIN PHENOTYPES IN CHIMPANZEES

Phenotypes	Orange Park Colony Inbred	Orange Park Colony Jungle born	Boyer and Young group
AA	0	1	1
AC	3	2	3
AD	1	1	5
BC	3	2	4
CC	35	11	9
CD	16	0	1
DD	0	2	2
Total	58	19	25

were born in the colony, the latter being an inbred group of chimpanzees. CC was the most common of the phenotypes in both these groups and also in the chimpanzees analysed by Boyer and Young. However, phenotype CD, which appears to be rather rare in jungle born chimpanzees (putting our data and that of Boyer and Young together), was the next most common phenotype in the chimpanzees born at Orange Park. An original breeder female in the colony (Wendy No. 4) has been typed as CD, which accounts in part for the rather frequent occurrence of the CD phenotype in the inbred group. It should be emphasized that as larger numbers of chimpanzees are surveyed new phenotypes and new molecular forms of transferrin in addition to the seven phenotypes observed by Boyer and Young[1] and ourselves might well be discovered. Nevertheless, the use of a nomenclature which in effect describes the transferrin phenotypes of chimpanzees in terms of an allelic series of genes is not inappropriate as the following communication demonstrates.

We thank Dr. Melvin R. Sikov of the Department of Radiology, Wayne State University College of Medicine, for his advice on the radioactive iron-binding analyses and for generously permitting us to use his facilities.

Inheritance of Serum Transferrins in Chimpanzees

By reviewing the familial relationships of chimpanzees born in the Orange Park Colony, the transferrin phenotypes of which were classified by the Boyer and Young scheme (preceding communication), it was possible to evaluate the genetic basis for the inheritance of these transferrins. The results are recorded in Table 1. To summarize the findings: of the twelve offspring of CC × CD matings, six were CC and six were CD. There were four offspring of AC × CC matings; three were CC and one was AC. The two offspring of BC × CC were BC and CC. The one offspring of CD × CD was CD, and the offspring of the CC × CC mating was CC. Thus without exception each offspring always had one major transferrin identical in type to one held by the mother and one major transferrin identical in type to one held by the father. Furthermore, there were fourteen offspring, each one having a transferrin phenotype which could be compared with the transferrin phenotype of only one of the parents; again, one major transferrin of the offspring was always identical in type to a major transferrin of the parent. Thus, as in the case of human transferrins[8] and rhesus monkey transferrins, these data support the hypothesis that a single autosomal multi-allelic series of genes without dominance controls the transferrin polymorphism of chimpanzees.

Brackets denotes that the animal was no longer available for drawing serum due to death.

There would be four genes in the allelic series controlling respectively transferrins A, B, C and D. The minor transferrin bands would be related to the major bands, and their presence along with these major bands would be controlled by the same allelic system at a single locus. The appearance of the seven chimpanzee phenotypes (Fig. 2 in the preceding communication) suggests that transferrins A, B and C each have one minor component migrating directly in advance of the major component, whereas transferrin D has two components migrating in advance of the major component, the slower of these more rapidly migrating bands occurring in the same position of the major component of transferrin C. Another genetic hypothesis to account for multiple transferrin bands in chimpanzees presumed to be homozygotic for the protein is that genes at more than one locus interact to control the molecular specificities of transferrin, with the observed phenotypes resulting from an allelic series at only one of the gene loci.

Our results by either genetic hypothesis support the assumption that CC is a homozygous phenotype and that AC, BC and CD are heterozygous phenotypes. As yet we have no information on the inheritance of phenotypes AA, AD and DD. Thus the assumption that the phenotypes designated DD and AA are homozygous in character still rests on very tenuous grounds. Clearly the genetic basis for the transferrin differences in chimpanzees cannot be thoroughly evaluated until a more extensive programme of breeding chimpanzees with these various transferrin phenotypes is carried out.

This work was carried out with support from grant G-14152 of the National Science Foundation, grant 226 of the National Multiple Sclerosis Society, and grant H-5691 from the National Heart Institute of the National Institutes of Health.

INCORPORATION OF AMINO-ACID BY ROOT NODULES OF *GALEGA OFFICINALIS*

By Dr. M. H. PROCTOR and ESAM MOUSTAFA

Plant Chemistry Division, Department of Scientific and Industrial Research, Palmerston North, New Zealand

AMONG plant tissues, root nodules have two unique features: they contain hæmoglobin[1] and fix nitrogen[2]. These characteristics in their turn imply that nodules can synthesize both hæmoglobin and the nitrogen-fixing enzymes, and hence are suitable organs for the examination of specific protein synthesis.

Root nodules of *Galega officinalis* (Linn.) are robust structures of up to 200 mg fresh weight and can be detached easily from the plant in a metabolically active condition[3]. These nodules contain hæmoglobins of the types normally found in plant tissues[3]. Previous work has shown that the nodules contain amino-acid-activating enzymes[4], and this article outlines experiments which show that intact detached nodules incorporate amino-acids into the water-soluble proteins, including hæmoglobin.

In order to obtain nodules which were actively fixing nitrogen and synthesizing hæmoglobin, a system of 'regenerating nodules' was devised. Young plants growing in the field were uprooted, the majority of nodules were removed from the roots, and the de-nodulated plants were replanted in coarse pumice. These plants were periodically irrigated with a nutrient solution containing: calcium chloride, 0·0045 M; potassium sulphate, 0·00225 M; sodium chloride, 0·0005 M; magnesium sulphate, 0·002 M; potassium dihydrogen phosphate, 0·001 M; dipotassium hydrogen phosphate, 0·001 M; ferric versenate, 0·5 ml./l. of a saturated solution; and 1 ml./l. of a trace element mixture. Within two weeks many new nodules were appearing on the roots. These new nodules incorporated amino-acids four times as fast as mature nodules, and were used in all the experiments described here.

Incorporation of amino-acid was examined with intact nodules bathed with 0·1 M potassium phosphate buffer *p*H 7·1 containing an excess of valine-1-^{14}C with a specific radioactivity of 2,000 counts/min/mg. This suspension was shaken in air by 120 reciprocal 1 in. stroke/min at room temperature. Valine was chosen as marker for protein synthesis because: it contributes mainly to protein valine[5,6]; proteins[7] and nodule hæmoglobin[8] are relatively rich in valine; nodules contain an active valine-activating enzyme[4]; and since the endogenous 'amino-acid pool' contains only traces of valine, the added radioactive valine is diluted very little. At intervals, samples of the incubating nodules were taken, washed with the phosphate buffer containing 5 per cent (w/v) valine-^{12}C, and then crushed with a glass rod in the phosphate buffer. When all the nodules were crushed, the homogenate was centrifuged at 25,000*g* for 15 min. The supernatant solution, containing water-soluble proteins and essentially all the hæmoglobin, was fractionated by boiling with an equal volume of 10 per cent (w/v) trichloroacetic acid. This precipitate (= total water-soluble protein) and the sediment from centrifugation (= sedimentable protein) were washed with 5 per cent (w/v) trichloroacetic acid containing valine-^{12}C. The washed precipitates were dissolved in ammonia solution, plated on planchettes 19 mm in diameter in the presence of cetyl-trimethyl-ammonium-bromide and dried under an infra-red lamp. These infinitely thin samples were monitored for at least 1,000 counts with a Geiger–Müller tube. The background count rate was of the order of 10 counts/min.

The results (Fig. 1) show that valine is incorporated into both sediment and water-soluble fractions, and suggest that both water-soluble and sedimentable proteins are being formed. Also, since the ratio of the radioactivity incorporated into each fraction remains constant, it would seem that there are a constant number of synthetic sites.

Whole nodules contain both bacterial and plant components, and the sediment after centrifugation contained most of the water-insoluble plant material, namely, cell walls and membranes, and the bacteria. The effect of inhibitors on the incorporation of amino-acids was investigated with the view of discriminating between incorporation by plant and incorporation by bacteria, a subsidiary aim being to be able to halt nitrogen assimilation between fixation and protein and thence move the equilibrium reactions in favour of the early products of fixation.

A series of inhibitors was screened with the results shown in Table 1. These results show that although inhibitors of energy production inhibit synthesis of both water-soluble and sedimentable proteins, chloramphenicol (an inhibitor of bacterial protein synthesis[9]) discriminates between these two syntheses. This result is consistent with the postulate that incorporation into the sedimentable protein is mainly by the bacteria, and in further support of this it was shown that 50 μg/ml. chloramphenicol completely inhibited the incorporation of valine-^{14}C by a suspension of the *Rhizobium* sp. from the *Galega officinalis* nodules.

In further experiments nodules were exposed to valine-^{14}C and the water-soluble proteins fractionated by electrophoresis on starch gel[8]. The gel was scanned for hæmoglobin[8] and cut into slices which were dried and monitored for carbon-14. The strip of the gel carrying the hæmoglobin contained between 30 and 47 counts/min. During electrophoresis free valine remained within 5 mm of the

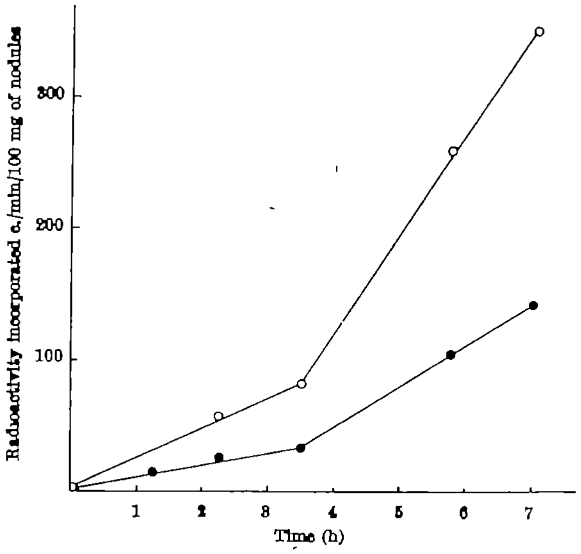

Fig. 1. Time course of incorporation of valine-^{14}C into the water-soluble and sedimentable proteins of intact nodules. The upper curve (open circles) is the incorporation into the sedimentable proteins, the lower curve (solid circles) the incorporation into the water-soluble proteins

Table 1. INHIBITIONS OF INCORPORATION OF AMINO-ACID BY INTACT ROOT NODULES

Inhibitor	Concentration	Counts/min valine-^{14}C incorporated into Water-soluble proteins	Counts/min valine-^{14}C incorporated into Water-insoluble proteins
None	—	34	84
Sodium azide	10^{-4} M	3	7
Sodium arsenite	10^{-4} M	1	2
Potassium cyanide	10^{-3} M	2	8
Chloramphenicol	50 mgm/ml.	32	27

Samples of nodules were fractionated after 3 h exposure to valine-^{14}C, and the results are expressed as counts/min/100 mg of nodules. Individual groups of nodules varied in fresh weight from 78–112 mg.

origin while hæmoglobin moved 70 mm; and electrophoresis of mixtures of valine and hæmoglobin gave a clear separation. These experiments suggest that detached nodules are able to synthesize hæmoglobin.

In the final series of experiments, nodules were crushed in the 0·1 M phosphate buffer pH 7·1 and the resultant homogenate clarified by centrifugation at 15,000*g* for 10 min. The supernatant fluid was carefully pipetted from the residue, supplemented with adenosine triphosphate, magnesium and sodium, then assayed for ability to incorporate valine-^{14}C. After incubation for 3 h the extract was fractionated with ammonium sulphate. The precipitate between 58 and 75 per cent saturation was collected, washed with 75 per cent saturated ammonium sulphate containing valine-^{12}C and then monitored for carbon-14. In a series of four experiments the precipitate contained between 12 and 27 counts/min, and a typical rationale is shown in Table 2. These results suggest that the extracts of the nodules are able to synthesize hæmoglobin. Considering the low specific radioactivity of the valine used even the low level of incorporation observed here indicates that the net synthesis of hæmoglobin under these conditions is considerable.

Table 2. INCORPORATION OF AMINO-ACID BY EXTRACT OF ROOT NODULES

Incorporation system	Counts/min in 58–75% ammonium sulphate precipitate
Complete	12
No adenosine triphosphate	7
Boiled extract	1
Complete + ribonuclease	3

An extract from 1 g of nodules was fractionated after 1 h exposure to valine-^{14}C.

Preliminary examination of this extract by plating samples on a mannitol–yeast extract medium showed that it was free of the *Rhizobium* sp. which inhabits the nodules of *Galega officinalis*. The extract contained amino-acid activating enzymes, soluble ribonucleic acid, ribonucleic acid sedimented by 105,000*g* for 2 h, and probably some mitochondria from the plant tissue.

Further experiments are in progress to extend the generality of these findings to nodules of *Lotus uliginosus* and *Trifolium* spp., and to determine in reconstructed systems the specific roles of bacterial and plant components in nodule hæmoglobin synthesis.

LEVELS OF NITRATE REDUCTASE ACTIVITY IN INBRED LINES AND F_1 HYBRIDS IN MAIZE

By PROF. R. H. HAGEMAN, J. F. ZIESERL and EARL R. LENG

Department of Agronomy, University of Illinois, Urbana, Illinois

THE enzyme nitrate reductase is of major importance in the nitrogen metabolism of maize[1-4]. Evidence from earlier work in our laboratory[1,2] suggested that it may be significantly involved in grain-yielding capacity, and also established[1] that the activity of nitrate reductase is drastically reduced by short-term artificial shading, at the level of 80–90 per cent reduction in incident light. These findings, when considered in connexion with McIlrath and Earley's demonstration[5] that similar shading at a critical period in ear formation greatly reduces grain yield, indicate that nitrate reductase activity-levels may serve as an index of protein-producing potential, which in turn may have an important influence on ear development and grain production.

These observations on nitrate reductase assumed additional significance when considered in relation to investigations of possible physiological bases for heterosis in maize, which were begun in our laboratory in 1954. As originally proposed, the intent was to determine whether the enhanced growth rate of hybrid plants is dependent on quantitatively greater amounts of certain enzymes, or qualitatively greater enzyme efficiency. Initial work[6] with triosephosphate dehydrogenase, extracted from acetone powders of seeds and seedlings, indicated that the hybrid *WF*9 × *M*14 exceeded both its parental inbred lines in the quantity of this enzyme per unit of protein or per gram of dry weight of seed or seedling. The same conclusion was reached for aldolase[6], maltase and amount of mitochondrial fractions[7]. Assay of partially purified triosephosphate dehydrogenase extracts indicated the presence of significantly more enzyme (V_{max}) in the hybrid, but suggested that the enzymes were qualitatively (Km) the same as in the inbreds.

Thus, our work with nitrate reductase logically raised the questions: (*a*) are there genetically controlled differences in nitrate reductase activity in maize; (*b*) are such differences involved in heterotic phenomena? Studies[1,2] conducted in 1958 and 1959 showed that the F_1 hybrid *Hy*2 × *Oh*7 had a higher level of nitrate reductase activity in leaf tissue than did the F_1 hybrid *WF*9 × *C*103. These findings were considered particularly interesting because *Hy*2 × *Oh*7 has repeatedly been shown[8-11] to have significantly higher grain-producing capacity than *WF*9 × *C*103 under high plant populations and other stress conditions. Preliminary studies in 1958 and 1959 indicated that the inbred parents of these hybrids differed in nitrate reductase activity-levels, with *C*103, *Hy*2 and *Oh*7 being approximately equal in nitrate reductase activity but all significantly higher (two-fold) than *WF*9. Insufficient information was available to test the significance of the differences observed.

In 1960 and 1961 more extensive studies were undertaken to evaluate nitrate reductase activity in a number of agronomically desirable inbred lines of maize, and to compare nitrate reductase activity-levels in inbred lines with those of F_1 hybrid progeny. Forty-seven inbred lines were assayed in 1960 and 12 of the same lines were re-tested in 1961. In 1960, the maize was sown on

May 23 and sampled from June 25 to August 24. The 1961 crop was sown June 1 and sampled at weekly intervals from June 28 through August 24. The entire aerial parts of the plants were assayed on the earlier sampling dates (June 27, 1960, and June 28, 1961). Subsequent samples in both years were taken only from the uppermost leaf of each plant chosen.

Four hybrids—the double-cross 'Illinois 1996' (*Hy*2 × *Oh*7) (*B*14 × *C*103) and three F_1 hybrids, *WF*9 × *C*103, *WF*9 × *Oh*7 and *Hy*2 × *Oh*7—were examined in 1960 under conditions comparable with those used for comparisons of the inbred lines. Two of these F_1 hybrids, *Hy*2 × *Oh*7 and *WF*9 × *Oh*7, were examined again in 1961.

Complete details of cultural conditions, sampling techniques and assay methods are being published in other reports[4,12]. Nitrate reductase assays and protein determinations were made according to the methods of Hageman and Flesher[1]. Specific nitrate reductase activity is defined as µm potassium nitrite produced per mg protein per h.

The results (Table 1) clearly indicate the existence of wide differences (up to three-fold) in specific nitrate reductase activity of the various inbred lines tested. Although the 1960 data were taken only from single field plots, without replication, their agreement with replicated data in 1961 for 12 inbred lines was very close (correlation between seasonal means for the two years, $r = +0·84$). Of the 12 lines tested in both years, only two showed significant deviations in specific nitrate reductase activity ranking. One of these inbreds (*R*181) is not considered to be genetically fixed, since it has exhibited considerable phenotypic variability in other characters. The difference in the specific nitrate reductase activity-levels in 1960 and 1961 is attributed to climatological seasonal effects and adds weight to the contention that specific nitrate reductase activity and productivity are closely interrelated. Mean grain yields on comparable university farm plots were 30–40 bushels per acre higher in 1961 than in 1960. The hereditary nature of specific nitrate reductase activity response is evident from the reproducibility of inbred specific nitrate reductase activity, seasonal patterns and relative rankings (Table 1) and from the observed resemblance between inbreds and their F_1 hybrids in specific nitrate reductase activity. Related inbred lines were found[4] to resemble each other in level and seasonal patterns of specific nitrate reductase activity.

Comparisons of seasonal specific nitrate reductase activity patterns (Fig. 1) or seasonal mean values (Table 1) gave no evidence of heterotic effects on specific nitrate reductase activity-levels in the material studied. With the exception of two early samplings in 1960, specific nitrate reductase activity in F_1 hybrids always was found to be intermediate between the specific nitrate reductase activity-levels of the respective parental inbred lines.

Table 1. COMPARISON OF THE NITRATE REDUCTASE ACTIVITY OF TWELVE INBRED LINES OF MAIZE GROWN UNDER FIELD CONDITIONS IN 1960 AND 1961 (Seasonal means)

Inbred or hybrid	Nitrate reductase activity (µm KNO$_2$/mg protein/h) 1960	1961*
*Oh*43	0·16	0·28
*H*49	0·23	0·34
*R*177	0·21	0·34
*WF*9	0·26	0·41
*R*168	0·42	0·55
*A*545	0·35	0·61
*Hy*2	0·35	0·70
*Oh*7	0·51	0·70
*M*14	0·51	0·78
CI.21*E*	0·48	0·82
*R*151	0·58	0·83
*R*181	0·37	0·94
*C*103	0·38	—
*B*14	0·17	—
Illinois 1996 (*Hy*2 × *Oh*7) (*C*103 × *B*14)	0·41	0·64
*Hy*2 × *Oh*7	0·35	0·69
*WF*9 × *Oh*7	0·34	0·49
*WF*9 × *C*103	0·31	0·46

* Duncan's multiple range test (for 1961 inbred data only) requires values of 0·27 and 0·30 for shortest significant range when 2 and 5 to 12 means, respectively, are to be compared.

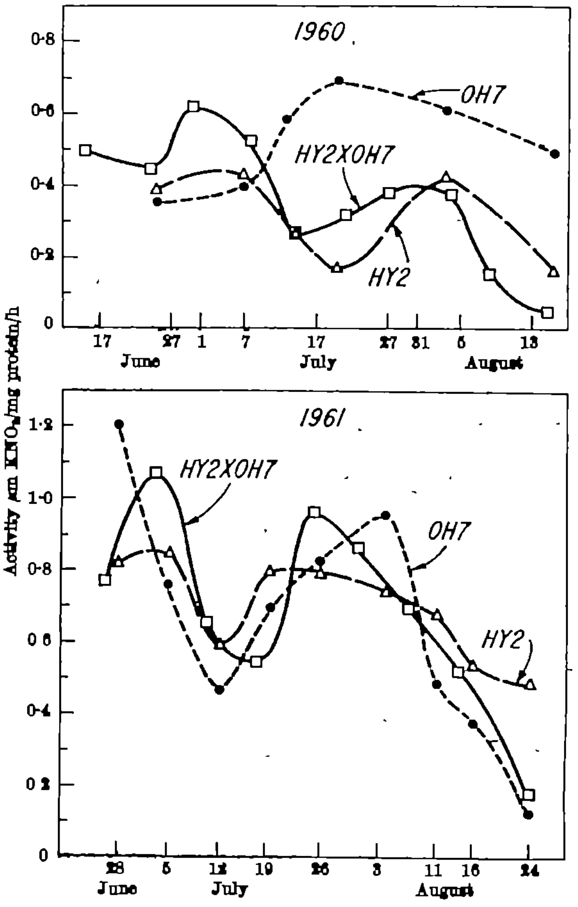

Fig. 1. Comparison of the seasonal pattern of nitrate reductase activity of the F_1 hybrid *Hy*2 × *Oh*7 with that of the parental inbreds in 1960 and 1961

Frequently, the F_1 specific nitrate reductase activity values were more nearly parallel to those of the lower parent inbreds than to those of the higher parent.

Variations in seasonal specific nitrate reductase activity patterns of certain inbred lines and hybrids were apparent when specific nitrate reductase activity values for the different sampling dates were plotted, and also are reflected in a significant (0·05 level) interaction between inbred line specific nitrate reductase activity values and sampling dates. In general, the data indicated that early-season specific nitrate reductase activity-levels were relatively low when whole plants were sampled. The specific nitrate reductase activity values were high for the initial leaf-tissue samples but then declined sharply to minimal levels 42–50 days after sowing, increasing rapidly again to peak activity at flowering time. Activity of the enzyme decreased markedly in all material sampled after flowering had been completed.

The observed early-season low levels of specific nitrate reductase activity almost certainly reflect differences in enzyme activity in the tissues sampled, since whole plants were used in these assays. Nitrate reductase activity is known[13] to be high in leaves and low in stems; thus, the inclusion of variable amounts of stem material in the early samples undoubtedly introduced a bias toward lower specific nitrate reductase activity in these data. With this exception, the observed specific nitrate reductase activity patterns in most inbred lines and hybrids studied closely parallel the cyclic pattern of auxin content in maize plants, reported by Laibach and Meyer[14]. Auxin (indolyl-3-acetic acid) and specific nitrate reductase activity have been shown[9,15] to vary diurnally. This apparent relation between specific nitrate reductase activity and auxin activity is so supported by recent evidence obtained in our laboratory (Beevers, L., unpublished), indicating that specific nitrate reductase activity in maize plants is increased by spray applications of 2,4-D (dichlorophenoxyacetate).

Interesting parallels also were noted between specific nitrate reductase activity seasonal patterns presented in detail elsewhere[12] and established information[16] on time-relationships in development of certain of the inbred lines studied. For example, inbred *M*14, an early-flowering line, showed an earlier date of increase, a more rapid rate of increase, and a slower decline in nitrate reductase activity than most other inbred lines tested. Inbred 38-11, a late-flowering line which has been shown[16] to exhibit an unusually long developmental period between tassel initiation and anthesis, had a high level of specific nitrate reductase activity in 4-week seedlings. This was followed by a sharp decrease in specific nitrate reductase activity and a long lag period before enzyme activity again increased at flowering time. Inbred *K*4, a slow-starting, very late-flowering line under Illinois conditions, showed a different seasonal specific nitrate reductase activity pattern, in that the initially high specific nitrate reductase activity-level declined sharply in early July and showed no return to high levels as the season progressed.

Probably the most significant information to be derived from this work and our previous studies of other enzyme systems is the indication of quantitative differences in enzyme activity between various inbred lines of maize, and between certain inbred lines and their F_1 hybrids. Moreover, our findings with all enzyme systems studied indicate either that the hybrids are intermediate between their parents in enzyme activity-levels (specific nitrate reductase activity) or else that superiority of hybrids over parental lines in enzyme activity resides in the presence of greater amounts of enzymes (triosephosphate dehydrogenase), rather than in the presence of different or more efficient enzyme systems. These findings appear to differ from those of Schwartz[17], who has proposed that heterosis may result from the formation of enzyme dimers or polymers in hybrid plants. Schwartz's work, based on starch-gel column electrophoretic separation of basic proteins, which were identified as esterases by a non-specific histochemical stain, does not indicate the presence of more 'esterase' activity in the hybrid material than in the parent lines.

More extensive and detailed studies are planned to gain information on the genetic control of nitrate reductase activity in maize, and to determine more specifically the role of this enzyme activity in conditioning grain-yielding ability in the crop. It would appear that such investigations, as well as similar work with other enzymes or enzyme systems, might also be expected to yield valuable information on possible physiological bases for heterosis in maize hybrids.

PHOTOKINETIC FUNCTION OF APHID ANTENNÆ

By C. O. BOOTH

Agricultural Research Council, Unit of Insect Physiology, Entomological Field Station, 34A Storey's Way, Cambridge

JOHNSON[1] reported that alate alienicolæ of *Aphis fabae* Scop. deprived of their antennæ could not be stimulated to fly as readily as intact aphids, when both were denied a foothold. Nevertheless, because the antennaless aphids took off from an unspecified surface as readily as intact ones, he inferred that aphid antennæ did not have the kinetic function shown by Wigglesworth and Gillett[2] for the antennæ of another hemipteran, *Rhodnius prolixus* Stål. He concluded that aphid antennæ served instead to control flight, on the grounds that, on take-off, the aphids failed to fly up out of the black-walled lower part of an open-topped box toward the light, unless their own, or an artificial, antennal flagellum was attached to the third antennal segment and freely movable so as to stimulate Johnston's organ in the second segment.

When aphids of the same form of the same species were deprived of their antennæ and released under the illuminated central roof window of a large black-walled flight chamber[3], they flew without any apparent loss of control. But, instead of flying persistently up toward the central light like intact aphids, they flew away almost immediately toward the dark walls or dark peripheral roof. This photonegative behaviour would have looked like uncontrolled flight if observed at the bottom of a box when photopositive behaviour was expected. In fact it resembled the behaviour of intact aphids after a long flight, when locomotor excitability is low[3]. Thus it seemed that the antennæ might have a kinetic function and experiments were undertaken to test this hypothesis by the simpler method of measuring the readiness of fresh *A. fabae* alatæ to take off from a host leaf, after various treatments of the antennæ. The hypothetical kinetic effect could very well depend on mechanical stimulation of the antennæ, as suspected in *Rhodnius*. But in view of the very pronounced photokinetic responsiveness of fresh winged aphids it was decided to examine first the possibility that the antennæ might contribute to that, as auxiliary light-sensitive organs.

The aphids for these tests were collected singly with a fine camel-hair brush as soon as they took off for the first time from their rearing plants and landed on a glass plate standing 45 cm away, in front of two 40-W, 2-ft. *MCF/U* fluorescent tubes. Each aphid was placed at once on filter paper in the bottom of a metal dish embedded in ice, which kept the aphid immobilized while both its antennæ were treated in one of the following ways:

(*A*) *Brushed*, left intact but stroked gently with the brush for about 45 sec, the period needed for the other treatments.

(*B*) *Clear-coated* from the tip of the last to the base of the third segment with a film of cod liver oil, by sleeving several times inside the tip of glass capillary containing the oil.

(*C*) *Clear-coated, weighted.* Since the black coating (*D*) was somewhat heavier than the clear coating (*B*), this treatment, giving a clear coating that was heavier than

D, was also included, using the same oil thickened to a 'sludge' with 'Vaseline' and applied in the same way.

(*D*) *Black-coated*, exactly as for *B* except that the oil now contained a dense suspension of pure carbon black.

(*E*) *Amputated* with fine-pointed forceps somewhere along the third segment. Treatments *B*, *C* and *D* were arrived at after many trials of other materials applied by brush or capillary, none of which gave such easy, controllable, uniform and apparently harmless cover without subsequent loss of mobility of the antennæ.

Immediately after its treatment each aphid was transferred with the brush to the upper surface of a fully expanded leaf of *Vicia faba* with the cut petiole in water. This was exposed to the same light intensity as the rearing plants, from another ventilated *MCF/U* lamp 25 cm away behind an upright sheet of 'Perspex'. The aphid promptly resumed activity on the leaf and the time elapsing before it took off toward the light was recorded. It was re-collected as it alighted on the 'Perspex' and replaced on the leaf, and this was repeated until it had taken off five times or had settled down on the leaf for 1 h or more. The collection, treatment and testing were all carried out in the same dark room kept at about 15° C.

Table 1 shows that the aphids with intact (*A*) or clear-coated (*B*) antennæ invariably took off in less than 6 min and frequently in less than 1 min; and the aphids with heavily weighted antennæ (*C*) were almost equally quick to take off. But a large majority of the take-offs by the aphids with black-coated (*D*) antennæ were delayed more than 6 min. The time to take off was very erratic in this lot *D*, but every individual stayed for more than 15 min before at least one of its take-offs, whereas none of the individuals in the control lots *A*, *B* and *C* ever did so. Table 1 in fact underestimates the arresting effect of blackening the antennæ. Only 73 instead of the intended 100 take-offs could be timed after this treatment because twelve of the aphids settled down on their leaves for 1–4 h and had to be abandoned before they had been given five tests. Amputation of most of the antennal flagella (*E*) also delayed taking off clearly but erratically, although not so much as the black coating did.

These results were confirmed when the experiment was repeated with 25 aphids per treatment and some technical improvements. The temperature was raised to 24° C to prevent over-long settling. Amputation was made more thorough and uniform by removal of the entire third antennal segment in every case. A major uncontrolled variable in the first experiment was the handling of the aphids with the brush, which sometimes produced struggling and speedy take-off. With more care and much practice this effect was virtually eliminated. The result was to unify the behaviour of the aphids with black-coated and amputated antennæ, and to bring out a clear difference between them and the three control lots at the first take-off, as seen in Table 2.

Table 1. PERCENTAGE FREQUENCY DISTRIBUTION OF TIMES TO TAKE-OFF FROM A HOST LEAF AFTER VARIOUS TREATMENTS OF THE ANTENNÆ

Antennal treatment	Aphids treated	Total take-offs timed	Time to take-off: 0–59″	1′–2′59″	3′–5′59″	6′–11′59″	12′–23′59″	24′–47′59″	48′–
(*A*) Brushed	20	100	46	42	12	0	0	0	0
(*B*) Clear-coated	20	100	38	48	14	0	0	0	0
(*C*) Clear-coated, weighted	15	72	38	45	15	1	0	0	0
(*D*) Black-coated	20	73	1	9	19	11	15	12	31
(*E*) Amputated	15	64	11	18	22	9	16	6	17

Table 2. FREQUENCY DISTRIBUTION OF TIMES TO FIRST TAKE-OFF FROM A HOST LEAF AFTER VARIOUS TREATMENTS OF THE ANTENNÆ (Second experiment)

Antennal treatment	Time to take off: 0 – 59′	1′ – 2′ 59″	3′ – 5′ 59″	6′ – 11′ 59″	12′ – 23′ 59″	24′ – 47′ 59″	48′ –
(*A*) Brushed	12	8	2	4	3	0	0
(*B*) Clear-coated	7	9	4	5	0	0	0
(*C*) Clear-coated, weighted	2	14	4	3	2	0	0
(*D*) Black-coated	1	0	3	0	5	7	9
(*E*) Amputated	1	1	1	1	4	12	5

That the akinetic effect of the coating of carbon black in cod liver oil was not peculiar to this mixture was evident from preliminary experiments in which a clear watery paste of 'Polycell' (a mixture of water-soluble cellulose ethers) was used in place of cod liver oil, and indian ink in place of pure carbon black. These coatings were physically less satisfactory but the results were the same: aphids with black-coated antennæ were slower to take off than aphids with clear-coated or intact antennæ.

It seems difficult to avoid the conclusion that the antennæ of these aphids bear photoreceptors of some kind which function as 'stimulatory organs'[3] (and perhaps in other ways also). The third and fourth segments of the antennæ of winged (but not wingless) aphids bear numerous placoid sensilla, once dubbed 'rhinaria' from their presumed olfactory function[4]. Slifer and Sekhon[5] could find no morphological support for the presumed olfactory function of similar sensilla on the antennal flagellum of the honey-bee and, among other possibilities, suggested, 'improbable as it may seem', that these organs might be sensitive to light. The aphids' photokinetic response certainly does not depend on the antennæ alone. The flight-delaying effect of darkening or removing the antennæ was readily counteracted by increasing the light intensity, as well as by other types of kinetic stimulation.

I thank Dr. J. S. Kennedy for his encouragement during the course of this work and his help in the presentation of the results.

NON-ENZYMATIC BROWNING REACTIONS: CONSIDERATION OF SUGAR STABILITY

By H. S. BURTON and D. J. McWEENY

Food Science and Plant Health Division, Ministry of Agriculture, Fisheries and Food, London, S.W.1

THE properties of the aldose sugars have proved intriguing and in the absence of full conformational data it is difficult to predict fully their behaviour.

In a recent study, Burton, McWeeny and Biltcliffe[1] showed that the addition of sulphites modified the reaction sequences in glucose/glycine solutions. This work showed that sulphite produced a more pronounced retardation in chromophore development when added initially (at $t = 0$) than when added at a later stage. Similar experiments to determine whether mannose would produce a chromophore more rapidly than glucose in aqueous solutions 1·0–2·5 M with respect to glucose and 1·0–1·5 M with respect to glycine showed that if the glucose in the system described in our previous publication was replaced in whole or in part by mannose, then the development of chromophores proceeded at a faster rate, and one which increased with increasing mannose content.

Thus we found that mannose gives chromophoric material at a faster rate than glucose, and at first we were inclined to believe that this was due to the *cis* hydroxyls on C_2 and C_3. A comparison showed that galactose reacted with amino-acids at a much greater rate than did mannose, with a more rapid production of unsaturated compounds prior to chromophore development. The aldose/glycine reaction appeared to depend initially on the conformational stability of the aldose molecule as a whole. On this basis one would expect the pentoses to be less stable than the hexoses, and it was apparent both from our own results and those of others that the aldopentoses reacted with glycine and amino compounds more rapidly than did aldohexoses to give chromophores.

A search of the literature revealed that on the question of sugar stability, Cantor and Peniston[2] found by polarographic studies that the wave-heights obtained in the aldohexose series were in the ascending order glucose, mannose and galactose, thus paralleling our observed rate of initial chromophore development, and that there appeared to be a correlation both with mutarotation velocity and the quantity of supposedly free aldehydic sugars as found by the cyanide addition experiments of Lippich[3].

Moreover, in the pentose series much greater polarographic wave-heights were recorded, and, unlike the hexoses, no pentose showed linear increase of current with increasing *p*H, at any concentration.

Wiesner[4] claimed that the height of the wave depended on the rate of non-reducible aldose–reducible aldose reaction. Delahay and Strassner[5] confirmed that the wave-heights were in the order: arabinose–xylose–galactose–mannose–glucose and stated that in aldoses the bond between the oxygen and hydrogen of the hydroxyl attached to carbon C_1 is slightly ionic. Consequently, the bond-strength is weakened as *p*H increases. Likewise, the rate of ring sugar aldehyde transformation increases rapidly with *p*H.

Tobi[6] found that whereas the aldoses gave no colour with Schiff's reagent, they did so provided that the sulphur dioxide level was sufficiently reduced, and Stepachenko[7], following up this work, found that the degree of colour obtained from hexoses was in the ascending order: glucose, mannose, galactose. The pentoses gave stronger colours than the hexoses and the order of colour there was arabinose, xylose, both pentoses giving stronger colours than the hexoses. The Tobi–Schiff's colour obtained varied in a notable way with concentration, being markedly greater with increasing aldose concentration. The reason given for this was that in dilute solution any free aldose form would be markedly hydrated. A consideration of the figures published by Downer[8] and by Ingram[9], in which the quantity of sulphur dioxide bound in a non-iodine-titratable, Monier–Williams recoverable manner were determined, leads us to believe that the same factor may be involved.

This effect of concentration appears to be significant in another way, for Lewin[10] has found that whereas some products of sugar/amino reactions are common to both dilute and concentrated solutions, a number of ninhydrin positive compounds are found only in highly concentrated solutions, while Leuck[11] claimed that sulphur dioxide could assist in the self-polymerization of glucose in the dry state.

Considering the sugars on the basis of Stewart models, it appeared that the stability of the sugars in the pyranose form depended on the degree of electronic balance between the two halves of the sugar, and on this consideration the sugars would be expected to have the order of stability as surmised from Lippich's 'instantaneous cyanide' addition, Cantor's polarographic current measurements, and the degree of Tobi–Schiff colour obtained.

We have now found that the same order holds true for initial colour development in aldose/amino-acid systems[12] and in those of the aldose/amino and aldose/organic-acid systems which we have examined, over the range 0·2–2·5 M, and it appears therefore that one factor in the speed of development of initial chromophores is the actual conformational stability of the sugar.

In the presence of sulphur dioxide or sulphites, the initial staes in colour development are markedly retarded in all these cases.

The effect of phosphates is to decrease the initial stability of the aldose sugar. In the presence of phosphates the polarographic wave height is increased, and both we and others (cf. Ellis[13]) have found that the rate of initial colour development is increased as a result for aldose/amino reactions in solution. This effect of phosphate did not occur in parallel lecithin/amino browning reactions (Burton and McWeeny, to be published), phosphate showing a very slight retarding action in this system, which is significant.

The role of ketose sugars in non-enzymatic browning has been largely obscured by the fact that aldoses are regarded as the main reducing sugars, and the ease of measurement of the latter has led to attempted correlation between the reducing sugar figures and browning observed. Ketoses in general give greater polarographic waves than the corresponding aldoses and in browning caused by ketose/amino reactions the initial chromophoric development is greater than for aldoses. The same is true for the rate of initial browning of ketoses as compared with aldoses in the presence of organic acids even in the solid state. In both cases sulphur dioxide has an early retardative effect on browning. We think that the later development of the more highly coloured products which sometimes appear in the case of the aldoses may be related to the character of the intermediates produced.

In general, one may say that the observed order of initial chromophore development in aldose/amino-acid systems follows the pattern shown by the polarographic results. Colour development increases rapidly above *p*H 7, but is much reduced with increasing acidity, at least down to *p*H 4. Ribose appears to have some special interest. Cantor found that ribose gave a *p*H minimum at around *p*H 6·8. In aldose/amino reactions, we have found ribose to be much less stable than xylose at concentrations 0·2–2·5 M, which is what one would expect, Stepachenko and Cantor results giving xylose the most stable character among the pentoses. In arsenate buffer a corresponding *p*H minimum effect for initial colour development was observed for the ribose/glycine reaction at 0·2–0·5 M concentration. In phosphate buffer, although a similar *p*H minimum effect was observed, the degree of initial coloration appeared to be reversed, discoloration occurring more rapidly at *p*H 6 than at 7·4. It is noticeable that ribose itself was originally held to be responsible for browning reactions in fish muscle, though now it is thought that ribose- and hexose-phosphates are responsible[14].

That the stability of the sugar present in natural products has a marked effect in the development of chromophores is indicated by the fact that when reducing sugars are removed by fermentation and replaced by glucose, brown colours take longer to develop. Under these conditions, too, replacement of the aldose sugar with fructose has been found to cause more rapid colour development than with glucose[15].

Later browning may well depend on a number of factors, but here again the initial hydroxyl configuration of the sugar seems to be of importance in some browning reactions. The speed of dehydration and the intermediates and complexes which form will naturally depend to some extent on this factor.

Anet[16] isolated the *cis* and *trans* forms of 3,4 dideoxy 3,4 unsaturated hexosone from aldose/glycine systems. The *cis* form dehydrates very easily, the reaction in 0·03 N acetic acid being half completed in 12 min. The *trans* form gives a half reaction time of 8 h, the same as for 3-deoxy-D-erythrohexosone. It would appear that 3-deoxy-D-threohexosone gives a very much greater yield of the *cis* unsaturated hexosone since a comparison of the rate of formation of hydroxymethylfurfural in 2 N acetic acid at 100° C showed that 3-deoxy-D-erythrohexosone (formed from glucose via di-D-fructose glycine) gave a 45 per cent yield in 2 h whereas the *threo* isomer (formed from galactose via di-D-tagatose glycine) gave an 80 per cent yield.

Thus the initial configuration of the aldose has an important bearing on the rate of production of potential chromophore-developing compounds.

We thank Mr. J. F. Hearne of this Department for initiating the project of which the work reported here is a part. The project is financed under U.S. Public Law 480 and under the auspices of U.S. Department of Agriculture.

IMMUNOLOGICAL ASPECTS OF PARASITISM

By DR. J. K. DINEEN

C.S.I.R.O., Division of Animal Health, McMaster Laboratory, Glebe, New South Wales

DURING evolution of many host/parasite relationships an intimate association of the parasitic species is developed with the host. In these cases survival of the parasitic species is largely dependent on persistence within, and as a consequence, tolerance by, the host. For this type of relationship, where survival of the parasitic species is dependent on a long-term, intra-mural association with the host, the immunological response of the host should not be regarded simply as a mechanism which may cause elimination of the parasitic infection, but rather as an environment which has a profound effect on evolution of the host/parasite relationship.

The role of the immunological environment in the partially immune host population as an intense selective pressure for antigenic variants of bacteria and viruses has been suggested by many workers. Burnet[1] termed this process in nature "immunological drift" and the proposed natural phenomenon is strongly supported by laboratory observations. In particular, studies on the selection of antigenic variants of the apparently highly-mutable influenza virus in the presence of immune sera in eggs and in partially immune mice are well documented (for review, see Edney[2]). Laboratory studies on the immunological selection of bacterial variants are also sufficiently well known as to require no further elaboration. The epizootic spread of a bacterial or virus infection may occur when the invading organism can multiply in individuals of the host population to transmissible levels before each member of the population can in turn elaborate an effective immunological response. When, however, a significant proportion of the surviving host population has elaborated an immune response this immunity may limit further spread of the epidemic strain of bacterium or virus and favour antigenic variants. It is important to note, however, that in this situation where the immune response is effective retrospectively in individuals of the host population, then any random mutation of antigenic characters associated with the stimulation of resistance will favour survival of the pathogenic organism.

With the metazoan endoparasite, however, it is necessary for the organism to reside in intimate contact with the host until termination of the reproductive phase of its life-cycle, that is, usually for a period extending beyond the minimum time required for the host to express an effective immune response. In this situation, where survival of the host/parasite relationship depends on persistence of the parasite within individual members of the host population for immunologically significant periods, the selective pressure provided by the contemporary immune response is likely to be more precise and may favour the survival of only those variants of the metazoan parasite which display a sufficiently reduced antigenic disparity with the host.

This process of immunological selection of genetic variants whereby a parasite may become less antigenically foreign to the host may be based on either simple loss of an appropriate antigenic character, or on acquisition of the antigenic character of the host, or on both.

The concept that there is a minimum or threshold level of antigenic information necessary for stimulation of an immunological response is both implicit in present theories on the mechanism of the immune response and compatible with observations on the nature of immunity. The factors which may determine the mean threshold level in any host/parasite relationship are: (1) the degree of antigenic disparity between host and parasite; (2) the rate of flow of antigenic information.

Potentially the degree of antigenic disparity may be dependent on evolutionary selection of genetic components of both host and parasite. Assuming the same rate of genetic mutation of host and parasite, it is likely that the relative fecundity of the interactants will play a major part in determining the contribution each may make to the evolution of this antigenic aspect of the relationship. As the fecundity of the parasite is much greater (and generation time is usually shorter) than that of the host, the component of antigenic disparity which may be due to the rate of genetic change of the antigenic character of the host population is likely to be unimportant. If, then, the threshold level for antigenic stimulation of an effective immunological response shows no great systematic drift during evolution of the relationship, antigenic disparity and flow rate should be inversely related. As flow rate is determined by the size of the parasitic burden it follows that reduction of antigenic disparity will result in subliminal tolerance of an increased population of the parasite. The term 'subliminal tolerance' is used here to describe a state of relative immunological unresponsiveness. However, the threshold level of antigenic information is, by definition, sensitizing, and consequently one may anticipate that the host will develop an acquired resistance to additional worm infections. Indeed, the 'self-cure' phenomenon[3] which is observed under field conditions in some host/parasite relationships may be due to exaggerated expression of an immunological response in a presensitized host. This response may be viewed as the extreme case of the general phenomenon postulated here. If the sensitized host is suddenly confronted by a relatively large parasitic infection then a gross antigenic insult beyond the threshold level of the immunological system may be provided. Some, or all, of both the incoming and established parasites are then eliminated. After an appropriate interval of time one might expect that the original threshold level will again prevail, and the subliminal worm burden acquired once more during subsequent grazing on infested pastures.

These theories regarding immunological aspects of parasitism are an extension of those advanced to explain some of the phenomena of transplantation immunity. The antigenic relationship between implanted tissue and host is a crucial factor which determines the nature of the homograft response. The greater the degree of histo-incompatibility between donor and host, the more vigorous is the immunological response developed following transplantation. When antigenic disparity is reduced to a minimum as, for example, in the case of tissue transfer between individuals of co-isogenic strains of mice, or when sex-linked histo-incompatibility provides the only basis for immunological rejection of tissues transplanted between individuals of the same homozygous strain, then prolonged survival of the tissue implants is observed. In a discussion of the nature of the homograft response when 'near compatibility' of host and donor is obtained, Woodruff[4] quotes the report of Longmire, Stone, Daniel and Goon[5], who observed the prolonged survival of a skin homograft on a human patient. A second graft obtained from the same donor was completely destroyed within 15 days, and only then, 6 weeks after grafting, did the first graft show signs of reaction. Apparently the immune response of the host was sensitized by the first graft and the 'subliminal' status of this graft was then disturbed by the excess antigenic stimulus provided by the second graft. Similarly, Dineen and Szenberg[6,7] have observed subliminal regeneration of donor epithelial elements in skin homotransplants following the acute phase of the homograft response. They observed that regeneration was not completed as normal hair did not occur in the regenerating tissues. It seems likely, therefore, that the regenerating epithelial cells were brought under immunological control at this stage because the threshold level of antigenic information had again been reached.

If evolution of the host/parasite relationship is characterized by subliminal tolerance of parasite burdens of increasing magnitude then it seems likely that such a trend could only occur if there were, at the same time, selection for attenuation of pathogenicity of the parasite. During this evolutionary process pathogenic activities of the parasite may reach the irreducible minimum due to competition of the parasite with its host for factors which satisfy common physiological and nutritional requirements, and effects which are related but incidental to these factors, for example, anaemia, where the oxygen requirements of the parasite (hookworm, *Ancylostoma caninum*) or the nutritional requirements (*Haemonchus contortus*) are satisfied by blood-sucking. It is important to stress that the evolutionary trend towards reduction of antigenic disparity and attenuation of pathogenesis relate to the population dynamics of parasitism. Great variation about the mean population response to parasitic infections will be observed in individual hosts under field conditions. As the host population is not homozygous for antigenic character, variations in degree of antigenic disparity will be observed among individual relationships between host and parasite. Thus the parasite burdens supported by individual members of the host population will vary greatly in magnitude, and their pathogenic effects may be expected to range from subclinical to lethal. Evolutionary attenuation of pathogenicity is expected to be associated with an increase in the mean worm burden of a host population. Those members of the host population which show extreme levels of antigenic disparity with the parasite may only support a parasite burden so small that the effects of infection are subclinical. In these individuals a state of immunity or premunition, depending on the persistence of a latent infection, is established.

The role of the immunological response as an environment for selection of genetic variants during evolution of the host/parasite relationship is the central theme of this discussion. As a result of this process it is postulated that many antigenic characters of the parasite which stimulate the immune mechanism of the host species are modified during evolution of the relationship. However, one must bear in mind that immunological selection will only affect those antigenic characters which stimulate responses influencing the survival or, in the precise evolutionary sense, 'fitness' of the parasitic species. Many characters, though antigenic, are, in this sense, immunologically impotent and therefore irrelevant to immunological aspects of the host/parasite relationship. Consequently, there will be no immunological selective pressure for modification of such characters which are likely, therefore, to remain highly antigenic notwithstanding evolution of the relationship. Circumstantial support for this argument is provided by the frequently reported failure to observe a correlation between humoral antibody and resistance to infection in many parasitic infections.

So long as infection with the parasite is potentially able to produce significant pathogenic effects then survival of the relationship will be favoured by some degree of relevant antigenic disparity. The effect of such disparity will be to confine pathogenicity within tolerable limits by control of the size of parasitic burdens. It is concluded, therefore, that the role of the immunological response in the 'adapted' host/parasite relationship is to control the parasitic burden rather than to cause complete elimination of the infection. A rational approach to the problem of prophylactic immunization in, for example, helminth diseases of domestic livestock, may be formulated on this basis. Accepting that the immunological response in the evolved host/parasite relationship may only limit the magnitude of the parasite burden, then the most appropriate approach to immunization is first to determine whether the worm burden subliminally tolerated to the primary threshold level of antigenic information is greater than the burden tolerated at the secondary, presensitized level. If a difference is found and this is significant in terms of pathogenic effect, then the aim of vaccination should be to modify the relationship in a manner such that: (1) the first natural infection will be associated with the smaller worm burden permitted by the immunological response of the sensitized host, while (2) the pathogenic effects usually observed when young animals are exposed for the first time to dense larval populations on pasture are avoided.

A similar view was recently expressed by Taylor[8] in a discussion of worm control in ruminants by pasture management.

TURN-OVER AND DISTRIBUTION OF WATER IN DESERT CAMELS, SHEEP, CATTLE AND KANGAROOS

By Dr. W. V. MacFARLANE, R. J. H. MORRIS and BETH HOWARD
Department of Physiology, Australian National University, Canberra

THE desert hardiness of the camel has impressed and intrigued observers for more than 2,300 years[1]. Schmidt-Nielsen[2] and Gauthier-Pilters[3] have examined many aspects of the water handling of these ruminants; but the mechanism of resistance to dehydration, particularly the part taken by alimentary water reserves under hot conditions, is difficult to measure and had been an elusive problem. We have estimated water content and water turn-over using tritium oxide in *Camelus dromedarius* and compared them with *Bos taurus* (Shorthorn) and *Macropus rufus* (red kangaroo) at Alice Springs, Central Australia, in further efforts to determine the dynamics of dehydration. These findings were compared with those on tropical Merino sheep studied earlier in similar conditions[4].

In late summer, air temperatures reached 45° C and daily maxima averaged 41° C with wet-bulb maximum temperatures between 20° and 25° C. Adult camels at large on the almost bare gibbous plain fed mainly on trees (*Acacia* and *Casuarina*). Those deprived of water were offered lucerne hay. The animals were weighed daily and body-water distribution was determined on 7 camels by *T* 1824 for plasma, thiocyanide space (SCN) for extracellular and $^{3}H_2O$ for total body-water. Tritium equilibration requires 8 h or more in camels. Measurements were made also on 4 Shorthorn cattle living on the same territory as the camels at the end of 4 years drought, and on 4 red kangaroos in an enclosure, partly sheltered from the sun.

Among the camels feeding at large, water content ranged from 650 to 755 ml./kg. The non-lactating adult females were used in sweat and urine estimations and were watered each second day. Their water turn-over in the heat was about half that of Merino sheep[4] and one-third that of Shorthorn cattle (Fig. 1). The shaded kangaroos turned over 88 ml./kg/24 h, 44 per cent more water than camels in the sun. Lactating camels with calves 1 year old used 82–104 ml./kg/24 h; but this amount was still less than that used by non-lactating sheep (100–130 ml./kg/24 h). The camel conserves water by economical sweating for evaporative cooling (up to 280 ml./m²/h) which wastes less energy and water than the more expensive respiratory cooling of sheep. Camel sweat contains four times more potassium than sodium and is high in bicarbonate, which results in a sweat pH of 8·2–8·5. Sheep sweat is similar except that concentration of potassium is up to 20 times greater than sodium[5]; but the camel sweats a ten-times greater volume per unit area at 40° C than the Merino. Sweat is produced under the influence of adrenaline injected locally or intravenously in camels, as in sheep and cattle, but noradrenaline is inactive on sweat glands. Camels also pass small volumes or urine when on dry feed (2–3 ml./kg/24 h compared with 8–10 ml./kg/24 h in sheep) but the highest camel urine osmolality observed is 3·17 osmols/l. compared with the 3·8 osmols/l. found in dehydrated sheep[6]. Vasopressin

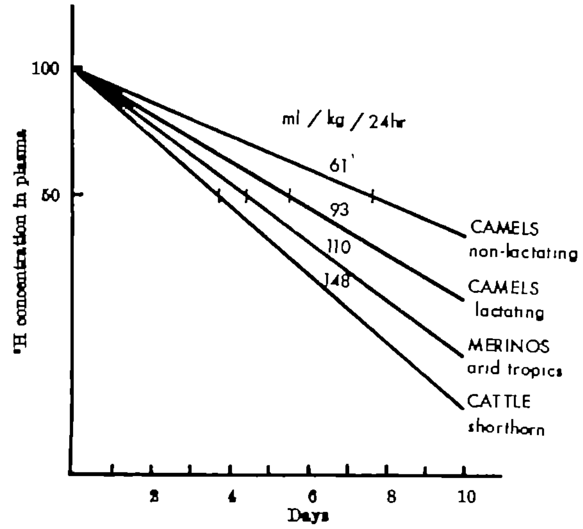

Fig. 1. Tritium oxide turn-over in grazing ruminants exposed during summer to average maximum daily temperatures of 41° C. The sheep were at lat. 21° S. and the other animals at 24° S. Two of the camels were lactating, but none of the other animals was giving milk. Ingested water, food and metabolic water are integrated by this method. Cattle used more than twice as much water daily as camels of the same weight

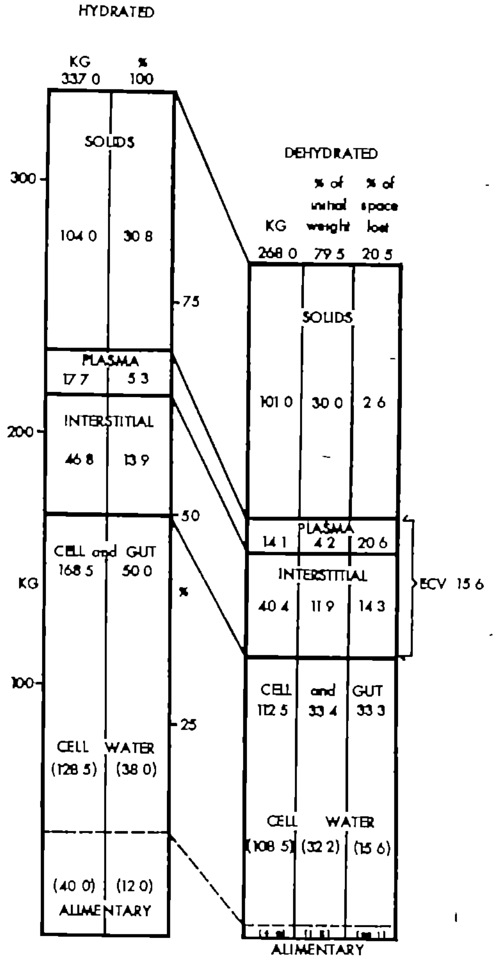

Fig. 2. Average body composition of 3 adult camels before and after 9 days without water in the sun at Alice Springs, with daily maxima of 41° C. The loss of extracellular water was less proportionally than the 20 5 per cent weight loss, but alimentary and cell water fell by 33 3 per cent. It was estimated that the alimentary tract yielded more than 50 per cent of the water

in a dose of 2 mU./kg/h intravenously increases the excretion of water and electrolytes in camels, as in sheep[7] so that the low urine flow of camels is as yet unexplained.

When deprived of water in the sun at mean maximum temperatures of 41° C (Table 1) three camels lost weight at rates of only 19–23 g/kg/24 h because of small losses of sweat, urine, respiratory and fæcal water[3], and lowered metabolism. This was half the rate of weight change observed in Merinos at the same temperature. The differential loss of fluids is, however, a point of great interest (Fig. 2). Whereas the average body-weight of camels fell by 20·5 per cent in 9 days, the SCN space was reduced by only 15·6 per cent. Of the weight lost the interstitial fluid yielded 9·3 per cent and the plasma 5·2 per cent. The cells and gut contributed water to the extent of 81·2 per cent of the loss in weight, in contrast with Merino sheep, which provided only 46·2 per cent of the weight lost as water from these sources, in similar environmental circumstances[4]. Measurements on sheep[4] indicate that differential losses of water occur between spaces and that at relatively slow rates of water loss (30 ml./kg/24 h) the sheep depletes the interstitial fluid faster than plasma, but during rapid dehydration relatively more water is drawn from the cell and gut space. In camels the slow rate of loss in weight during exposure to high temperature (41° C) allows adjustments of fluid spaces which resemble those of sheep at lower temperatures (32° C).

	Camels*	Merino sheep*
Days without water mean max. temp. 41° C.	9	5
Rate of dehydration, ml./kg/24 h	22	47
Weight lost (% body-weight)	20·3	23·5
% from SCN space	14·5	50·4
% from cells and gut	81·2	46·4

* Mean of 3 in each case

The question of whether the cells and alimentary fluids share equally in providing water is hard to answer directly because gut water is not readily estimated. It is known, however, that in camels rumen contents may comprise an average of 110 g/kg (ref. 7) and the alimentary tract may hold up to 180 g/kg, of which more than 80 per cent is water. During dehydration the passage of gut fluids was reduced to about 5 per cent of the initial flow in a fistulated camel studied by Stepankina and Tashenov[8]. The abdomen also of a dehydrated camel has a highly concave contour, as though little contents remain in the gut. These observations suggest that the alimentary tract may provide much of the water lost.

If it be assumed that the camel begins dehydration with 120 g water/kg in the alimentary tract and that at the end of 9 days without water there is approximate osmotic equilibrium between cells and interstitial fluid, it would then be likely that 52·2 per cent of the weight lost was provided by the gut fluids and 29 per cent by cell water, if both extracellular and cellular water spaces fell by 15·6 per cent. In this sense, the alimentary reserve would not be pure water but a more or less isotonic solution. By using the water component of gut fluids for cooling, and by excreting electrolytes in urine and sweat, the circulating volume would be preserved. In man and sheep the extracellular water takes most of the strain of rapid dehydration, and circulation is likely to be correspondingly unstable, so that men in the sun without water at 41° C succumb in 1–2 days, and tropical Merino sheep in 6 days after losing half the extracellular fluid. Camels survive probably more than 15 days in such conditions while sustaining, like sheep, over 30 per cent of loss of body-weight.

No major difference between the electrophoretic and ultracentrifuge pictures of sheep and camel plasmas was found, so that the differential fluid losses from extracellular and alimentary compartments appear to result from peculiarities of permeability of vascular and intestinal membranes, and the rate of dehydration modifies the amount of transfer from the different compartments.

We thank Prof. K. Schmidt-Nielsen for making it possible to undertake these measurements as part of investigations supported by grant No. G–17619 from the U.S. National Science Foundation. The Northern Territory Administration, Animal Industry Division (Mr. J. Whittem and Mr. A. Newsome) kindly made animals and laboratory space available.

A DIFFERENCE BETWEEN REAL AND APPARENT VISUAL MOVEMENT

By PAUL A. KOLERS

Center for Cognitive Studies, Harvard University

A NUMBER of workers have confirmed the fact that detectability of the first of two briefly presented flashes of light varies inversely with the luminance of the second and the temporal separation between them. The results of many experiments on this topic have recently been summarized[1]. Extending these investigations on asynchronous stationary visual stimuli to the case of a moving masking stimulus has produced complementary data[2]. The results in the latter case were that the detectability of a brief fixed target stimulus flashed in the path of a moving line varied with the luminance and position of the latter. The brighter the moving line and the closer it was to the target, the less detectable was the latter.

These results provide the opportunity to investigate some properties of a related kind of visual perception, that of apparent (beta) movement. This illusion of movement occurs when two neighbouring stimulus objects of proper luminance are alternated in place at an appropriate rate. When two lines such as *A* and *B* of Fig. 1 are presented, each for 50 msec and a proper pause intervenes between the offset of each and the onset of the other, the observer sees a single line moving smoothly and continuously between *A* and *B*. The perception is referred to as 'optimal movement'[3]. The apparent movement of the line is a compelling illusion; and many investigators have reported that, for given rates of apparent displacement, the perceptions of real and apparent movement are indistinguishable one from the other. Since a number of these authors have been led by the phenomenal identity of the two perceptions to infer that the underlying mechanisms are similarly identical, the question arises whether a line in apparent movement will affect detectability of a target in the way described here for real movement.

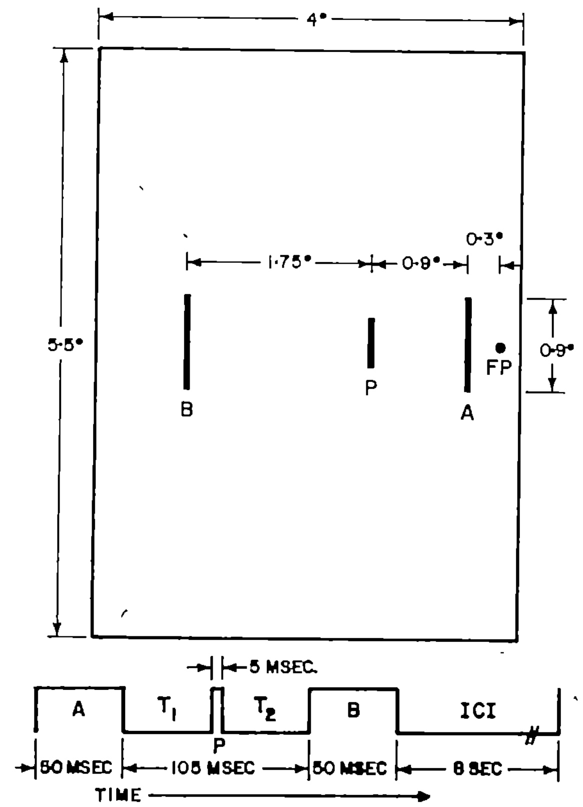

Fig. 1. Spatial arrangement of the alternated forms. *A* and *B* are the termini of apparent movement; *P*, the target or probe flashed in the path of movement; *FP*, the fixation point. The time diagram shows one sequence of presentations

To answer the question, it is necessary to specify the 'position' of the line in apparent movement during its traverse. This was done by fractionating the temporal interval between *A* and *B* that yielded optimal movement, and presenting the small line *P* for 5 msec at various times between the offset of *A* and the onset of *B*. One sequence of presentations is shown in the time diagram of Fig. 1. Let T_1 be the time between the offset of *A* and the onset of *P*, and T_2 the time between the offset of *P* and the onset of *B*. In the experiments, the sum of $(T_1 + P + T_2)$ was 105 msec, while the particular values of T_1 and T_2 were varied. For example, when T_1 was 5 msec, T_2 was 95 msec; when T_1 was 25 msec, T_2 was 75 msec; and so on. In this way, the 5 msec long *P* was made to appear when the line seen as moving between *A* and *B* had proceeded through various portions of its path.

The luminance of the lines *A* and *B* was 3 foot-Lamberts, while the luminance of *P* varied from 0·09 to 0·3 foot-Lamberts for each of three subjects. The latter value was established by finding for each subject the luminance of *P* when it was presented alone that enabled him to detect it with probability of 0·90+. The stimuli appeared in a 4 × 5·5° field of 0·002 foot-Lamberts luminance. Viewing distance was 75 cm and observations were made monocularly with a dark-adapted eye from within a light-tight booth through a 3-mm artificial pupil. A minute red light (< 2 min visual angle) provided a fixation point. Presentations were made at the rate of one every 8·2 sec, and a warning bell sounded 2 sec before the onset of a presentation.

The results were collected by presenting the subject with identical sets of stimulus conditions a large number of times in various mixed random orders and having him signal each time whether or not he had detected *P*. The relative frequency of detections, that is, the empirical probability of detection, is the measure used on the data. Each plotted point, thus, is the result of 80 or 100 observations for a given pair of T_1–T_2 values.

In addition to these conditions, the precaution was taken of presenting catch-trials: on approximately 16 per cent of all presentations, *P* was absent. The 'false alarm' rate in these trials was found always to be less than 10 per cent for all subjects, and will not be further considered.

The results are presented in Fig. 2, each curve showing the results for a single subject. The abscissa plots the time after the offset of *A*, and the ordinate shows the probability of detecting *P*. The curves show a generalized inhibitory effect: the probability of detecting *P* is always less than 0·90, its minimal values in the absence of *A* and *B*. Within that generalized inhibition, $p(P)$ increases slightly with an increase in T_1 and then decreases, for two subjects, while for the third, $p(P)$ decreases only.

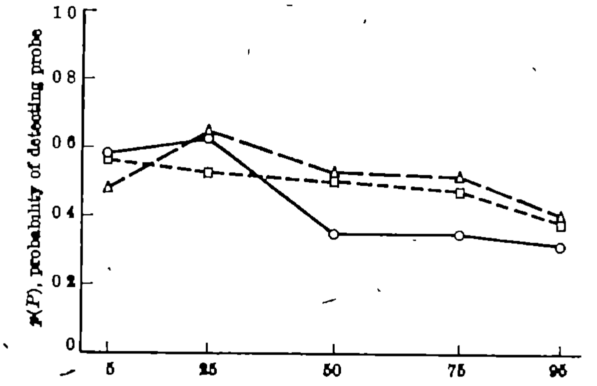

Fig. 2. Probability of detecting the target, *P*, in the path of apparent movement. The 5 msec long target appeared at a variable interval after the offset of *A*, that interval shown on the abscissa. Subjects *D* (○), *K* (△) and *P* (□)

As is shown in Fig. 1, *P* was placed approximately one-third of the distance between *A* and *B*, so that $T_1 = 25$ msec is the position closest to 'overlap' of the apparently moving line and the target. It is at this position, in Fig. 2, that detectability of *P* is highest for two subjects. Thus, while Fig. 2 shows that detectability of *P* varies with the 'position' of the apparently moving line, the form of this variation is exactly opposite that found with the line in real movement, cited here[3]. If the apparently moving line had acted on *P* in the same way as a physically moving line, the curves of Fig. 2 would be U-shaped: *P* would be maximally detectable when the apparently moving line was at the beginning or at the end of its traverse, and would be least detectable in the region $T_1 = 25$ msec. The curves clearly are not of this shape.

One major difference characterizes the stimulus conditions required for the perceptions of real and apparent movement: no image moves across the retina in the latter case. Apparently, then, the image of an object on the retina is required if the detectability of a contiguous object is to be affected. It may be inferred then that the phenomenal identity of the two perceptions notwithstanding, real movement and apparent movement partake of different processes, since their effects are different. The illusion of movement seems to be constructed by the observer out of the information provided by the order and timing of the flickered stimuli. The fragility of this construction will be described in another report.

The experimental work was performed in the U.S. Naval Medical Research Laboratory. Preparation of this report was supported by National Science Foundation grant *G*-16486 to the Center for Cognitive Studies, Harvard University.

LETTERS TO THE EDITOR

ASTRONOMY

Distribution and Origin of Lunar Craters

THE communication by McCall[1] leads me to make some further comments. It is certainly true that the non-random distribution of the large craters is a serious and probably fatal objection to the impact hypothesis so far as the major formations are concerned, though no doubt many small meteoric craters exist. The Mare Crisium seems to be nothing more than an exceptionally large crater-like formation, and is a member of the great western chain which also includes Petavius and Langrenus; in which case it seems that the other circular-type maria are basically similar. Moreover, in the case where one crater breaks into another, the wall of the broken formation is perfectly preserved up to the point of junction; Thebit is a good case. This could not be so were the second, younger crater produced by a violent impact. I directed attention to this in 1956[2], and the same point has since been made independently by Kopal and others.

It seems, however, that this argument can also be used against the idea of violently explosive vulcanism, and it may be argued that the process of crater formation was relatively gentle and prolonged. In making this suggestion[3], I had in mind an uplift and subsidence process which, if repeated several times with interior remelting, would result in the production of a terraced crater.

PATRICK MOORE

East Grinstead, Sussex.

[1] McCall, G. J. H., *Nature*, 196, 255 (1962).
[2] Moore, P., *Formacion de los crateres lunares*, *Urania* (Tarragona, 1956).
[3] Moore, P., *J. Brit. Astro. Assoc.*, 71, 362 (1961).

I HAVE elsewhere[1] expressed agreement with Mr. Moore's view that the lack of shaking-down effects provides an important clue to the origin of lunar craters, and at the same time expressed my own view that the structure of the crater Porter is inexplicable in terms of explosive evisceration, a process which I have never favoured, though simple dish-craters in maria could be produced by a bubble-burst through a thin plastic veneer. The fact that craters appear to have been the product of slow and gentle processes does not, in my view, invalidate my hypothesis. Certainly the large craters stem from subsidence, and, as on Earth, the initiating upwards push may not necessarily have been explosive in every case. The blisters seen in some craters probably reflect gentle pressures without break-out. It remains possible that many of the large cirques were initiated by point-focus explosion, forming axial vents and confocal fractures, not craters. This seems most likely in the case of early structures, since, once fractured, the retaining crust would allow slow gas leakage rather than explosive discharge. It is interesting to note that at least one carbonatite complex reveals some evidence of a recessive stage involving cauldron subsidence[2]. Moore's suggestion of gentle uplift and subsidence, repeated several times, fits in well with patterns of history in terrestrial volcanic foci, but, as on Earth, one must expect no uniformity of detailed history, and I do not think point-focus explosion can be ruled out, entirely, because of the objection made.

One of the most potent arguments for a volcanic origin of lunar craters is the progressive decrease in size with age. A large crater never shows evidence of developing on the same focus as an earlier smaller structure. This is the essential pattern of history displayed by terrestrial calderas: I do not know of a single recorded case where a secondary caldera has not been of diminished magnitude compared with its predecessor. I would be interested to know if other geologists can record such a case.

PHYSICS

Re-entrant Motion in Special Relativity

THE argument by Dr. T. E. Phipps[1], in which he claims to show that the velocity at the edge of a rotating disk is not ωr and that ωr can be greater than c, contains a simple fallacy from the point of view of relativity theory.

The fallacy lies in the assumption that if the radius of the rotating disk is r then the "rest length" circumference of the disk will be $2\pi r$. This relation is true only when the disk as a whole is at rest in the inertial frame S. Of course, the radius of the disk when it is stationary in S will in general be different from its value when rotating. In the actual rotation considered an element of the boundary which has rest length δx^* in S^* suffers the Lorentz contraction when witnessed by the observer in S. Thus the observer in S ascribes to the circumference the total length $\Sigma\delta x = 2\pi r$, which is appropriate to the Euclidean geometry in his frame; on the other hand, the aggregate of measurements by observers in the local frames S^* on the boundary will be $\Sigma\delta x^* = 2\pi r/(1-v^2/c^2)^{\frac{1}{2}}$, albeit the disk dwellers would also ascribe a total length r to the radius. The non-Euclidean character of the geometry in accelerating frames of reference was inferred in this way by Einstein long ago and led him to adopt the Riemannian metric in general relativity.

Subject to this correction the rest of Phipps's calculations are now seen to be consistent with $|v| = |\omega r| < c$. Thus his equation (2) should read $2\pi r/T = -v$ and since, as Phipps agrees, $T = 2\pi/\omega$, (3) then becomes $v = -\omega r$ and because of the appearance of v in the factor $\sqrt{1-v^2/c^2}$ we can conclude as usual that $|\omega r| < c$.

Thus there is no question, as Dr. Phipps goes on to suggest, that the much discussed identical twins age equally and that both "stay young". The experiment of Hay *et al.*[2], discussed by Sherwin[3] to whom Phipps refers, is actually in reasonable agreement with the expected age discrepancy proportional to the factor $\sqrt{1-v^2/c^2}$.

Note added in proof. Since this communication was submitted letters from Dr. R. H. Boyer and Dr. D. B. Lichtenberg, pointing out the error in Dr. Phipps's argument that I have indicated above, have appeared in *Nature* together with Dr. Phipps's reply[4]. Nothing that has been said in these communications alters my view of the correctness of the interpretation of relativity theory given here.

Observation of Mixing at Optical Frequencies in a *p–n* Junction

MIXING of light corresponding to adjacent axial standing wave modes of a ruby laser has been effected in a silicon *p–n* junction. The junction was prepared by grinding down the side of an *S.T.C. RS–28A* power rectifier diode to expose the junction. After protecting the metal casing with wax, the junction was treated with *CP*–6 etch, washed, dried and coated with distrine cement.

The reverse current after this treatment was 15 μamp at 100 V.

Light from the ruby laser was focused on to the junction, reverse biased at 108 V. The diode was situated in the centre conductor of a coaxial line feeding directly into a Rhode and Schwarz type *USVD* microwave receiver the output of which was displayed on an oscilloscope triggered at the beginning of the laser pumping flash.

Microwave output was observed in a narrow band at 1,635 Mc/s as a spiky trace on the oscilloscope. This frequency corresponds to the difference between neighbouring axial modes in the ruby rod 5 cm long. The power in a single spike in a 1 Mc/s band at the centre frequency was about 1 μW at the 50 ohms input to the receiver.

Output from the diode was also found at 3,270 Mc/s, which is the beat frequency associated with a pair of next-nearest neighbour axial modes.

Electron-hole pairs are generated in the semiconductor at a rate proportional to the intensity of the incident radiation so the device acts as a square law detector. The carriers generated in the depletion layer are swept out by the high field in a time short compared with a period of the beat frequency of the incident light from the laser, and it is this transit time in the depletion layer rather than minority carrier lifetime which limits the high-frequency performance of the mixer.

Inaba and Siegman[1] have reported mixing in a reverse biased *p–i–n* junction photodiode. The use of a *p–n* junction may offer an advantage at higher frequencies, since the carrier transit time across the depletion layer can be very short.

Phenomena occurring at Electrically Stressed Metallic Surfaces in Long Gaps in Vacuum

Many hypotheses have been put forward attempting to explain the initiation of electrical breakdown between metallic electrodes insulated by high vacuum[1]. Of these, several depend on the removal of a loosely attached aggregate of material (a clump) from one of the electrodes[2,3]. Attempts to prove the existence of clumps in a vacuum gap have already been reviewed[4].

The main objections to a clump-type mechanism have been that the electrostatic forces acting prior to breakdown appeared to be insufficient to pull off clumps[5] and that loose aggregates would not exist on smoothly polished clean electrodes.

During an investigation of the breakdown mechanism in long vacuum gaps, smooth uniform-field commercial copper electrodes and 1/50 negative impulse voltages were used, and the resultant markings at the electrode surfaces due to single breakdowns were examined[6]. In several cases 'clover leaf' patterns, which were indicative of the removal of material from the actual electrode metal, were found on the anode surface. At the corresponding cathode surfaces damage was found similar to that caused by the impact of particles[7].

In the case shown in Figs. 1 and 2 the electrodes had been polished to a 1μ diamond paste finish, the gap was 2 cm and the peak of the applied voltage wave-form causing breakdown was 73 kV. The strain marks at the anode and the impact bands at the cathode can be clearly seen. The embedded particles in the cathode are almost certainly those torn out from the anode as the distance between the centres of the two sets of markings is identical, being 2×10^{-3} cm. These particular clumps did not cause the breakdown because damage caused by the arc was found elsewhere on the electrodes, and had the arc arisen in this area the markings would have been destroyed due to the heating by the arc. This then is direct evidence that clumps can arise due to the tearing out of material rather than the removal of loosely attached aggregates, even though the forces acting at the surface are many magnitudes below the ultimate tensile strength of the material. The mean electrostatic stress acting on the surface in the present case was about 10^{3} dyn/cm².

Carbon replicas were taken from a thermally etched surface of the same grade of commercial copper which had been heated to 1,000° C in vacuum in a hot-stage microscope. Apart from general etching effects, these revealed the presence of dendritic inclusions, a typical example being shown in Fig. 3. The close resemblance in shape to the previously mentioned anode markings seems significant. Comparison of the diameters of the markings and the inclusions from photographs showed that the relative sizes were within an order of magnitude. The larger diameter of the anode markings may be attributed to the

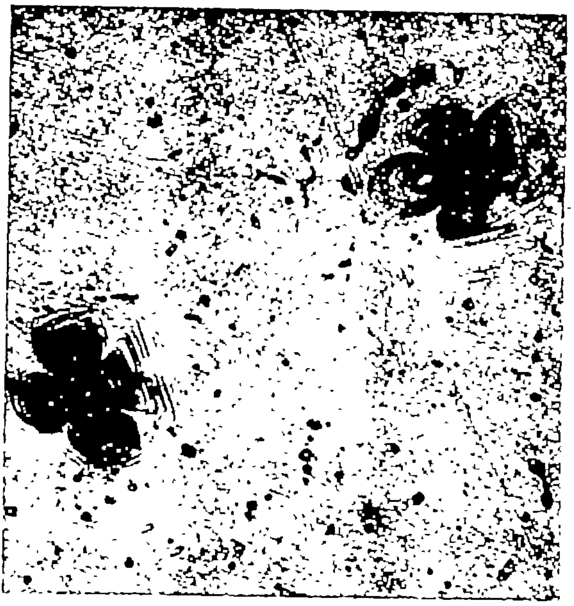

Fig 1. Photomicrograph showing 'clover leaf' patterns on copper anode (× c. 244)

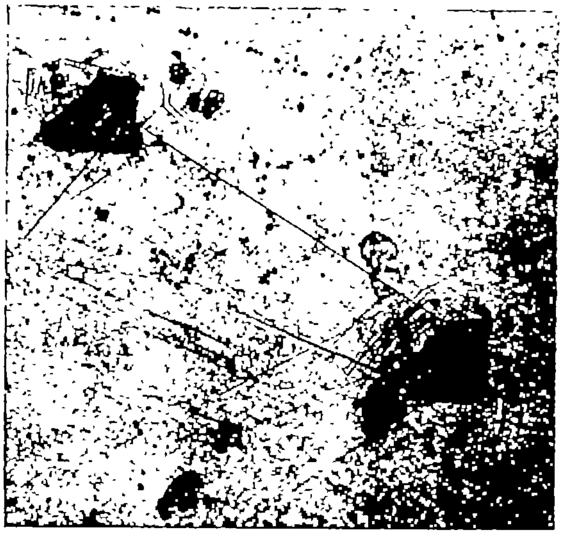

Fig 2. Photomicrograph showing impact damage on copper cathode (× c. 225)

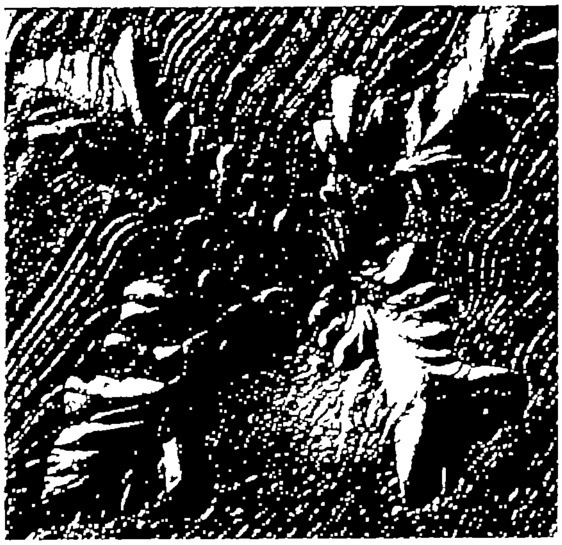

Fig. 3. Electron micrograph of inclusion in commercial copper (× c. 4,000)

deformation accompanying removal of the inclusions. The electrostatic stress required to remove such inclusions would be considerably less than the ultimate tensile strength of the metal itself due to the low cohesive forces usually existing between inclusion-metal interfaces. This is generally about 10³ dyn/cm, the average surface tension for most metals.

Interaction of Amino-Acids with Riboflavin

IN two recent papers it has been shown[1,2] that amino-acids, both aromatic and non-aromatic, interact with the electron acceptors oxygen and chloranil (tetrachloroquinone) in a very similar manner to the aliphatic amines. It is thought that $n-\pi$ charge transfer complexes are formed, the donated electron being one of the lone-pair electrons localized on the nitrogen atom in the amino group.

Isenberg and Szent-Györgyi[3] have investigated the interaction of amino-acids with another quinone, riboflavin-5′-phosphate, and have come to the conclusion that only tryptophan reacts with this salt, forming a $\pi-\pi$ charge-transfer complex. They showed that adding tryptophan to riboflavin-5′-phosphate decreased the optical density of the quinone salt and caused a new absorption band to appear at about 510 nm. Weber[4] has investigated purine–riboflavin complexes and has shown that the absorption spectrum of riboflavin is weakened on adding purine but a slight increase occurs in the long wave-length tail.

Studies have been made of spectra of mixtures of riboflavin and amino-acid in aqueous buffer. It was observed that adding a 10^{-2} M amino-acid solution to 10^{-4} M riboflavin solution in aqueous *p*H 7 buffer caused certain changes in the absorption spectrum of the riboflavin. These changes were observed as the difference spectra of riboflavin and riboflavin plus amino-acid. The difference spectra appeared as a negative mirror image of the riboflavin absorption in the region of 340–500 nm. The difference spectra also give a positive peak at about 300 nm and in some cases a very faint positive peak at 500 nm. There is an isobestic point at about 330 nm. These effects were found to be quite similar for the aromatic amino-acids, tryptophan, phenylalanine and tyrosine and the non-aromatic amino-acids, glycine, alanine and leucine. Typical spectra are shown in Fig. 1. It was found that the riboflavin solutions were not stable, but that over a period of a day or so, the spectrum of the riboflavin changed from that of the oxidized form to that of the reduced form[5]. It was found that the reduction of riboflavin occurred quite rapidly in aqueous *p*H 9 buffer. The difference spectra between riboflavin and riboflavin plus amino-acid in aqueous *p*H 9 buffer were found to be positive with an isobestic point in the region of 330 nm as shown in Fig. 2. All the amino-acids behaved in a similar manner with riboflavin in aqueous *p*H 9 buffer.

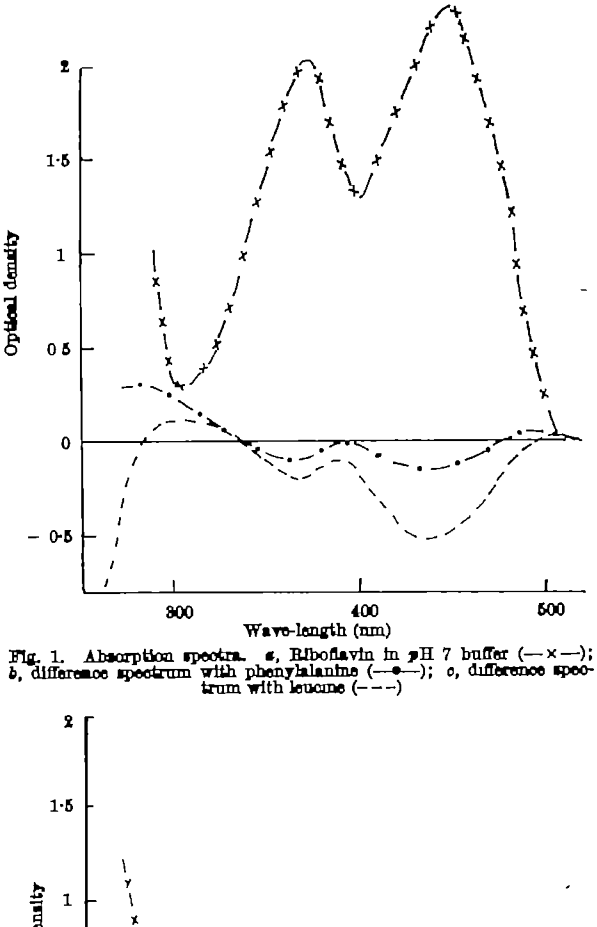

Fig. 1. Absorption spectra. *a*, Riboflavin in *p*H 7 buffer (—×—); *b*, difference spectrum with phenylalanine (—●—); *c*, difference spectrum with leucine (– – –)

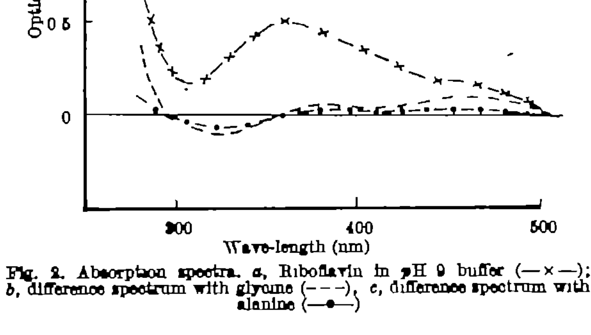

Fig. 2. Absorption spectra. *a*, Riboflavin in *p*H 9 buffer (—×—); *b*, difference spectrum with glycine (– – –), *c*, difference spectrum with alanine (—●—)

Beinert[5] has investigated the spectrum of riboflavin as it goes from the oxidized to the reduced form. The absorption spectrum of oxidized riboflavin has peaks at 375 and 445 nm whereas the reduced riboflavin only has a peak at 251 nm and has less absorption than the oxidized form. There is an isobestic point in the spectrum at 330 nm. Beinert has concluded that the spectrum of riboflavin is due to the sum of three components, the oxidized form, the reduced form, and an intermediate form, the semiquinone.

The difference spectra observed in amino-acid–riboflavin mixtures at different pH's can best be explained by the stabilization of the semiquinone form of riboflavin by the amino-acid. Isenberg and Szent-Györgyi[3] have suggested that the tryptophan riboflavin-5′-phosphate interaction can be explained by the tryptophan forming a $\pi - \pi$ charge-transfer complex with the riboflavin-5′-phosphate thus:

$$\text{tryptophan} + \text{riboflavin-5}'\text{-phosphate} \rightleftharpoons \left(\begin{array}{c}\text{oxidized tryptophan–semiquinone}\\ \text{riboflavin-5}'\text{-phosphate}\end{array}\right)\text{complex}$$

Such a scheme could well describe the interaction of the amino-acids with riboflavin, except that the donated electron reducing the riboflavin should be a lone-pair (n) electron, probably from the amino-group. There appears no reason why only tryptophan should interact with riboflavin-5′-phosphate to give a $\pi - \pi$ complex, whereas the amino-acids as a whole react with other quinones such as chloranil and riboflavin in such a manner that an n-electron is transferred from the amino-acid to the quinone.

GEOPHYSICS

Formation of Mountains by Radial Contraction of the Earth

MODERN ideas on the origin of the planets suggest that the Earth began as a cool solid body, and on this basis the development of a liquid core, of gradually increasing size, would be ascribed to subsequent radioactive heating.

The elastic constants of the liquid core and of the solid mantle for the actual Earth are known, and these imply that the core-material, although liquid, is more compressible than the mantle-material at the pressures prevailing deep within the Earth. Making use of the known values, the properties of a linear series of Earth-models of gradually increasing core-mass can be investigated, beginning with an entirely solid Earth. Calculations show that the radius decreases as the core-mass increases, and that an initial solid Earth would have outer radius 1·043 times the present value R_E, while allowance for the lower uncompressed density of the material of the outer layers would increase this figure to 1·056 R_E. This result would mean an initial circumferential length more than 2,000 km greater than the present value, and an initial surface-area exceeding by nearly 60 million square kilometres the present area of the Earth.

The importance of such a contraction of the Earth as a whole to the problem of the formation of mountains is evident, since it would gradually build up shearing stresses in the outer layers that the materials there would eventually be unable to withstand, and periods of folding and thrusting would have to occur intermittently to relieve the stresses. The mechanism appears to be fully capable of providing the seemingly enormous amounts of contraction that have long been considered necessary by geologists to explain the actual mountain systems on Earth.

The mathematical theory and detailed calculations leading to these conclusions are in course of publication.

GEOCHEMISTRY

Low Concentration of Tritium in Iron Meteorites

A SERIOUS geochemical problem that is not yet solved is the quantity of tritium found in iron meteorites. Although all other isotopes produced by cosmic rays in both iron and stone meteorites are in close agreement with expected values estimated by cross-section measurements using large accelerators[1], tritium is either absent or at least an order of magnitude less than expected in iron meteorites (for example, ref. 2, and the references listed in that article). The tritium content of stone meteorites is not abnormal.

Two explanations have been proposed for the low concentration of tritium in iron meteorites. It has been suggested that the chemical treatment methods are inefficient and the tritium is not extracted from the iron. This, however, seems difficult to believe since the two different chemical methods used[2,3] are both reliable and completely attack the iron. Furthermore, the hydrogen gas added as carrier and dissolved in the iron is always recovered, quantitatively.

The other explanation proposed is that tritium diffuses out of iron meteorites. However, direct diffusion measurements of tritium in iron do not agree with this and the ratio of helium-3 to helium-4 in iron meteorites is in close agreement with that predicted from accelerator measurements[4]. This requires that the tritium formed in the meteorites during the flights in space must have remained in the meteorites and decayed to helium-3. Another suggestion is that a special mechanism permits the tritium to diffuse out of the iron meteorites only after they have reached the Earth. At present, there is no plausible theory that would predict this.

Further evidence supporting the diffusion loss hypothesis is the observation of what is called a diffusion of tritium out of iron acceleration targets[5,6]. However, an examination of the experiments reveals that diffusion was not directly observed, but merely the phenomenon that the longer the iron targets remained untreated after the irradiations, the less tritium was extracted. It is noted that this is not observed in other metal targets.

Since neither of the two aforementioned hypotheses seems reasonable, the tritium content of iron meteorites is now an important mystery for science and, therefore, all sorts of possibilities should be checked. I suggest here the possibility that a completely new phenomenon is being observed. That is, that tritium dissolved in iron, possibly denuded of its electrons and held in a strong magnetic field, no longer decays with its ordinary 12-years half-life, but much more rapidly, perhaps with a half-life of the order of several days or even less. It seems that both a combination of a nucleus without an ordinary electron cloud and the presence of a magnetic field would be necessary.

An experiment is possible to test this proposition. A stack of iron foils irradiated in an accelerator or otherwise concentrated with dissolved tritium could be submitted, after various lengths of time, to helium-3 analyses. Presumably, if the tritium formed in the iron is decaying with an abnormally short half-life, a progressive build-up of helium-3 in the target foils would be observed which would be analogous to the decreasing amount of tritium that could be extracted.

It is realized that the suggestion of a half-life change is contrary to the at present well-established theory of β-decay, but the low concentration of tritium in iron meteorites is so great a puzzle it appears possible that a new effect is acting on the tritium.

Rates of Calcium Carbonate Deposition by Deep-Sea Organisms, Molluscs and the Coral-Algae Association

WHILE completing reports on the marine geochemistry of strontium and on calcium carbonate sedimentation in the Atlantic Ocean, I found that sufficient information was available to make an estimate of the calcium carbonate accumulation rates in the sea by deep-sea and littoral processes. The major agents of calcium carbonate accumulation in the littoral areas are presumably molluscs and the coral–algae association.

In considering the alkaline-earths, calcium and strontium, it is evident that, if the sea is in the steady state (an assumption which seems reasonable at least from the Tertiary), then a material balance equation may be written for each element in the following manner:

$$\text{calcium: } R_M + R_C + R_D = R_S$$
$$\text{strontium: } 1{,}500R_M + 8{,}000R_C + 2{,}500R_D = 2{,}500R_S$$

where R_M, R_C, and R_D are the rates of molluscan, coral–algae, and deep-sea calcium carbonate accumulation respectively and R_S is the rate of supply of calcium, as calcium carbonate, from streams (corrected for cycled calcium from the sea). In the strontium equation the numerical coefficients represent the strontium concentrations (in parts per million) in molluscs[1], corals and algae and 'inorganic aragonite' associated with them[2], deep-sea carbonate sediments[3], and streams[4].

Because of the observed identical values of the strontium–calcium ratios in deep-sea carbonates and streams, these equations can be easily solved for the R_M/R_C ratio. This solution indicates that calcium carbonate is put into the littoral sediments five and a half times more by molluscs than by the coral–algae association. The reasonableness of this ratio is, of course, contingent on the magnitudes of the littoral and deep-sea accumulation rates being similar.

It is possible to calculate the total accumulation rate in the deep-sea if we know the average calcium carbonate concentration of the deep-sea sediments of the major oceanic areas and the corresponding clay accumulation rates, using the relation:

$$\text{Rate calcium carbonate accumulation} = \text{rate clay accumulation} \times (\%\ \text{calcium carbonate}/100 - \%\ \text{calcium carbonate})$$

The mean calcium carbonate concentrations of sediments for both the Atlantic and Pacific Oceans are derived from the average concentration in sediments at different ocean depths[5] and the percentage of each depth in the two oceans[6] (Table 1).

Table 1. CALCULATION OF TOTAL RATES OF CALCIUM CARBONATE ACCUMULATION IN THE OCEANS

Depth (m)	Atlantic % area	Atlantic Average % $CaCO_3$	Atlantic Weighted contribution	Pacific % area	Pacific Average % $CaCO_3$	Pacific Weighted contribution
0–200	5·6	80	4·49	1·7	78	1·33
200–1,000	4·0	80	3·20	2·2	78	1·72
1,000–2,000	3·6	80	2·88	3·4	78	2·67
2,000–3,000	7·6	70	5·32	5·0	78	3·90
3,000–4,000	19·4	70	13·58	19·1	74	14·13
4,000–5,000	32·4	63	20·40	37·7	35	13·20
5,000–6,000	26·6	20	5·32	28·8	3	0·87
6,000–7,000	0·8	5	0·04	1·8	0	—
> 7,000	—	—	—	0·3	0	—
Average % $CaCO_3$			55·23			37·82
Total area (× 10^6 km^2)			82·441			165·246

Using the palaeontological index for the 11,000-year break between the last glacial and post-glacial deposits observed in a number of Atlantic carbonate-rich cores[7], I have been able to calculate clay accumulation rates in post-glacial time for the seven Atlantic cores listed in Table 2. The post-glacial rates of accumulation determined by assuming that the tops of the cores represent an age of 3,000 years is preferred because many radiocarbon-dated core tops indicate that this is the most common age to expect. Most probably this old age is due to loss of the sediment tops by the sampling procedure. The beginning of the last major glacial series (Wurm ?) has been estimated at 73,000 years B.P.[8] and the average glacial rates are calculated on this basis.

Table 2. RATES OF CLAY ACCUMULATION IN THE ATLANTIC DEEP-SEA (G/CM^2 1,000 YEARS)

Lamont No.	Post-glacial rate *A*	Post-glacial rate *B*	Glacial rate *C*
*A*164–44	0·11	0·15	0·45
*V*9–27	0·13	0·18	1·02
*SP*8–4	0·14	0·19	0·33
*A*180–39	0·15	0·21	0·35
*R*5–60	0·24	0·33	0·43
*A*180–74	0·22	0·22	0·66
*A*180–76	0·25	0·34	0·54
Average	0·18	0·23	0·54

A, Assuming top of core not missing; $\Delta t_{\text{post-glacial}} = 11{,}000$ years.
B, Assuming top of core missing; $\Delta t_{\text{post-glacial}} = 8{,}000$ years.
C, Assuming beginning of last glacial sequence is 73,000 B.P.; $\Delta t_{\text{glacial}} = 62{,}000$ years.

The Pacific Ocean apparently has a clay accumulation rate which is one-third or less of the Atlantic rate[8] and on this premise we can calculate the Pacific carbonate accumulation rate. With the paucity of data on the Indian Ocean at present, I will assume that the total calcium carbonate accumulation rate in the Indian Ocean is the same as in the Pacific.

The amount of uncycled calcium brought to the sea by streams is 62 × 10^{14} g calcium/1,000 years, or 154 × 10^{14} g calcium carbonate/1,000 years, using Clarke's estimates[9]. Knowing the supply of calcium to the sea by streams and the amount removed in the deep-sea, we can arrive at the removal rate of calcium by the littoral processes.

Having determined the ratio of molluscan to coral accumulation rates, we can now distribute the calcium carbonate supplied by streams among the three major modes of accumulation in the oceans. These are listed in Table 3 for various rates of clay accumulation. *A*, *B*, and *C* correspond to the three accumulation rates under the same headings in Table 2. *D* is calculated for a model[10] of the oceans which implies that though the Atlantic clay accumulation rate is sensitive to the climatic events of the Pleistocene, the Pacific is relatively insensitive so that for the past 11,000 years the maximum post-glacial rate (*B*) is used to calculate the Atlantic carbonate contribution and

Table 3. MATERIAL BALANCE FOR CALCIUM CARBONATE SUPPLY AND REMOVAL IN THE SEA (IN UNITS OF 10^{14} G $CaCO_3$/1,000 YEARS)

		Stream supply	Deep-sea	Molluscs	Coral–algae
A	Minimum post-glacial rate	154	30	106	18
B	Maximum post-glacial rate	154	39	97	18
C	Average glacial rate	154	91	53	10
D	Atlantic at maximum post-glacial rate and Pacific and Indian at 1/3 Atlantic glacial rate	154	60	80	14

one-third the Atlantic glacial rate (*C*) is used for the Pacific contribution from which the Indian Ocean contribution is then derived.

As our calculations of material balance are based on post-glacial data from the Atlantic cores and present-day stream supply of calcium and strontium, we are constrained to consider only estimates *B* and *D* seriously. This limits our range of accumulation rates of calcium carbonate (in units of 10^{16} g calcium carbonate/1,000 years) to: deep-sea, 39–60; molluscs, 80–97; and the coral–algae assemblage, 14–18.

From these calculations, several conclusions may be drawn:

(1) Of the calcium carbonate supplied to the sea by streams, the percentage deposited by deep-sea processes is between 25 per cent and 39 per cent. The major role of littoral processes in removing calcium from the sea at the present time implies that only small changes in the calcium carbonate accumulation in littoral areas are necessary before the Mesozoic when deep-sea carbonate accumulation may have been trivial. Indeed, if the present time represents a high supply of calcium to the sea compared with the past, as a consequence of extensive limestone exposure and erosion, no unusual requirements are necessary for carbonate deposition in the past.

(2) Because of the major role of littoral deposition it is not possible to decide whether the higher-than-present calcium carbonate deposition rate observed in the Atlantic Ocean during glacial times[8] was due to greater run-off or a higher ratio of the deep-sea to littoral accumulation rate.

(3) Coral reefs represent only 10 per cent of the total calcium carbonate deposition at present. Variations in their rate of formation will not seriously affect the total calcium budget of the sea though it might be reflected in the strontium budget.

This communication was written during the tenure of a John Simon Guggenheim Memorial fellowship based on data obtained under a grant from the National Science Foundation.

RADIOCHEMISTRY

Separation of Radioiodine from Tellurium by Means of Column Chromatography

THIS communication describes some experimental work carried out concerning the separation of iodine-131 from tellurium-131 by means of column chromatography. The method can also be applied to the separation of ^{132}I (half-life, 2·3 h) from ^{132}Te (half-life, 77 h) which is obtained as a fission product following neutron bombardment of uranium.

The nuclide ^{131}I (half-life, 8·04 days) is produced by the bombardment of natural tellurium with neutrons according to the nuclear reaction: $^{130}\mathrm{Te}(n,\gamma)^{131}\mathrm{Te} \xrightarrow{\beta^-} \mathrm{I}^{131}$. The mother product, ^{131}Te, decays with a half-life of 1·25 days to form ^{131}I. Other isotopes produced in the bombardment are ^{129}I from the reaction: $^{128}\mathrm{Te}(n,\gamma)^{129}\mathrm{Te} \xrightarrow{\beta^-} {}^{129}\mathrm{I}$ (half-life = 1·7 × 10^7 years), and also ^{129}Sb (half-life = 4·6 h), the origin of which is not clearly known, but is thought to be due to an (*n,p*) reaction. Neither of these isotopes presents any difficulty so far as the separation is concerned.

In the present case the target material took the form of telluric acid and was irradiated as the solid for a two-day period in a neutron flux of 10^{13} n/cm^2/sec, in the *Astra* reactor at Seibersdorf near Vienna.

The column was prepared in the following manner: A sheet of glass paper, of type Schleicher and Schull No. 6, was cut into small sections and treated for about 10 min in a mixture of 10 per cent sodium fluoride, 5 per cent hydrofluoric acid and weak hydrochloric acid in the ratio 1 : 1 : 1. This treatment etched the paper surface making it rougher. The liquid was then poured off and the paper washed with distilled water until all trace of the acid wash had been removed. Finally, the paper was soaked in absolute alcohol and packed into the column. The column-packing material could also consist of glass wool or glass powder.

The neutron irradiated telluric acid was dissolved in 1–2 ml. of distilled water and poured on to the top of the column bed. In this way about one-fourth of the absorbent material becomes saturated with the telluric acid solution. Allowing absolute alcohol to flow through the column precipitates the telluric acid in a finely distributed form while simultaneously eluting radioactive iodine.

Both analytical and nuclear spectroscopic studies have shown that the separated iodine is completely free from other contaminants. We would therefore like to point out that the described method has the advantage of being suitable for use where high levels of activity are to be processed since none of the components involved is likely to be effected by radiation damage. The method is, therefore, especially useful for the separation and production of ^{131}I and ^{132}I for medical purposes.

Rapid Non-destructive Analysis for Gold in Copper–Gold Mixtures by Neutron Activation

IT is known that 7·3-sec gold-197m is formed by neutron irradiation of natural gold and that it emits 0·279-MeV γ-ray. A preliminary experiment was made by Anders[1] using neutrons at a flux of 2 × 10^8 n/cm^2/sec, where only relatively few counts of γ-rays were collected for samples containing 15 mg of gold.

In our method a neutron flux of 3 × 10^{11} n/cm^2/sec is used. A sample is placed in a nuclear reactor for 4·5 sec, cooled for 5 sec, counted for 5 sec, again cooled for 1 sec and counted for 5 sec. The cadmium ratio at the irradiation position is about 3·1. The counter used is a 2-in.

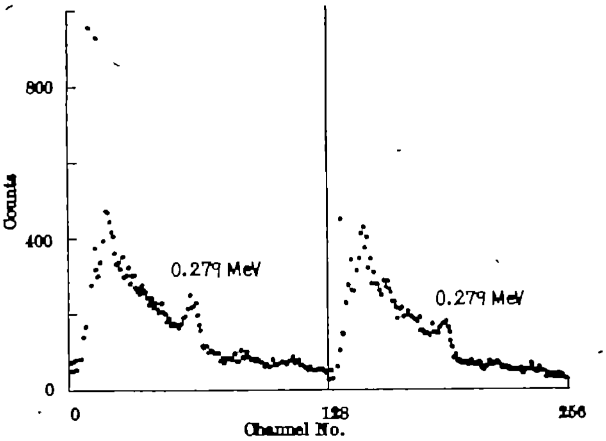

Fig. 1. γ-Ray spectrogram. Sample: 11·95 mg of a mixture of gold (9·4 per cent) and copper (90 6 per cent), both of which are in pieces

thick, well-type sodium iodide crystal attached to a 256-channel pulse-height analyser. During the counting operation the sample is placed 1 cm above the crystal together with its container. An aluminium disk of 2,150-mg/cm^2 thick is used as an absorber for β-rays from the sample.

An example of successive spectra thus obtained is shown in Fig. 1. From both γ-ray energy and half-life, gold is identified on the basis of the fact that, in the half-life range of 1–10^2 sec, there is no other nuclide having nearly the same γ-energy as gold-197^m. From Fig. 1, which represents the spectra of a sample of 9·4 per cent gold content, it is deduced that one-third of this concentration would produce an adequate size of photo-peak. The lower limit of the coefficient of variation of single analyses can be deduced to be about 5 per cent in comparison with a similar method[2] of the determination of ytterbium.

Though the neutron-absorption cross-section of gold is rather high, the self-shielding effect is negligible for 12-mg sample used in this work. The effect can be estimated, by use of experimental data[3], at less than 5 per cent if the amount of gold in a sample is less than 0·06 g. (Larger amounts can be applied if the sample is not a massive block, or if gold is dispersed in copper.)

We thank Prof. Shoji Makishima for helpful suggestions, Dr. Fumio Aoki and Dr. Toshio Nakai for their interest, and Mr. Shigeru Yamagishi for assistance.

Rapid Microdetermination of Indium by Neutron Activation

IT is known that 2·5-sec indium-116mm (ref. 1) is formed by neutron irradiation of natural indium and that it emits 0·15-MeV γ-ray. The size of the photopeak due to this γ-ray, obtained immediately after irradiation, can be estimated by the use of the data presented in a γ-ray spectra catalogue[2]. The peak size per 1 μg of indium is as large as that of silver when they are irradiated respectively for a period equal to the half-life of the nuclide formed, that is, 2·5 sec for indium and 24 sec for silver. Since silver is the most sensitive[3,4] in γ-ray counting after neutron irradiation, it is deduced that indium is also very sensitive.

In our experiment, varying amounts (0·01 ~ 10 g) of a sample were placed by turns in the nuclear reactor *JRR*–1 for 2·5 sec to be irradiated with neutrons at a flux of 3 × 10^{11} neutrons per cm^2/sec, cooled for 5 sec, counted for 4 sec, again cooled for 1 sec and counted for 4 sec. The counter used is a 2-in. thick, well-type sodium iodide crystal attached to a 256-channel pulse-height analyser. During the counting operation the sample was placed at 1 cm above the crystal together with its container. An aluminium-disk of 2,150-mg/cm^2 thick was used as an absorber for β-rays from the sample.

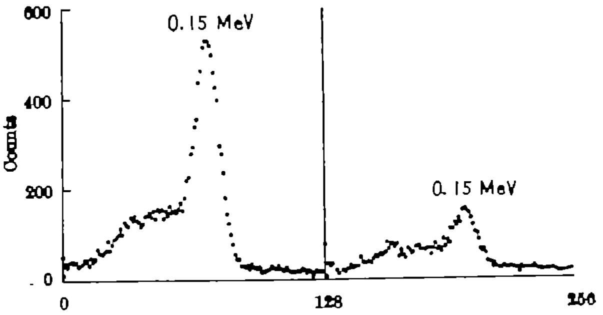

Fig. 1. γ-Ray spectrogram. Sample, 43·5 mg of zinc blende

A typical spectrogram thus obtained is shown in Fig. 1. From such successive spectra as Fig. 1 the half-life of the nuclide formed can be roughly determined. From both γ-ray energy and half-life, indium can be identified on the basis of the fact that, except indium-116mm, there is no nuclide, formed on pile-neutron irradiation, which emits a γ-ray of about 0·15 MeV and has a half-life of 1 ~ 10 sec. The amount of indium in the sample can be determined by the comparative method as usual. The results of analyses are shown in Table 1.

Table 1. RESULTS OF ANALYSES FOR INDIUM

Sample	Sample weight used (mg)	Indium found (p.p.m.)
A (zinc blende powder)	43·5	1 3 × 10^2
B (thallium slab)	3,715	3·6 × 10^{-1}
C (zinc grains)	6,019	< 3 × 10^{-3}

The coefficient of variation of single analyses can be deduced (from a similar experiment[5] in which erbium was determined by use of the formation of 2·5-sec erbium-167m) to be about 10 per cent if the activity-level is suitable to the analyser used and interferences are negligible.

We thank Prof. Shoji Makishima for helpful suggestions, Dr. Fumio Aoki and Dr. Toshio Nakai for advice, and Mr. Shigeru Yamagishi for assistance.

Some Products of the γ-Radiolysis of Liquid Acetone

BY irradiation of air-free liquid acetone the radicals H˙, $\dot{C}H_3$, $CH_3\dot{C}O$ and $CH_3CO\dot{C}H_2$ are formed[1–3]. Besides the known gaseous products[1] (methane, hydrogen, carbon monoxide and ethane), a mixture of oxygen containing liquid products arising from the radical–radical and radical–excited acetone reactions is formed.

I have studied this mixture partly by paper chromatography (carbonyl compounds as 2,4-dinitrophenylhydrazones (DNPH), hydroxyl compounds as 3,5-dinitrobenzoates (DNB) and acids as ammonium salts), partly by thin layer chromatography on alumina. Separated products were identified by comparison with authentic specimens, by their R_F values and by detection.

Acetone (reagent grade) was purified according to Timmermans and Gillo[4], dried over calcium chloride and potassium carbonate, distilled on a 40 *TP* column in an atmosphere of nitrogen and degassed in a 10 ml. 'Sial' cell at $-196°$ C on the vacuum line until a static pressure of about 10^{-5} mm mercury was obtained and finally sealed off. The irradiation was carried out at room temperature using γ-rays from a cobalt-60 source[5] with a dose rate of 0·5–1·2 × 10^{17} eV/ml. min. The Fricke dosimeter was used ($G_{Fe^{3+}} = 15{\cdot}6$) and total doses of about $10^{20} - 10^{21}$ eV/ml. were attained.

For paper chromatography of DNPH and DNB, sheets of Whatman paper No. 3 were impregnated with a 25 per cent ether solution of dimethylformamide and the mixture hexane/benzene acetone/dimethylformamide/water (75 : 25 : 10 : 10 : 0·5, v/v) was used as developing solvent; after having been reduced with stannous chloride the DNB were detected with *p*-dimethylaminobenzaldehyde[6]. Ammonium salts of acids were analysed as usual[6]. Thin layer chromatography on alumina grade III–IV (Brockmann) was carried out in a mixture of hexane/acetone (4 : 1, v/v), the products being detected by iodine vapour or by spraying with ammoniacal solution of silver nitrate at 140° C.

By the use of paper chromatography we have found these products in form of DNPH : formaldehyde, acetaldehyde, biacetyl, acetonylacetone, diacetone alcohol and traces of two other substances, probably methyl ethyl ketone and methyl isobutyl ketone; DNPH of an unknown substance with R_F value 0·61 was also found. In the form of DNB we have found methanol, ethanol, isopropyl alcohol, diacetone alcohol, pinacol, acetyl acetone in enol-form and several unidentified spots with R_F values 0·11, 0·20, 0·31, 0·37, 0·45 and 0·91. Some of them might be by similar R_F values mono-DNB and di-DNB of glycol, 1,2-propanediol and 2,3-butanediol. Only acetic and oxalic acids have been found on chromatographing the ammonium salts.

Acetyl acetone, acetonylacetone, diacetone alcohol, pinacol and acetic acid were identified also in free form by thin layer chromatography on alumina. In some of the samples biacetyl was found, too. In addition to these, spots of unknown compounds with R_F values 0·21, 0·50, 0·55 and 0·82 were found. The first of them exhibits strong fluorescence in ultra-violet light; the last is probably phoron. The other (R_F values, 0·50 and 0·55) can be revealed by spraying with ammoniacal solution of silver nitrate at 140° C; therefore it might be some hydroxy compounds.

According to our chromatographic analysis we are able to estimate that acetonylacetone and isopropyl alcohol are the main liquid products of irradiated acetone so far. Obtained results are also corroborated by infra-red spectra. The details of these experiments as well as related studies and the supposed mechanism of the γ-radiolysis of liquid acetone will be reported at length elsewhere[7].

CHEMISTRY

A Mathematical Basis for the Solvent-Reversal Technique of Paper Chromatography

THE applications and limitations of one- and two-dimensional paper chromatographic techniques have been well documented[1]. There remain, however, problems in the separation of certain compounds which cannot be resolved satisfactorily by either of these conventional approaches. Weiss and Rossi[2] recently described a chromatographic method which enables separation of several catecholamines on a single paper strip.

Briefly, the method consists of developing the chromatogram with one solvent system, by the ascending or descending technique, drying the paper, and then redeveloping with a second solvent system, again by the ascending or descending technique. However, the second solvent is run in a direction opposite (180°) to the first solvent.

The solvent-reversal method, by the proper choice of solvent systems, will permit certain separations which could not be achieved by conventional procedures. This may be accomplished by selecting two solvent systems in which the mobilities of the compounds which are most difficult to separate are in reverse order (that is, compound *A*, R_F with solvent 1 > R_F with solvent 2; compound *B*, R_F with solvent 1 < R_F with solvent 2). Migration of the compounds behind the original starting line is prevented by designating as the first solvent system that in which the compounds have, on the average, higher R_F values.

With reference to Fig. 1, we define the quantities 'net R_F' and 'solvent distance ratio' as follows:

$$\text{net } R_F = R_N = \frac{D_3 - D_4}{D_1} \qquad (1)$$

$$\text{solvent distance ratio} = X = \frac{D_2}{D_1} \qquad (2)$$

(When the second solvent front does not cross the original starting line, D_2 is negative, and X is negative.)

The following relationships are then evident:

$$R_{F1} = \frac{D_3}{D_1} \qquad (3)$$

$$R_{F2} = \frac{D_4}{D_3 + D_2} \qquad (4)$$

Substitute in equation 1 for D_3 (from equation 3) and re-arrange to obtain:

$$D_4 = R_{F1}D_1 - R_N D_1 \qquad (5)$$

From (2), (3) and (4), it follows that:

$$D_4 = R_{F2}(R_{F1}D_1 + XD_1) \qquad (6)$$

Equating (5) and (6), eliminating D_1, re-arranging and simplifying, the final equation, in its most useful form, is obtained:

$$R_N = R_{F1}(1 - R_{F2}) - R_{F2}X \qquad (7)$$

This relationship (equation 7) is a linear equation relating the variables R_N and X; slope $= -R_{F2}$, and intercept $= R_{F1}(1 - R_{F2})$. A plot of R_N versus X for a given compound having known R_F values for two solvent systems will yield a straight line from which R_N at any value of X may be determined by inspection. If this procedure is followed for two or more compounds, a series of straight lines is obtained and a value of X may be determined which permits separation of the compounds.

As an illustration of the method, plots were made for several compounds (Fig. 2) and checked experimentally by using the solvent-reversal technique to achieve separation. In the studies reported in Table 1, all R_F values in individual solvent systems were determined in our ble 1. Adsorption of Oxygen (Press 0·4–0·2 mm) on Nickel Oxide at 20° C.

sorption	Pretreatment	Volume adsorbed (c.c. g^{-1}) in 2 min No cold trap	Cold trap
1	Outgas 550° C 16 h	0·0185	0·0125 ± 0·0023*
2	Outgas 20° C 5 h	0·0380	0·0062 ± 0·0006*
3	Outgas 20° C 16 h	0·0255	
4	Outgas 20° C 16 h	0·0125	

* S.D.

Calculated monolayer coverage for oxygen = 3·4 c.c. g^{-1}.

mercury there was a fast initial adsorption of oxygen, mplete within 2 min, followed by a slow adsorption.

In another series in which no cold trap was used, the mple was outgassed for 64 h at room temperature after e initial oxygen saturation, and the uptake in the second dsorption experiment was then as high as 0·0600 c.c. g^{-1}. ualitatively similar results were obtained using a different ickel oxide preparation of surface area 5·9 m^2/g also erived from the nitrate. The following conclusions ere reached:

(1) After outgassing at 550° C in the presence of mercury apour, the adsorption at 20° C is rather higher than usual.

(2) Further outgassing at 20° C, still in the presence of ercury vapour, leads to an enhanced adsorption which creases with the time of pumping and may exceed the itial uptake by a factor of three.

(3) The volume adsorbed diminishes with successive utgassings and adsorptions at room temperature.

Control experiments in a greaseless system confirmed hat the effect was caused by mercury vapour and not by topcock grease, the presence of which in a vacuum system id not influence oxygen adsorption results.

able 2. Adsorption of Oxygen (Press 0·4–0·2 mm) on Nickel Oxide at 20° C

dsorption	Pretreatment	Volume adsorbed (c.c. g^{-1}) in 2 min
1	Outgas 550° C 1 h in absence Hg vapour	0·0117
2	Outgas 20° C 23 h in absence Hg vapour	0·0091
3	Outgas 20° C 20 h in presence Hg vapour	0·0225
4	Outgas 20° C 5 h in absence Hg vapour	0·0084
5	Outgas 550° C 16 h in absence Hg vapour	0·0156
6	Outgas 20° C ½ h in absence Hg vapour	0·0106
7	Outgas 20° C ½ h in absence Hg vapour followed by residence in closed system for 5 h in presence of mercury vapour	0·0187

A further series of experiments was carried out in hich the adsorption of oxygen was measured on a single pecimen before and after exposure to mercury Table 2). A different vacuum system was tilized.

Adsorption 4 indicates that prior exposure to ercury vapour does not affect the magnitude of he reversible adsorption (that is, oxygen which an be desorbed at 20°) since the value observed 0·0084 c.c. g^{-1}) agrees with that for a mercury-ree sample (Table 1). Thus, oxygen absorbed at ercury centres is irreversibly bonded at 20° C, in greement with the decline in oxygen uptake after uccessive outgassings at 20° C (Table 1). Adsorption demonstrates that the enhanced adsorption effect still ersists if, instead of outgassing, the sample is simply llowed to stand *in vacuo* in a closed system containing ercury vapour. The reduced magnitude of the mercury ffect noted in Table 2 compared with Table 1 may be scribed to a difference in geometry of the two vacuum ystems used; this influences the diffusion rate of mercury apour to the specimen. Direct confirmation that chemiorption of mercury vapour occurred was obtained y admitting the vapour to a part of the apparaus containing a Pirani gauge, isolating the merury source and then expanding the vapour to the ickel oxide; the pressure fell as adsorption proeeded. Finally, in order to determine whether ercury atoms gave rise to fresh oxygen adsorpion sites through interacting with the oxide urface itself or with oxygen adsorbed in the reliminary adsorption, the sample was first outgassed at 50° C. in the absence of mercury vapour, and then further vacuated for 16 h at 20° C, while exposed to mercury apour, without an intermediate adsorption. Again the subsequent oxygen uptake was large, indicating that mercury interacts with the outgassed surface to provide extra sites for oxygen adsorption.

Mercury vapour can then be regarded as a 'promoter' rather than a 'poison' for oxygen adsorption on nickel oxide. The mechanism of this effect has not been established, and any discussion is necessarily speculative. Associated experiments with neutron-irradiated nickel oxide[5] have established the importance of metal excess centres for oxygen chemisorption, and it is now suggested that adsorbed mercury may act as such centres. In both cases there is an increase in irreversible adsorption, while reversible adsorption scarcely changes. In the gas phase, mercury atoms are well known as scavengers for oxygen atoms in chain reactions. The decline in oxygen uptake after successive outgassings at 20° C and the low surface coverages involved (Table 1) indicate that the sites on the nickel oxide surface which may adsorb and activate mercury atoms are restricted in numbers. These results emphasize the importance of avoiding mercury contamination in chemisorption investigations on oxides.

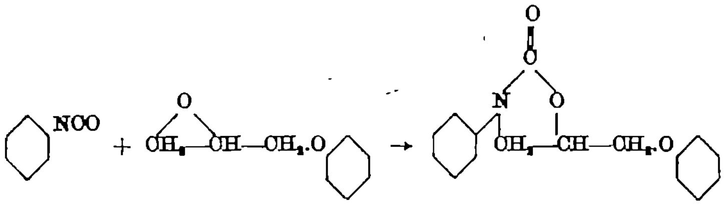
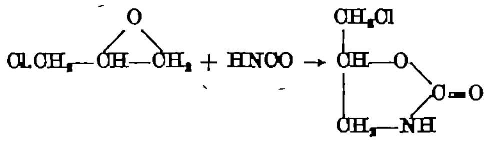
Reaction of Phenyl Isocyanate with 2,3-Epoxy Propyl Phenyl Ether (Phenyl Glycidyl Ether)

Reaction of phenyl isocyanate and 2,3-epoxy propyl phenyl ether gives a one-to-one addition compound, and there is evidence to suggest this is 3 phenyl 5 phenoxy methyl 2 oxazolidone. The reaction is believed to be:

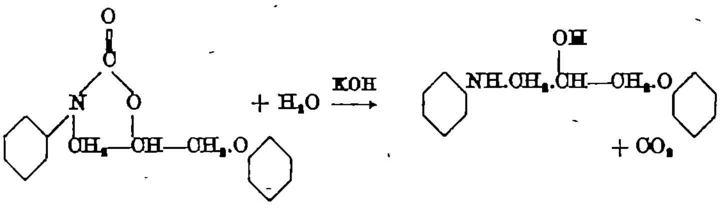


This is similar to a reaction reported by A. Thompson[1] between acidulated potassium cyanate and epichlorhydrin.



Evidence for the foregoing scheme is:

(1) Reaction with alcoholic potash yielded a compound in agreement with the reaction:



The product of this reaction gave a yellow oil on reaction with nitrous acid, suggesting a secondary amine.

(2) There was no reaction of the reaction product with nitrous acid. The nitrogen of this compound is thus

not present in the form of a primary or secondary amine.

(3) The product of the reaction was broken down by heating with concentrated hydrochloric acid in a sealed tube at 200° C to give an oil, which was shown to be a chlorine containing compound. This is in agreement with the concept of acid hydrolysis of the oxazolidone ring.

It was also noted that the material did not yield an oxime on reaction with hydroxylamine hydrochloride.

Phenyl isocyanate (11·6 g) was refluxed with phenyl glycidyl ether (15 g) for 6 h at 170° C. On cooling, a dark solid mass was obtained which was extracted with chloroform (300 ml.). After decolorization with charcoal and reduction in volume by distillation a white material was obtained (10·1 g). Complete evaporation of the chloroform left a reddish-brown tar (6·2 g). The white material was recrystallized from chloroform to give needles of m.p. 134°–135°.

$C_{16}H_{15}NO_3$ required: C, 71·32 per cent: H, 5·61 per cent; N, 5·20 per cent; obtained: C, 71·44 per cent; H, 5·76 per cent; N, 5·16 per cent.

1 g of the above material was refluxed wiih 40 ml. of a solution of 80 per cent ethanolic potash for 2 h. The ethanol was removed by fractional distillation leaving a small amount of water behind, which was extracted with ether. Ether was removed by evaporation and left a yellow oil, which crystallized to a pale yellow solid (0·57 g), m.p. 46°–48° C. On reaction with nitrous acid this gave a yellow oil, suggesting it was a secondary amine. Required for 1 phenyl-amino 2 hydroxy propyl phenyl ether, $C_{15}H_{17}NO_2$: C, 74·11 per cent; H, 7·03 per cent; N, 5·75 per cent; obtained: C, 72·73 per cent; H, 7·14 per cent; N, 6·06 per cent. This material is reported by Fourneau and Poulenc[2], but attempts to repeat their work gave a material the analysis of which did not agree with theory. No analyses are quoted in their paper.

0·5 g of the original substance was sealed in a tube with approx. 0·5 ml. of concentrated hydrochloric acid and the tube was heated in an oil bath for 15 min at 170° C and for 1½ h at 200° C. After cooling the tube was broken under water and washed with water. The tube broke in a manner suggesting it was under pressure at room temperature. The water was extracted with ether and the ether extract evaporated down, to yield a small quantity of a dark oil. The Lassaigne test indicated the presence of chlorine in this material.

I thank the Department of Materials for the facilities and materials with which the work was done.

BIOCHEMISTRY

Molecular Deficiency of Glucose-6-Phosphate Dehydrogenase in Primaquine Sensitivity

GENETICALLY determined deficiencies in activity of human glucose-6-phosphate dehydrogenase (G–6–PD) occur among various ethnic groups. The deficiency affecting 8–12 per cent of American Negro males is known as primaquine sensitivity and is incompletely expressed: affected persons have 7–15 per cent of the normal activity of erythrocytic G–6–PD and an even higher proportion of activity of this enzyme in some other tissues[1,2]. In view of similarities in qualitative characteristics between the partially purified G–6–PD of affected Negroes and that of normal persons, one of us has questioned the possibility that sensitive Negroes have a G–6–PD that is impaired in its catalytic efficiency (turnover number)[3]. A comparative examination of more extensively purified G–6–PD's seems to offer new evidence on this subject.

Glock and McLean assay[4] for G–6–PD permitted identification of day-old pints of enzyme-deficient blood provided by Negro males at the University Medical Center Blood Bank. On starch-gel electrophoresis[5], that G–6–PD of each pint migrated slightly faster than that of normal Caucasians, as has been noted previously[6,7]. The enzyme from each pint of blood from control, G–6–PD-active males migrated at the same rate as the G–6–PD prevalent in Caucasians. The enzyme was purified by a method previously described[8]. Five pints of deficient blood provided 0·31 mg (protein) of a preparation with a specific activity[8] of 9·1 units/mg, representing 16,000-fold purification and a yield of 2 per cent. From five pints of normal blood 0·55 mg of a preparation was obtained with specific activity of 94 units/mg. This represented 17,000-fold purification and a yield of 3 per cent. When subjected to starch-gel electrophoresis and staining with amido-schwartz, 33 μg (3·1 units) of normal preparation appeared predominantly as a single band. It had a position identical to the location of activity of the G–6–PD, as indicated in Fig. 1 by the 1·23 : 1 distance from the origin of the activity relative to hæmoglobin A. This position of activity relative to hæmoglobin also has been observed with more than 200 normal hæmolysates previously studied in this laboratory. In contrast, 98 μg (0·89 unit) of sensitive enzyme did not migrate predominantly as one band of protein (Fig. 1, channel 3). An arrow indicates the position of sensitive enzyme expected from the location of activity in channel 3a and in the gel pattern of 30 previously studied hæmolysates from sensitive persons. Elutions from serial sections of gel from another channel, containing 0·52 unit of sensitive enzyme, revealed the relative location of activity to be identical to that of the smaller amount of enzyme in channel 3a. The total activity of sensitive enzyme added to channel 3 was almost one-third that of the normal enzyme in channel 1. About a ten-fold difference in specific activity exists between hæmolysates of normal subjects and sensitive Negroes. If this difference were due largely to a difference in turnover number, the arrowed position in channel 3 should have shown a band of protein staining several times more intensely than that of the normal enzyme.

Titration of the enzymes with reduced triphosphopyridine nucleotide (TPNH) offers additional evidence against a ten-fold difference in turnover numbers. TPNH fluoresces when excited with light of 360 mμ wave-length. The fluorescence of TPNH bound to human G–6–PD is

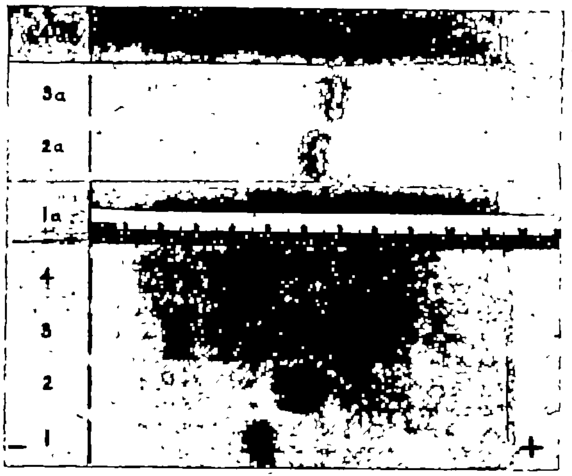

Fig. 1. Location of human hæmoglobin and G-6-PD on starch gel after vertical electrophoresis. First gel. 1 and 4, 37 μg of hæmoglobin; 2, 33 μg (3 1 units) of G-6-PD from normal males; 3, 98 μg (0·89 unit) of G-6-PD from primaquine-sensitive males. Second gel: 1a and 4a, 31 μg of hæmoglobin, 2a, 0·01 μg (0·97 × 10⁻³ units) of G-6-PD from normal males; 3a, 0·11 μg (1·02 × 10⁻³ units) of G-6-PD from primaquine-sensitive males. Channels 2a and 3a were stained for activity of G-6-PD. All other channels were stained for protein with amido-schwartz. Relative distance in the second gel should be corrected for shrinkage of gel in amido-schwartz solvent, resulting in the slightly greater length of channels 2a, 3a

		Estimate of total TPNH bound			
0·088		0·44		0·35	

Fluor. represents fluorescence emitted at 460 mμ wave-length by 0·1 ml. of sample excited by light of 360 mμ wave-length (ref. 8). Fluorescence is corrected for change in volume caused by the (5 μl.) additions. G-6-P, TPN and TPNH are expressed as total millimicromoles added. The end-point of each titration is taken from the intersection of the initial slope with a straight line drawn through the final readings (refs. 8 and 9).

Sensitive: 0·35 mg (0·384 unit) of G-6-PD with a specific activity of 1·1 units/mg. Normal: 0·045 mg (2·96 units) of G-6-PD with a specific activity of 66·0 units/mg.

approximately 2·7 times more intense than that of free TPNH[8]. Serial addition of small amounts of TPNH (or TPN in the presence of excess G–6–P) to normal enzyme previously stripped of TPN disclosed that normal G–6–PD binds approximately 0·14 × 10^{-8} moles of TPNH per unit of activity[8]. The results in Table 1 indicate that the sensitive enzyme binds 0·23 × 10^{-8} moles of TPNH per unit. In an earlier experiment, apparently irreversible loss in activity of the sensitive enzyme occurred during preliminary removal of TPN by the usual washings[8] with 2·7 M ammonium sulphate and dialysis against 0·05 M *tris* (hydrochloric acid), *p*H 8·0. The number of washings and duration of dialysis were halved. Consequently, TPN was not completely stripped from the normal preparation simultaneously studied (Table 1). Nevertheless, a ratio of 0·15 × 10^{-8} moles of TPNH bound per unit of activity can be computed for this normal preparation by assuming that the rise in fluorescence after G–6–P represents bound TPNH with 2·7 times the fluorescence of free TPNH. A similar ratio (0·12 × 10^{-8} moles per unit) is obtained by titrating the normal preparation with TPNH in the absence of G–6–P.

Activities of the sensitive enzyme following dialysis, purification, or mixing of purified sensitive G–6–PD with sensitive hæmolysates, offer no evidence of a reversible inhibitor of G–6–PD in sensitive hæmolysates. We therefore conclude that the deficiency of activity in erythrocytes of sensitive Negroes is due principally to a deficiency in number of molecules of G–6–PD. These findings do not permit a distinction between a deficiency due to increased destruction[10] or due to impaired synthesis of the active enzyme.

We thank Dr. F. L. Scharf and personnel of the Blood Bank for their co-operation. This work was supported by a grant (*A*–3823) from the U.S. Public Health Service and by funds from the National Foundation.

Effects of Colchicine and Colchemid on Synthesis of Deoxyribonucleic Acid in the Skin of the Guinea Pig's Ear *in vitro*

COLCHICINE and colchemid have been used extensively *in vivo* and *in vitro* as a means of halting cells at metaphase in order to make the counting of mitotic figures easier. It is generally assumed that both have a fairly specific action in this respect, although colchicine is considered to be more toxic to the whole animal than colchemid. Experiments were performed to determine whether colchicine and colchemid, at the concentrations normally used, had any direct and immediate action on the initiation and rate of DNA synthesis in guinea pig epidermal cells as measured by tritiated thymidine and autoradiography, since any such effect would alter the number of cells collected at metaphase.

Slices of skin were taken from the dorsa of the ears of albino guinea pigs, and were floated on 1 ml. of a medium of Hanks's *B.S.S.* and horse serum in the proportion of 3 to 2, containing tritiated thymidine 0·3 μc./ml. (specific activity 360 μc./μm). Skin slices from the same animal were incubated for 1–4 h in an atmosphere of 5 per cent carbon dioxide in oxygen on this medium and the medium containing either colchicine or colchemid at concentrations of 4–12 μg/ml. Autoradiographs were afterwards made of sections prepared from the skin slices, with Kodak *AR* 10 stripping film, and exposed for 3–7 days. They were developed and stained through the film with Harris's hæmatoxylin and basic fuchsin[1,2].

It was found (Table 1) that the colchicine-treated samples showed a significantly lower proportion of labelled epidermal cells even after incubation for 1 h, the mean per cent reduction being 13·2 ± 2·4. The colchemid-treated samples were not significantly different from the controls. When the skin slice was incubated in the colchicine for 2 h and the thymidine added for a further 2 h, the depression was 14 ± 0·9 per cent. When the colchemid was similarly used, there was no depression. Some experiments with colchemid which had been stored in solution at 4° C for some three months suggested that under these conditions it caused slight inhibition. Increasing the concentration of colchicine from 4 μg/ml. to 12 μg/ml. increased the percentage depression to 24 per cent in 1 h. With 12 μg/ml. colchemid, there was 10 per cent depression at 1 h.

Table 1. EFFECTS OF COLCHICINE AND COLCHEMID 4 μG/ML. ON THE PROPORTION OF CELLS IN DNA SYNTHESIS DURING 1 H *in vitro*

Colchicine				Colchemid			
Animal No.	Percentage of positive cells Control	Percentage of positive cells Colchicine	Depression (%)	Animal No.	Percentage of positive cells Control	Percentage of positive cells Colchemid	Depression (%)
1	10·6	8·8	17	9	7·7	8·2	−6
2	10·9	8·8	19	10	6·9	7·0	−1
3	10·8	10·8	0	11	7·5	8·0	−7
4	10·6	8·3	22	12	6·0	5·5	8
5	10·9	8·8	19	13	5·6	5·2	7
6	9·2	8·0	13	14	5·4	5·2	4
7	9·0	7·9	12	15	5·3	5·0	6
8	8·1	7·8	4	16	5·1	4·7	8

Grain counts over 300 labelled cells per section indicated that colchicine caused a significant mean depression of 14·5 ± 2·2 per cent during 4 h. The reduction in grain count caused by colchemid was not significant (6·5 ± 0·48 per cent).

The appreciable drop in the number of cells engaged in synthesis of DNA as a result of incubation for 1 h with colchicine may represent cells being arrested in the *S* period with an incomplete replication, or failure of cells newly arrived at this stage to start synthesis. The depression of grain counts per positive cell indicates that the rate of synthesis is slowed so that even if the normal DNA complement were to be reached the number of cells arriving at metaphase per unit time would be less. Since these two effects are cumulative it follows that the counting of metaphases after colchicine 'block' is very likely to give an underestimate of mitotic activity. Colchemid would appear to suffer less from these disadvantages, but nevertheless before using it for this purpose it would be wise to exclude any such effects under the actual conditions of the experiment.

A Comparison of the Plasma Proteins of C_3H Strain Mice, found by Cellulose-Acetate and Starch-Gel Electrophoresis

THIS experiment described here gives a comparison of the plasma protein patterns found with two electrophoretic techniques—those using cellulose-acetate and starch-gel as supporting media. The plasma used was that obtained from adult C_3H strain mice.

The zone electrophoresis method of Kohn[1] for cellulose acetate was used with the buffer modifications recently described by Aronsson and Grönwall[2]. The dimensions of the acetate strips were 18 × 5 cm. A voltage gradient of 6 V/cm was applied across the strip and a running time of 20 h was allowed. Staining of the strips was effected with lissamine green. A ribbon of acetate was cut from the main acetate strip, fixed immediately at 110° C for 10 min and afterwards stained in the dye for 10 min. This enabled localization of the protein bands on the remaining parent strip to be made. The full remaining pattern was then sectioned into three segments, each containing one of the three main fractions. Each segment was cut into six small ribbons which could then be inserted into the same slot of a starch-gel plate. The technique for starch-gel electrophoresis described by Smithies[3], with the slightly modified discontinuous buffer system of Poulik[4], was usec The electrophoretic run was made in a borate buffer of *p*I 8·6 at 6 V/cm for 15 h. The starch-plate had the dimen sions of 27 × 18 × 0·6 cm. Staining was made witl amido black 10 *B*.

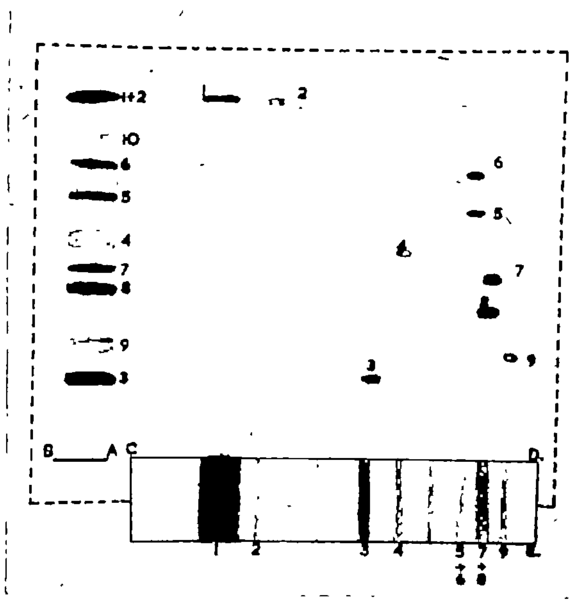

Fig. 1. Diagrammatic representation of two-dimensional electrophoresis in cellulose-acetate and starch-gel media. *AB*, Origin of control C_3H serum in the starch-gel, *CD*, origin of acetate ribbon in the starch-gel; *DE*, origin of original C_3H serum on acetate ribbon. Fractions: 1, albumin; 2, α_1-globulin *B*, 3, $S\alpha_2$-globulin; 4, β-globulin *A*; 5, fast haptoglobin group; 6, $F\alpha_2$-globulin, 7, β-globulin *B*, 8, β-globulin *C*; 9, slow haptoglobin group, 10, an α_1-globulin which has not been located on the acetate

Fig. 2. Two-dimensional pattern of C_3H serum in cellulose-acetate and starch-gel media. The photograph was taken with transmitted light, thus giving a greater resolution of the fainter fractions. This method gave, however, a diffuse picture of the control serum and so a normal C_3H serum pattern, taken with direct light, is interposed on the right of the figure. *AB*, Origin of normal C_3H serum; *CD*, origins of acetate ribbon and control serum in the starch-gel. Fractions: 1, albumin; 2, α_1-globulin *B*; 3, $S\alpha_2$-globulin; 4, β-globulin *A*; 5, fast haptoglobulin group; 6, $F\alpha_2$-globulin; 7, β-globulin *B*; 8, β-globulin *C*; 9, slow haptoglobulin group; 10, an α_1-globulin which has not been located on the acetate

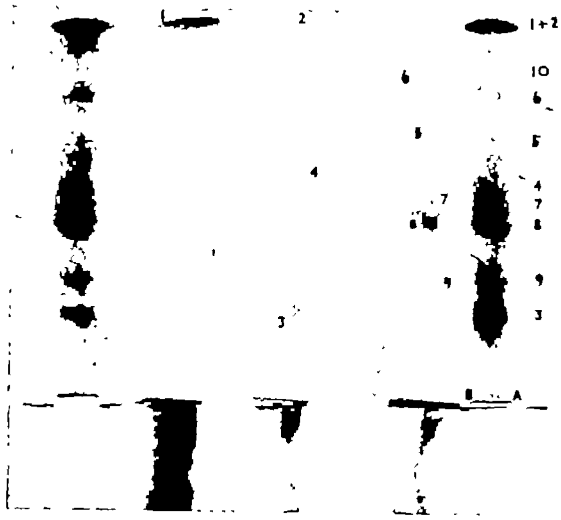

Fig. 3. Two-dimensional pattern of C_3H serum in cellulose-acetate and starch-gel media. The acetate strip can be seen to have been sectioned into three, each section being inserted into the starch at a different point. *AB* is the origin of the control serum in the starch-gel. Fractions: 1, albumin; 2, α_1-globulin *B*; 3, $S\alpha_2$-globulin; 4, β-globulin *A*; 5, fast haptoglobin group; 6, $F\alpha_2$-globulin; 7, β-globulin *B*; 8, β-globulin *C*; 9, slow haptoglobulin group; 10, an α_1-globulin which has not been located on the acetate

A comparison of the plasma protein pattern of th acetate with that of the starch was made possible by thi two-dimensional system. The comparison was based o the proteins having the same mobilities off the acetat strip into the starch as they have off the filter-paper whic was used in application of the control plasma. Fron Figs. 1, 2 and 3, the identity of the acetate fractions ca be made out, and their sequence compared with that o the starch. The most striking difference is the reversa in positions of the $S\alpha_2$-globulin (fraction 3) and th β-globulin complex (fractions 4, 7, and 8). The $S\alpha_2$ i shown to form the second main fraction on the acetate while on the starch it is the slowest-moving fraction, apar possibly from the γ-globulins, for which no evidence ha een obtained. The $F\alpha_2$ is identified with acetate fraction , which is located in the same acetate band as fraction 6, ut forms the more anterior portion of the band. Fractions and 9 are interpreted as haptoglobulins, but this still mains subject to question. Fraction 9 might also be terpreted as an α_2–β type globulin, similar to that escribed by Poulik and Smithies[5], for human serum. raction 2, which has the same mobility as the main lbumin band, is identified as an α_1-globulin. The fact at it has exactly the same mobility as the albumin ould suggest it to be similar in nature to the α_1-globulin of Poulik and Smithies.

Effect of Linoleic Acid on the Deposition of Dietary-saturated Fatty Acids in Chicken Tissues and Eggs

KAUNITZ *et al.* have postulated that linoleate functions 1 the regulation of fatty acid composition of depot fat by acilitating the laying down of depot fat more representaive of the diet[1]. In confirmation of their report, we have bserved that the depot fat of chickens fed a diet with 5 er cent laurate and 4 per cent myristate contained igher proportions of these fatty acids when linoleate was dded to the diet[2]. However, we could not adequately neasure the effect of linoleate on the proportion of laurate nd myristate in other, non-adipose tissues. In the work escribed here 12 per cent methyl laurate was included in a urified diet (diet *C*-21, Table 1) with and without a ource of linoleate. The diets were fed to 7-day-old chicks naintained previously on a low fat diet. At several timentervals the chickens were fasted overnight, killed, and he liver and heart analysed for fatty acids using gas hromatography[3].

Table 1. EXPERIMENTAL DIETS

§ Registered trade-mark of the Monsanto Chemical Co. for 6-ethoxy, 2-dehydro, 2,2,4-trimethylquinoline (an anti-oxidant).

In a second experiment, White Leghorn hens were fed , purified basal diet (diet *C*-20–*G*-5, Table 1). Two levels f methyl myristate were added with and without a ource of linoleic acid. Eggs were collected after 112 days n this régime and analysed for fatty acids. Five or six eplicates per analysis were conducted.

The results given in Table 2 demonstrate that the liver nd heart of chickens fed diets containing linoleic acid ontained a higher proportion of laurate than chicks fed inoleate-free diets. Dietary linoleate resulted in an ncreased proportion of myristate in eggs laid by hens fed nyristate. One would expect an increased proportion of laurate and/or myristate in tissue lipids if addition of linoleic acid resulted in: (1) increased absorption of dietary laurate and myristate from the intestine; (2) decreased oxidation of these fatty acids; (3) altered membrane permeability in ovary, liver, or heart cells resulting in greater uptake of laurate and myristate from the blood.

Table 2. EFFECT OF DIETARY LINOLEIC ACID ON THE DEPOSITION OF SHORT CHAIN FATTY ACIDS IN TISSUES

Tissue	Duration of feeding (days)		Dietary linoleic acid* 0%	1·5%
		% of diet (*C*–21)	Lauric acid % of tissue fat†	
Liver	4	11·4	0·3 ± 0·2	0·9 ± 0·5
Liver	30	11·4	1·2 ± 0·2	3·8 ± 0·8
Heart	12	11·4	2·0 ± 0·5	5·0 ± 1·9
		% of diet (*C*-20–*G*-5)	Myristic acid % of egg fat	
Egg	112	0·9	2·2 ± 0·3	5·1 ± 1·8
Egg	112	14·1	10·9 ± 0·5	26·0 ± 3·2

* 2·0 per cent safflower was the dietary source of linoleic acid, 12 per cent methyl laurate the source of lauric acid and 1·0 and 15·0 per cent methyl myristate the dietary source of myristic acid.
† Average ± *S.D.* The addition of linoleic acid resulted in a significant ($P < 0·01$ by *t* test) increase in deposition of lauric or myristic acid in all comparisons.

Mead *et al.*[6] have reported that essential fatty acid deficient mice oxidize stearate at a higher rate and incorporate less stearate in their tissue lipid than mice fed a source of essential fatty acids. More work is necessary before the biochemical mechanism underlying the change in saturated fatty acid composition following ingestion of linoleate can be defined.

Distribution of Radioactive Sulphur after Oral Administration to the Rat of a Water-insoluble Fraction of Sulphur-35-labelled Thermal Amino-Acid Copolymer

THE preparation of amino-acid copolymer labelled with sulphur-35 by thermal polymerization of hydrolysates of yeast (*Torula utilis*) incubated with $^{35}SO_4$ has already been described by us[1]. The polymerization resulted in at least two different types of copolymers. One part of the preparation was absolutely insoluble in distilled water, while the other part could be dissolved in water. Both fractions showed protein-positive colour reactions and radioactivity.

By chromatography on ion exchange columns ^{35}S-activity could be observed at the positions of cysteic acid (sulphate) and methionine. The radioactivity of the cystine peak was very low. Another radioactive component could be eluted from the 150 cm 'Dowex 50' column by 0·2 N sodium hydroxide. This component could also be detected in hydrolysates of ^{35}S-labelled *T. utilis*[2].

We ourselves have reported recently on a feeding trial using the soluble fraction of proteinoid. In further experiments the water-insoluble fraction of proteinoid was collected and administered to a rat. The male rat had a weight of 85 g at the beginning of the experiment. The animal was kept in an air-tight cage in which a separate collection of urine and fæces was possible. The air passed through the cage by suction was filtered through traps to remove gaseous metabolites from the air.

The rat received food and water *ad libitum*. The diet consisted of 86 per cent maize, 10 per cent skimmed milk powder, 3 per cent mineral mixture *U.S.P. XIV* and 1 per cent of a vitamin mixture essential for rats.

The water-insoluble proteinoid fraction was suspended in 0·2 N sodium phosphate buffer *p*H 6·8. Twice daily 0·5-ml. portions of this suspension were applied to the rat by tube. The experiment was continued for 28 days. During this time the rat showed normal behaviour; the increase in weight was 90·5 g. 24 h after administration of the last ^{35}S-proteinoid portion the animal was decapitated. The macroscopic inspection and the histological examination indicated no abnormal change in organs or tissues.

The components labelled with sulphur-35 in blood, liver, kidneys and brain were separated by 20 per cent trichloroacetic acid into a protein-containing fraction and a non-protein fraction. Each of these fractions, as well as the rest of the tissues and the excrements, were hydrolysed with 6 N hydrochloric acid and the activity of sulphur-35 was determined in the manner already described[1]. Moreover, hydrolysates of urine and fæces were chromatographed on ion exchange columns and the activity of sulphur-35 of the effluent was registered continuously[3]. The specific activity of other tissue hydrolysates was too low for chromatography.

The results of the determination of activity of sulphur-35 are summarized in Tables 1 and 2.

Table 1. DISTRIBUTION OF ACTIVITY OF SULPHUR-35

(Percentage of recovered activity)

	In hydrolysate	In hydrolysate residue	Total
Body	1·14	1·44	2·58
Intestinal tract content	0·21	0·22	0·43
Fæces	12·05	76·45	88·50
Urine	7·73	0·63	8·36
Air			0·13

Table 2. DISTRIBUTION OF ACTIVITY OF SULPHUR-35 IN RAT BODY

(Percentage of recovered activity of the body)

	Non-protein fraction	Protein fraction	Total
Blood	8·21	28·68	36·89
Liver	7·99	1·05	9·04
Kidneys	1·93	1·70	3·63
Brain	5·87	0·81	6·68
Skin and hair	—	—	13·56
Intestinal tract	—	—	3·79
Rest of body	—	—	26·41

Table 1 shows that the main part of the administered sulphur-35 activity is excreted in the fæces. When the sulphur-35 activity of the stomach-intestine content is added to the radioactivity of the fæces the results indicate that about 89 per cent of the radioactive material was not absorbed, while about 61 per cent of the water-soluble fraction was absorbed[1]. Most of the absorbed radioactivity of the insoluble proteinoid fraction was excreted in the urine, so that 2·58 per cent only of the total activity was retained while 34·35 per cent of the radioactive sulphur could be found in the body in the case of the soluble fraction[1].

These results indicate that the water-insoluble fraction can be utilized essentially less by the rat than the soluble fraction.

Table 2 shows that most of the radioactivity in the body was found in the blood. The liver contained the highest amount of radioactivity of the organs analysed. When sulphur-35 content is calculated on the basis of the weights of the organs, the brain yielded the highest rate of radioactivity. While the protein fraction of the blood showed more radioactivity than the protein-free fraction all the other organs indicated reversed proportions.

Chromatography of hydrolysates of fæces showed the same elution pattern of radioactivity as the proteinoid administered. The chromatograms of urine, however, showed only one radioactive peak, situated directly behind the 'hold up volume' of the columns containing a mixture of ninhydrin-positive components, probably cysteic acid, other acid sulphur-components and sulphates. Consequently the absorbed part of ^{35}S-proteinoid fraction applied must have been included in the intermediat metabolism.

We thank Dr. Sidney W. Fox, Institute for Space Bi sciences, Florida State University, Tallahassee, Florid for his advice in the course of this work.

Spectrophotometric Micro-Estimation of some Simple Plant Amines

VERY little is known about the mode of origin of th simple amines in higher plants. Stein von Kamienski[1] an Guggenheim[2] have reviewed the biosynthesis of amines i plants. Work in this laboratory[3] has indicated tha *N*-methyl ethanolamine may be a precursor of methyl amine in *Mercurialis perennis* L. Alternatively methyl amine may arise by decarboxylation of glycine. Evidence for the occurrence of amino-acid decarboxylases i plants is scanty[4–7], but recent work by Simon[8] has show the presence of a valine decarboxylase in the spadix o *Arum maculatum* L.

1-fluoro-2,4-dinitrobenzene (FDNB) has been used as quantitative reagent for the determination of histamine[9,1 and *d*-deoxyephedrine[11]. This reagent has been used i studies on the ion-exchange chromatography of some o the simpler plant amines. The method used was substantially as reported by McIntire *et al.*[11] with the followin modifications. Aliquot volumes of 1 ml. of each amin could be dealt with provided that 0·1 ml. of the FDN reagent was used, followed by 1 ml. of sodium bicarbonate The resulting 2,4-dinitrophenylamines were extracted int 10 ml. of *sym*-tetrachloroethane, followed by a furthe portion of 10 ml. of the solvent to remove turbidity. Th optical densities were determined in a Unicam *S.P.* 500 using the tungsten 1 amp, 1-cm silica cells, slit-width 0·04–0·09.

Table 1

Amine	λ_{max}(mμ)	μmole at λ_{max} E 1 cm
Ammonia	335	0·112
Methylamine	352·5	0·832
Ethylamine	352·5	0·902
Ethanolamine	352·5	0·839
Isoamylamine	352·5	0·863
Isobutylamine	352·5	0·859
β-Phenyl ethylamine	352·5	0·771
Dimethylamine	377·5	0·924
Diethylamine	385	0·774
N-Methyl ethanolamine	377·5	0·845
Putrescine	355	1·121
Cadaverine	355	1·451
Dimethyl ethanolamine	—	—
Trimethylamine	—	—
Choline	—	—
Betaine	—	—

Table 1 shows the absorption maxima of the simple amines which have been reported in higher plants[1,2,12–14]. The optical densities given result from the 2,4-dinitrophenyl derivatives of µmolar quantities of the amines in a total 20 ml. of solvent.

The 2,4-dinitrophenyl derivatives of the following amino-acids: glycine, L-valine, L-alanine, L-lysine, L-leucine, DL-serine, L-threonine, DL-glutamic acid, L-arginine, DL-methionine, L-proline, L-histidine, L-ornithine, in quantities of 100 µg, were insoluble in *sym*-tetrachloroethane and therefore gave no absorption at 352·5 mµ. Similar quantities of DL-phenylalanine and L-tyrosine, however, gave absorbancies of 0·012 and 0·070 respectively.

This method makes possible the direct determination of nine production in the presence of amino-acids and there- re possesses advantages over previously reported ethods[15,16]. A further advantage of the method is that is possible to estimate methylamine and *N*-methyl hanolamine simultaneously in mixtures of the two by termining the optical densities at the respective absorp- on maxima and substituting in the following equations:

$$\text{Methylamine} = \frac{(0{\cdot}080 \times E^{377\cdot5}) - (0{\cdot}112 \times E^{352\cdot5})}{-0{\cdot}00186}\,\mu\text{g}$$

$$\text{-methyl ethanolamine} = \frac{(0{\cdot}268 \times E^{377\cdot5}) - (0{\cdot}142 \times E^{352\cdot5})}{0{\cdot}00186}\,\mu\text{g}$$

ixtures of different known concentrations of the two mines were examined by this method. Results from ten ich mixtures gave only 2·5 per cent error for each of the wo amines.

The method has been particularly useful in studies on he ion-exchange chromatography of plant amines, since was found that, using the method of Blau[17] with columns f 'Amberlite *CG*-50' and 'Permutit *ZK*-226', the peaks f methylamine and *N*-methyl ethanolamine showed close roximity under certain conditions. Furthermore, the nethod is being used in studies of the metabolism of these wo compounds in *Mercurialis perennis* L., *Nicotiana ibacum* L., and *Elodea canadensis* Michx.

I thank Dr. B. T. Cromwell, under whose supervision his work is being carried out, Dr. J. Friend for many elpful suggestions, and the Agricultural Research ouncil for financial assistance.

Enhancement of the Effect of Prednisolone by 2-Methyl-1,4-naphthoquinone

IN conjunction with the microbiological transformation of steroids, small ring compounds were found to inhibit the breakdown of sterane structure. Since this phenomenon was encountered in the case of both fungi and bacteria[1–4], the idea presented itself that this biochemical observation might be of more general validity. We therefore undertook to investigate the influence of 2-methyl-1,4-naphthoquinone (MNQ), found to be the most efficient by ourselves, on the effect of prednisolone in various pharmacological tests.

In these studies we used three methods: the thymus involution and liver glycogen tests, and the antiphlogistic action, generally used for the pharmacological evaluation of glucocorticoids, with the modifications devised by ourselves[5].

The experiments consisted of administering prednisolone itself in two doses in a ratio of 1 : 3, and then studying how far the effect of the smaller dose of prednisolone could be enhanced by the aid of simultaneously applied MNQ. Untreated animals and groups given only MNQ were used as controls. In all the tests, both prednisolone and MNQ were injected subcutaneously; in case of concurrent use, from separate syringes at different sites.

The results of tests for thymus atrophy are given in Table 1. Thymus atrophy was more marked with animals given small doses of prednisolone (P) and MNQ than with those given three-fold amounts of prednisolone alone; hence the effect was intensified to more than three-fold. It may furthermore be seen that in itself MNQ was completely without effect.

Table 1

No.	No. of animals	Treatment	Thymus (mg %)
1	12	0·9 mg P	134
2	12	0·3 mg P	170
3	12	0·3 mg P + 0·06 mg MNQ	116
4	12	0·06 mg MNQ	225
5	12	control	222
		$P_{2-3} < 0{\cdot}001$	
		$P_{1-3} > 0{\cdot}05$	

Table 2

No.	No. of animals	Treatment	Liver glycogen (mg %)
1	7	0·45 mg P	1,660
2	7	0·15 mg P	259
3	7	0·15 mg P + 0·0075 mg MNQ	198
4	7	0·15 mg P + 0·075 mg MNQ	1,840
		$P_{2-4} < 0{\cdot}01$	
		$P_{1-4} > 0{\cdot}2$	

Table 3

No.	No. of animals	Treatment	Paw volume (mm³)
1	40	2·4 mg P	305
2	40	0·8 mg P	350
3	40	0·8 mg P + 0·2 mg MNQ	240
4	40	0·2 mg MNQ	422
5	40	control	431
		$P_{1-3} < 0{\cdot}01$	
		$P_{2-3} < 0{\cdot}001$	

The liver glycogen tests were undertaken with two doses of MNQ in an attempt to enhance the effect of prednisolone. As shown in Table 2, the smaller dose was completely ineffective, whereas the larger dose of MNQ, similarly to the results of the thymus tests, increased the effect of the smaller dose of prednisolone to such an extent as to cause the formation of larger deposits of liver glycogen than did three-fold doses of prednisolone alone.

Table 3 presents the results obtained by tests for antiphlogistic action. As demonstrated by our findings, MNQ alone practically failed to exert any influence on œdema due to dextran. On the other hand, when added to prednisolone, MNQ strongly intensified the effect of the latter; administered simultaneously with MNQ, 0·8 mg/kg of prednisolone inhibited the development of œdema induced by dextran much more efficiently than did 2·4 mg of prednisolone in itself.

According to our results, the efficiency of prednisolone is significantly intensified by concurrently administered MNQ. Attempts to elucidate the mechanism responsible for this action are now being made.

Isolation of Lampterol, an Antitumour Substance from *Lampteromyces Japonicus*

AN intensive screening of about 600 mushrooms for antitumour substances[1] revealed that *Lampteromyces japonicus*, a bioluminescent mushroom which grows on rotten beech in October, possessed high activity. The mushroom is also known for its toxicity, which has occasionally caused fatal accidents due to its similarity in appearance to edible mushrooms. Isolation of the toxic principle in a semi-pure state was reported by Nakai in 1958 [2].

We have been carrying out isolations of the antitumour and toxic principles, respectively, by different methods, the former being checked by the cell–agar-plate[3] method and the effect on Ehrlich mouse ascitic tumour, and the latter by injection into ordinary mice. However, at the final stages of fractionation it became clear that the two activities were due to the same substance. A preliminary account of the extraction of the crystalline substance, which we wish to designate 'lampterol', is given here. A total of one ton of the fresh mushroom was collected in Yamagata (Mogami), Aomori (Towada), and Shizuoka (Fuji) Prefectures, and these were: (1) boiled for 10 min in water; (2) steamed for 20 min; (3) or soaked in methanol, at the site of collection in order to prevent the marked loss in activity which was encountered with dried mushrooms.

Processing of the initial material treated by method (1) was as follows. The boiling-water extract (10 kg) from a batch of 150 kg of mushrooms was concentrated *in vacuo* to 500 ml., and the residual syrup was treated with a three-fold amount (volume) of methanol to remove mannitol. The methanol filtrate was concentrated at 50°, the residue (190 g) was made into a 500 ml. aqueous solution, and this was defatted by several extractions with petroleum ether. The aqueous layer was extracted repeatedly (eight times) with the same volume of butyl acetate, and the combined butyl acetate extract was concentrated *in vacuo* to give 12·34 g of residue. This residue was mixed with 5·0 g of 'Sephadex *G*–25', placed on top of a 2·5 × 10 cm 'Sephadex' column, and eluted with 1 l. water. The combined eluate was passed through an 'Amberlite *CG*–45' column (2·5 × 20 cm) to remove acids (mostly succinic acid), and the eluate was concentrated *in vacuo* below 50° to yield 2·54 g of dried residue. The residue was chromatographed on a 1·8 × 21 cm silicic acid partition column, using water-saturated ether as the solvent. The eluate was again submitted to silicic acid partition chromatography and eluted with chloroform–ether mixtures (1 : 0, 1 : 1, 1 : 4, 0 : 1).

The activity was found in the chloroform–ether (1 : 4) eluate, which when dried up *in vacuo* gave 500 mg of a yellow gum. Crystallization of the gum from methanol and finally from benzene afforded, after some difficulty, crystalline 'lampterol', m.p. 124°–127°; the yield from the gum was about 20 per cent; found: C, 67·47; H, 7·39. $C_{15}H_{20}O_4$ (the molecular formula was based on analyses and nuclear magnetic resonance spectra of 'lampterol' and derivatives); requires: C, 68·16; H, 7·68 per cent. λ_{max}^{MeOH} 235, 320 mμ (log ε 4·10, 3·54); ν_{max}^{KBr} 3,300 (broad), 1,698, 1,660, 1,602 cm^{-1}. The acetate was easily prepared by treating the gum with pyridine and acetic anhydride, m.p. 102°; found: C, 65·74, H, 7·17. $C_{19}H_{24}O_6$ requires: C, 65·50; H, 6·94 per cent. λ_{max}^{MeOH} 227, 245 infl., 313 mμ (log ε 4·08, 4·02, 3·54); ν_{max}^{KBr} 3,540, 1,740 shoulder, 1,731, 1,698, 1,666, 1,603 cm^{-1}; NMR, two acetate peaks at τ 8·02 and 8·03 in carbon tetrachloride. Passage of 'lampterol' through an alumina column converted it into 'isolampterol', m.p. 179°–180°; found: C, 67·62; H, 7·28. $C_{15}H_{20}O_4$ requires: C, 68·18; H, 7·63 per cent. λ_{max}^{MeOH} 252 mμ (log ε 4·31); ν_{max}^{KBr} 3,400 (broad); 1,697, 1,645, cm^{-1}.

The activity of 'lampterol' was 120 γ/kg as measured b the effect on Ehrlich mouse ascitic tumours, and th toxicity was 5 mg/kg on intraperitoneal injection int ordinary mice. More detailed animal tests are bein carried out.

We wish to acknowledge Dr. S. Inagaki, Nakamur Chemical Company, Tokyo, for providing us with th material used in the very early stages, and Mr. N. Suzuk for valuable assistance. We are also indebted to the Taked Pharmaceutical Company for concentration of crud extracts.

PHYSIOLOGY

Progestational Activity of 4-Hydroxy-17-Alpha-Acetoxyprogesterone

RECENT biological research in the field of the gestagens has been directed at finding out new compounds having oral progestational activity but lacking virilizing effects on fœtuses.

Since dioxyprogesterone (4-hydroxy-17-α-acetoxyprogesterone) has such properties, we summarize here such properties of this new derivative.

Progestational activity was determined by evaluation of the endometrial proliferation according to McPhail[1] in immature female rabbits primed with œstrogens and treated subcutaneously or orally with the different compounds.

In Table 1 are presented the relative potencies of the tested steroids, calculated according to Gaddum[2] at two dosage-levels.

Table 1. PROGESTATIONAL ACTIVITY OF DIOXYPROGESTERONE

Steroid	Route	Relative potency
Progesterone	s.c.	1
Dioxyprogesterone	s.c.	4·73
17-α-Acetoxyprogesterone	os	1
Dioxyprogesterone	os	5·50
17-α-Ethynil-19-nortestosterone	os	8·00
9-β,10-α-pregna-4,6-dien-17-α-ol-3,20-dione 17 acetate	os	< 0·3
17-α-Allyl-17-β-hydroxy-oestr-4-ene	os	2·18
17-α-Acetoxyprogesterone-3-cyclopentyl-enol-ether	os	2·07
6-α-Methyl-17-α-acetoxy-progesterone (MAP)	os	51·28

Progesterone is assumed as standard for the subcutaneous treatments and 17-α-acetoxyprogesterone for the oral administrations.

As is shown in Table 1, dioxyprogesterone has a good subcutaneous and oral progestational activity; orally it is less active than MAP, but definitely more active than other compounds recently described. Furthermore, dioxyprogesterone induces endometrial proliferation in rabbits after local intrauterine application of 20 μg. The progestational activity of dioxyprogesterone is also shown by the increase of uterine carbonic anhydrase activity in immature female rabbits primed with œstrogens, according to Lutwak-Mann and Adams[3]: at a total dose of 0·5 mg, it ncreases carbonic-anhydrase activity to 68·8 U/g and at the total dose of 1 mg to 94·7 U/g (activity of control animals: 13·7 U/g).

At 1–2 mg/day subcutaneously injected dioxyprogesterone shows a deciduomatogenic activity in ovariectomized rats[4] of the same order of that of progesterone.

Dioxyprogesterone maintains pregnancy in ovariectomized mice at a subcutaneous dose of 5 mg/day (97 per cent foetuses alive at the end of pregnancy) and in ovariectomized rabbits at the oral daily dose of 10 mg (63·5 per cent of foetuses alive).

While most progestins virilize foetuses, dioxyprogesterone does not influence the ano-genital distance or causes morphological changes in the secondary sexual characters of female and male rats born from mothers treated from the 15th to the 20th day of pregnancy with doses up to 50 mg day subcutaneous or *per os*. Dioxyprogesterone presents no androgenic or myotrophic properties both by oral or subcutaneous route[5]. It does not increase the weight of the uterus of young immature female mice. Its anti-oestrogenic activity[6] is about 0·89 times that of progesterone and its anti-gonadotrophic effect[7] is only 0·08 times that of testosterone propionate (subcutaneous administration).

Up to a dose of 5 mg/day both by oral and subcutaneous route, dioxy-progesterone does not alter the oestral cycle n normal female rats.

It does not possess any corticoid effects (survival of adrenalectomized rats, liver glycogen deposition, anti-inflammatory properties, sodium-retaining activity).

Effect of Posterior Pituitary Polypeptides on the Flow of Urine after Injection in Lateral Ventricle of the Brain of a Cat

Previous observations in this laboratory have ndicated that the injection of catecholamines and certain posterior pituitary polypeptides into the lateral ventricle of the cat is associated with characteristic and drug-specific pressor–depressor responses of the peripheral circulation[1]. During the course of these earlier experiments, it was noted that the intraventricular introduction of posterior pituitary polypeptides was followed by a prompt increase of flow in urine. Other observers have reported that the peripheral administration of various posterior pituitary preparations may, on occasion, be attended by a rise of urine flow consequent to a solute diuresis[2,3]. The present experiments were designed to define certain aspects of the 'diuretic' effect of these drugs during their central administration.

Using standard renal clearance techniques, acceptable experiments were obtained in 30 healthy cats maintained on normal diet of cat chow. Appropriate local anaesthetic techniques were used in place of general anaesthesia. After curarization of the animal, respiration was maintained with a positive-pressure respirator through a tracheotomy tube. After surgical exposure of the urethra, an indwelling Foley catheter was placed in the bladder under direct vision in order to secure complete bladder emptying. A constant infusion of creatinine via the femoral vein was maintained after the initial dose. When creatinine equilibration occurred, control clearance periods of 5–20 min were obtained. Control rates of flow of urine were differed by changing the rate of infusion of creatinine. When the flow of urine was stabilized at a constant rate, the drugs were injected into the left lateral ventricle via a 21 tapered needle inserted under stereotaxic control. Sandoz *L*8 vasopressin (10–15 units), Sandoz *PLV*2 vasopressin (0·5–1·0 unit), surgical pituitrin (1·0–3·5 units), oxytocin (0·5–1·5 units), and hypertensin Ciba (0·005 mg) were used and after drug injection additional clearance periods were obtained.

Blood samples were drawn at the mid-point of every third clearance period for the determination of creatinine, osmolality, sodium, potassium and chloride. Similar measurements were performed on each urine sample. Blood pressure and pulse were recorded at appropriate intervals throughout the study. Respirations were constant at the rate of 24/min. Calculations of creatinine clearance, osmolar clearance, and either free-water clearance or T_cH_2O were made for all clearance periods.

The *L*8 vasopressin was associated with a significant rise of urine flow and no change was noted with *PLV*2, surgical pituitrin, oxytocin and hypertensin. It appears that this effect is most evident after administration of the *L*8 vasopressin at low rates of urine flow. In most studies, the increased urine flow was accompanied by an increased osmolar clearance which could be attributed to an increased excretion of sodium. Since filtration-rate and plasma sodium usually remained unchanged or decreased slightly, the observed solute diuresis may be tentatively attributed to a diminished tubular re-absorption of sodium. This effect could not be prevented by prior trans-section of the spinal cord at the *C*-1 level. Peripheral administration of the same amounts of *L*8 vasopressin under similar conditions of study was followed by the usual antidiuretic response unassociated with changes of electrolyte excretion.

Additional studies are still in progress to evaluate the exact nature of this *L*8 vasopressin 'diuretic' effect more conclusively. Tentatively, the present findings suggest that the central administration of this drug produces renal effects which are dissimilar to those obtained after the peripheral administration of identical amounts of drug. Although the stimulus may be mediated via the nervous system, further studies are needed to evaluate the relative roles of neural and humoral factors to its occurrence.

Relation between Calcium Ions and the Action of Serotonin on a Fundus Strip of the Rat

According to Gaddum[1] and Vane[2] serotonin added to the medium in which smooth muscle is suspended causes muscular contraction. The mechanism of the action, however, is not understood. In the mechanical response of isolated muscle, changes in the membrane permeability and ionic movements are supposed to be involved. Some observations support the view that ionic movements across the cell membrane establish a binding chain between events which occur in the cell membrane and the contractile system of the muscle fibres[3,4].

It was found that binding of calcium ions by sodium ethylenediamine tetraacetic acid (NaEDTA) (Na_2H_2-EDTA·$2H_2O$) may lead to blocking of the action of serotonin on the isolated rat uterus. It is believed that serotonin acts by carrying calcium ions across the cell membrane of the smooth muscle fibre[5].

We have therefore examined the effect of calcium ions on the action of serotonin in the isolated stomach strip of the rat[4]. The fundus strip was immersed at 37° C in a bath containing 6–7 ml. Tyrode solution with 0·1 per cent glucose. A rapid stream of pure oxygen was bubbled through the bathing fluid. Contractions of the muscle strip were recorded by isotonic lever on a kymograph. Test compounds (serotonin, acetylcholine, potassium chloride, NaEDTA, CaEDTA) were added in a small volume to the bathing solution while it was in contact with the tissue. NaEDTA was neutralized to *p*H 7 before adding by 2 N sodium hydroxide. The contraction was allowed to develop for 90 sec, then the bath was washed out and a weight was added to the lever so that it came to the former baseline immediately. After 30 sec the extra weight was removed and the muscle was allowed to rest for a further 2 min. The following contractions were examined in 4-min cycles.

The effects of NaEDTA (3 mg/7 ml. and 6 mg/6 ml.) were similar to those found on the rat uterus[5]. NaEDTA added to the solution 1 or 2 min before the addition of serotonin, according to the concentration used, decreased or fully inhibited the activity of serotonin (0·03 μg 5-HT/6 ml.). NaEDTA alone, especially in higher concentration (6 mg/6 ml.). evoked contraction which was very fast (lasting about 20 sec), and which was followed by relaxation although NaEDTA was still present in the solution. The next contraction produced by serotonin was, in the presence of NaEDTA, remarkably smaller. When NaEDTA was washed out (after 2 min action on the muscle) the serotonin activity returned to its former level and there was no irreversible damage of the muscle fibres. It was also possible to remove the blockage of serotonin contractions (0·1 μg/7 ml.) caused by NaEDTA (6 mg/7 ml.) by adding calcium ions (3·6 mg $CaCl_2$/7 ml.) to the bathing solution. Calcium not only removed the blockage, but also strongly potentiated the sensitivity of the muscle toward serotonin.

This action of NaEDTA cannot be explained by isolation of the calcium ions present in the bath fluid only. This view is supported by the failure to obtain large changes in serotonin activity in the modified Tyrode solution where calcium ions were omitted. NaEDTA also blocked under these conditions the response of the muscle to serotonin. It thus seems probable that the action of NaEDTA may be associated with its direct effect on calcium present in the cell membrane.

The relation of calcium ions to the action of serotonin was confirmed in further experiments on the effects of CaEDTA. This salt which is not able to isolate calcium ions had no effect on the sensitivity of the fundus strip to serotonin. The dose of CaEDTA tested was 4·1 mg/7 ml. of the Tyrode solution. Response of the fundus strip preparation to serotonin under various experimental conditions is qualitatively presented in Table 1 (blockage of serotonin activity indicated by minus sign).

Table 1

Suspension fluid	Test compounds		
	Control	NaEDTA	CaEDTA
Normal Tyrode solution	+	−	+
Tyrode solution without calcium ions	+	−	

Further results were in agreement with Woolley[5] that the action of NaEDTA is not a specific one. NaEDTA also blocked the response of the stomach preparation to acetylcholine and potassium.

According to these observations the close relation between calcium and serotonin activity has been confirmed. It seems, however, that the mode of serotonin action cannot be interpreted by getting the calcium across the cell membrane only as was suggested by Woolley[5] working on the isolated rat uterus.

Antagonistic Action of Urokinase to Bradykinin- and Plasminogen-induced Capillary Permeability

Previously we reported observations on the inhibitory action of fibrinolysin and streptokinase, as well as of other proteolytic enzymes, on capillary permeability induced by different mediators in rats and guinea pigs[1,2]. These findings led to investigations on urokinase and plasminogen. We used the blueing reaction, a semi-quantitative test, in these animals and found in control studies that urokinase did not induce capillary permeability. The failure of plasmin to induce capillary permeability was already published by Bhoola, Calle and Schachter[3], and we could confirm this both with streptokinase and chloroform activated fibrinolysin (plasmin). We have now found that urokinase behaves in a similar manner. In control experiments using buffered plasminogen, we found that it produced the opposite effect to that obtained with fibrinolysin, streptokinase and urokinase, respectively.

Guinea pigs and rats under sodium pentobarbital anaesthesia were used. The skin on the ventral side was closely shaved for intradermal injection of 0·02 ml. volumes with No. 30 gauge needle. Intravenous injection of Evans blue was used for the blueing reaction followed by intradermal injection of bradykinin or plasminogen and/or the intravenous injection of urokinase with subsequent intradermal testing. The diameter and intensity of the blue lesion at the site of injection, due to the dye from the leaking vessels, was recorded from its first occurrence until it attained its largest size. In charting the findings, we utilized a method similar to that used by Miles[4]. The mean values are derived from a minimum number of 8 lesions in not less than 4 animals.

Plasminogen prepared by Dr. D. L. Kline was buffered at *p*H 7·1 with 1-lysine hydrochloride, while the preparation made by Dr. W. Baumgarten contained phosphate buffer at *p*H 7·4. Both lysine and phosphate buffers, when used intradermally as controls, resulted either in a trace of blueing or in none at all. All our findings gave similar results in guinea pigs and rats.

The inhibitory action on capillary permeability induced by plasminogen was also examined in the capillary bed of the cremaster muscle of the rat, a preparation recently developed by Majno and Palade[5]. This qualitative test was used to see whether an entirely different capillary bed would yield similar results. This is the case.

In comparing Figs. 1 and 2, it can readily be seen that plasminogen is as effective in inducing capillary permeability as is bradykinin. The quantities used for the data presented in Figs. 1 and 2 are 0·2 mg plasminogen and 2 μg bradykinin, respectively. By reducing the amount of bradykinin to 0·2 μg its capillary permeability inducing effect corresponded to that produced by 0·025 mg. The inhibitory effect of urokinase was undiminished when the plasminogen or bradykinin was combined with 100

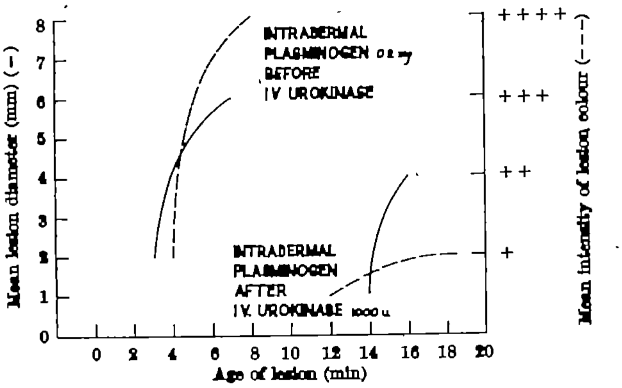

Fig. 1

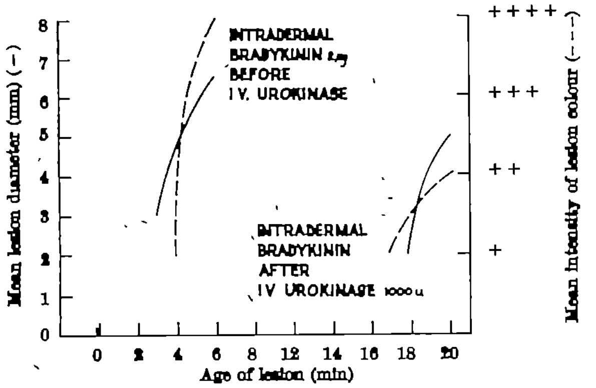

Fig. 2

Ploug units or equally following intravenous injection of 1,000 Ploug units. Figs. 1 and 2 follow the course of the actual experimental results.

Table 1 compiles our findings in guinea pigs and rats in which capillary permeability is induced with bradykinin and plasminogen before and after intravenous administration of urokinase. The differences between the maximum points of the graphs of all experiments described here are tabulated in an effort to establish certain patterns of response. Urokinase inhibits markedly the optimal development of lesions regarding the time, size and intensity induced by bradykinin or plasminogen with or without the mixture of urokinase in both species. In comparing the mean time of occurrence, bradykinin appears to be more inhibited than plasminogen, particularly in the guinea pig. Any change in comparing the mean diameter and intensity of colour in capillary permeability induced by bradykinin and plasminogen in the two species does not appear to be significant.

Table 1. Bluing Reaction induced with Bradykinin and Plasminogen in Guinea Pigs and Rats, before and after Administration of 1,000 Ploug Units of Urokinase per 100 g Weight

Intradermal agent	Animal	Differentials of optimally developed blue lesion		
		Mean time of occurrence (mm)	Mean diameter (mm)	Mean intensity of colour (deg.)
Bradykinin, 2 μg	Rat	14	1	+ + +
	Guinea pig	14	2	+ +
Plasminogen, 0·2 mg	Rat	11	2	+ +
	Guinea pig	9	2	+ + +
Bradykinin, 2 μg + urokinase, 100 u.	Rat	16	2	+ +
	Guinea pig	13	2	+ +
Plasminogen, 0·2 mg + urokinase, 100 u.	Rat	10	3	+ +
	Guinea pig	7	2	+ +

Comparisons are also shown in Table 1 between results secured with intradermally administered mixtures of urokinase with bradykinin or plasminogen, respectively. The mean time of occurrence is again higher with bradykinin than with plasminogen. The mean diameter and intensity of colour do not exhibit significant differences with the two substances.

The capillary permeability inducing action of plasminogen remains obscure. It may be due to contamination with bradykinin or similar mediators, or it may be due to a direct or indirect action of the plasminogen itself or some breakdown product. These considerations are at present under experimental study.

The inhibitory action of urokinase on capillary permeability is explained by the concept of Copley on the endothelial fibrin film modified recently[1,2] to include the basement membrane on the basis of electron microscopic observations by Majno and Palade[5]. Copley contends that a special kind of fibrin of sub-microscopic dimensions is a physiological constituent of the microstructure of the capillary wall, functioning as a vascular cement which coats the endothelial cells and is contained also in the basement membrane. In the capillary wall, fibrin deposition is controlled homeostatically by fibrinolysis which appears to act against mediators inducing capillary permeability.

HÆMATOLOGY

Anti-Js^b, the Expected Antithetical Antibody of the Sutter Blood Group System

The serum of Mrs. Y. M., a 34-year-old Memphis negress, was found to be incompatible with all donors cross-matched when she was admitted with vaginal hæmorrhage and hypofibrinogenæmia complicating the missed abortion of her eleventh pregnancy. After having five normal live births, her sixth pregnancy resulted in a macerated stillborn at eight months; the last five were missed abortions at four or five months, and hypofibrinogenæmia occurred with four of these. In the management of these pregnancies she was given 16 pints of blood between 1955 and 1957. No evidence of any transfusion reactions could be found in her hospital records.

The antibodies in her serum reacted strongly by the antiglobulin technique with all 20 cells of a highly selected panel of donors (Milwaukee Blood Center), but not with the patient's own cells. The reactions were less intense by Löw's papain method[1] and were not demonstrable by other commonly used procedures. The antiglobulin titre was 1:256.

Testing of the patient's red cells and subsequent family studies revealed her blood groups to be $O,MsMS^u$, P_1+, cDe, Lu^bLu^b, k^bk^b, Le (a−b+), Fy (a−b−), Jk^aJk^b, Di (a−), Js (a+). It was noted that the reaction with anti-Js^a was very strong and that all her four living children (the first had died in infancy) were Js (a+). At this point it was thought that the antibody might well be anti-Js^b. For this reason the serum was tested with the Js (a+), S^uS^u red cells of two sisters whom we had earlier believed to be homozygous for Js^a because dosage studies were suggestive and family investigations showed all 10 of their children to be Js (a+). Their red cells were found to be compatible with Mrs. Y. M.'s serum. Dr. R. Sanger and Dr. R. R. Race[2] kindly tested our patient's serum against the red cells of eight Js (a+) children from two Js (a+) × Js (a+) matings and found two of them to be negative or Js^aJs^a.

The identity of the antibody as anti-Js^b was further established by population studies. Eight of 705 Memphis negroes and none of 105 from Milwaukee were found compatible with the patient's serum. One of the Memphis donors gave weak reactions and since his red cells are the only ones possessing the Rh factor C we suspect the presence of anti-C in a titre of 1 : 16 by the antiglobulin test. It has not yet been possible to establish the identity of this second antibody. The specimens of one of the Memphis donors did not arrive in suitable condition for testing, but the other seven all reacted strongly with anti-Js^a. The probability of selecting seven consecutive Js (a+) negroes by chance would be 1 in 78,125. The incidence of eight non-reactors among the 810 negroes tested is equivalent to a proportion of 0·0099, which agrees well with Giblett's[3,4] estimate of 0·0106 for Seattle negroes ($\chi^2 = 0{\cdot}04$, $0{\cdot}9 > P > 0{\cdot}8$). No Js (b−) individuals have been found among 820 Caucasians tested.

We thank Drs. E. R. Giblett, R. E. Rosenfield and E. E. Muirhead for supplies of anti-Js^a serum.

Production of Specific Hæmagglutinins in Pigs after receiving Skin Homografts

SEVERAL workers have reported recently on the relationship of blood group differences to rejection of homografts. Silber *et al.*[1] state that they were unable to demonstrate any apparent relationship of rejection of graft to blood group compatibility in turkeys. On the other hand, Schierman and Nordskog[2] report that the locus of the B blood group system in chickens was involved in histocompatibility in this species. Production of anti-A hæmagglutinins by *CBA* mice after receiving skin homografts from A strain mice was observed by Micklem and Brown[3]. Griffiths and Crikelair[4] found that, in man, the titres of anti-A and anti-B were increased following skin homotransplantation from donors possessing the specific blood group substances.

A preliminary investigation of skin homograft reactions in pigs was carried out using a series of litters of various breeds. The purpose of these experiments was to ascertain whether the length of survival of homografts is affected by genetic differences demonstrable by erythrocyte antigen–antibody reactions. The possibility that epidermal cells carry some of the antigens present on red blood cells was investigated. The red blood cells of siblings were tested against a panel of antisera and the animals were matched in pairs showing one, two, or three blood factor differences, or no known differences. The antisera used for the blood typing of the animals were prepared by iso-immunization, with the exception of anti-A, which is a naturally occurring antibody in the pig. Reciprocal grafts were performed between pairs, and each animal also received an autograft. When an extra pig was available in a litter, an autograft was performed on it, also, to act as an additional control. Full thickness skin grafts, about 1 cm² in area, were made high on the shoulder, just lateral to the mid-line. This site was chosen because it was easily bandaged, and the grafts would not be readily damaged by the pigs rubbing against walls, etc.

In the first litters, surgical and bandaging techniques were not perfected and the autografts, as well as the homografts, were eventually sloughed. In later litters all autografts survived. Animals were bled before grafts were made and at regular intervals thereafter.

The first litter used in the experiment consisted of eight pigs. The homografts were all sloughed between the fourteenth and twentieth days. There was no apparent correlation between immune response and time of the rejection of the homografts.

Table 1 shows the blood group differences between pairs, and the antibodies, produced in response to skin homotransplants, which react with blood group antigens. Pre- and post-graft sera were tested by direct agglutination and antiglobulin methods against a panel of pig red blood cells for antibody specificity.

Five of the pigs produced antibodies and no antibody production was detected in the other three. Three of the recipients lacking the E^a factor received grafts from E^a positive donors. This factor is known to be strongly antigenic and is easily produced by iso-immunization with red blood cells. Two of the recipients, Nos. 486 and 491, produced anti-Ea, but no antibodies were demonstrated in the serum of the third pig, No. 488.

Table 1. IMMUNOLOGICAL RESPONSE OF RECIPIENTS TO BLOOD GROUP ANTIGENS OF SIBLING DONORS AFTER RECIPROCAL SKIN HOMOGRAFTS

(Breed: Large Black/Wessex Cross)

Recipient	Donor	Known red cell antigens present in donor and lacking in recipient	Antibody produced
486 ♀	492 ♂	E^a	E^a
492 ♂	486 ♀	None	None
488 ♂	489 ♀	E^a	None
489 ♀	488 ♂	K^a	Weak anti-L*
490 ♀	495 ♂	None	Anti-L (probably)*
495 ♂	490 ♀	None	Unidentified antibody
491 ♀	493 ♀	E^a K^a R	Ea
493 ♀	491 ♀	None	None

* New antibody—characterized afterwards.

The K^a factor is also known to be strongly antigenic, but neither of the recipients receiving grafts from K^a positive pigs responded to this antigen. No. 489 produced an antibody to a previously unknown antigen, but no anti-Ka. No. 491 produced only anti-Ea in response to a graft from No. 493, whose cells possessed three antigens not present on the recipients' red blood cells; E^a, K^a and R.

Nos. 489, 490 and 495 all produced antibodies in response to the homografts. In the cases of No. 490 and No. 495 there were no known antigenic differences demonstrable by red cell agglutination prior to skin transplantation. However, each produced an antibody after receiving reciprocal skin grafts. In order to identify the antibodies made by these pigs, intravenous inoculations were done, using the whole blood of the donor pig. Unfortunately, pig No. 495 died, but the cells of No. 491, which reacted with the unidentified antibody in the serum of No. 490, were used for inoculating pig No. 490. In both cases a strong antibody was produced which has been designated anti-L. After the transfusion of red blood cells, No. 489 made anti-Ka, to a lower titre, and No. 490 produced a second antibody which has not yet been characterized.

The second and third litters used in these experiments produced no antibodies. The fourth and fifth litters produced some antibodies in response to the skin homografts. In litter No. 4 there were seven pigs. One pig made a very weak antibody, specificity unknown; a second made a weak anti-G; a third, anti-Ea; the remainder failed to produce any demonstrable antibody.

Of the fifth litter, two pigs responded with a weak antibody and two showed no antibody response. In these two litters all autografts survived and hair growth was evident. Grafts were oriented with the hair growth going in the opposite direction to that of the host. By this method it was possible to identify growth of hair from the graft as opposed to that of the host.

To summarize the results, five litters of pigs were used in these skin-grafting experiments comprising a total of thirty-three pigs. Of these, three were used as controls, receiving only autografts. Three pigs died under anaesthesia. The remainder received autografts and homografts. Of the twenty-seven pigs receiving homografts, ten animals from three litters produced antibodies to red blood cell antigens in response to skin homografts from litter mates. Six of these antibodies were identified and four are of unknown specificity.

We thank Dr. A. J. Cawley and Dr. C. K. H. Roe for their assistance with the surgery in these experiments.

PATHOLOGY

Ontogenesis of Brain Thromboplastin and of Encephalitogenic Substance

THE accidental detection of the low thromboplastic activity[1] of encephalitogene-free vaccines from the brain of suckling rats produced in this laboratory against neuroviral infections[2] led us to a comparative examination of the ontogenetic development of thromboplastin and of the encephalitogenic substance.

The encephalitogenic activity of the cerebral substance was assayed by administering them together with the Freund adjuvant according to a technique described elsewhere[3]. The thromboplastic activity was assayed according to the modified[4] Quick method[5] from the clotting time of recalcified oxalated rabbit plasma on addition for 15 min at 58° of the centrifuged homogenate of the cerebral substance as thromboplastin. In addition thromboplastic activity was estimated from the time of clotting of heparinized plasma (antiheparin test).

A distinct parallelism will be seen in Table 1 in the development of thromboplastic activity and of encephalitogenicity of the albino rat brain in ontogenesis. The absolute values of thromboplastic activity vary from one experiment to another, in particular, according to the kind of plasma sample, and yet the thromboplastic activity of the brain of new-born rats is invariably lower than in adults. Similarly, the non-encephalitogenic brain of embryos and new-born rabbits and mice (not presented in Table 1) exhibits a lower thromboplastic activity than the adult brain. On the other hand, the encephalitogenic spinal cord of the new-born animals shows a high thromboplastic activity.

Table 1. THROMBOPLASTIC ACTIVITY AND ENCEPHALITOGENICITY OF THE ALBINO RAT BRAIN IN ONTOGENESIS

Age of rats (days)	Thromboplastic activity: With oxalated plasma (sec.)	Thromboplastic activity: With heparinized plasma (min)	Encephalitogenicity*
0	90–95	> 15	0/10
1	85–90	> 15	0/10
3	85–90	> 15	0/10
8	90–95	> 15	0/10

* Numerator indicates the No. of guinea pigs with clinical signs of experimental allergic encephalomyelitis; denominator, the No. of inoculated animals.

† Not tested.

The bovine spinal cord successively defatted by organic solvents, namely, acetone, benzene, ether, chloroform, methanol and ethanol, is devoided of any thromboplastic activity although it remains encephalitogenic. The collagen-like encephalitogenic protein prepared according to Roboz *et al.*[6] is likewise devoid of thromboplastic activity. On the other hand, various phospholipids isolated from the cerebral substance or synthesized exhibit the thromboplastic activity[7]. Although these substances are far from identical, namely, thromboplastin-lipid[7] encephalitogenic substance-protein[6], the appearance in the brain of encephalitogenicity coincides with an appreciable increase in its thromboplastic activity. These substances might possibly be constituents of the same macromolecular myelin structures.

In any event, the strict correspondence between encephalitogenicity and thromboplastic activity rendered it possible to use thromboplastic activity as an additional criterion for the allergen-free antirabies vaccine from the brain of rat sucklings. The low thromboplastic activity of this vaccine is by itself useful since the conventional antirabies vaccine of Fermi increases the clotting capacity of human blood.

With regard to the connexion between thromboplastic activity and encephalitogenicity, of interest are Allegretti's[8] recent results concerning encephalitogenicity of the pulmonary tissue which, along with the cerebral tissue, is known to possess the highest thromboplastic activity.

If Allegretti's results are confirmed they might cast new light on the concepts on the pathogenesis of demyelinizing allergic processes. In this case the initiation of such processes does not require any contact of lymphatic organs with the cerebral substance, while lesions of the pulmonary tissue, particularly in tuberculosis, might give rise to the process.

Tumour Induction in C_3H and Swiss *ICR* Mice by Tissue Culture Preparations of Polyoma Virus

'Plaque-purified' lines of polyoma virus are capable of inducing more than one type of tumour[1] and this property is neither strain- nor species-specific[2,3]. However, mice show a wider variety of tumours than other rodents, and although evidence for some strain specificity in mice has been presented[1], the incidence of parotid gland tumours has exceeded that of any other histological type.

In work on the oncogenic activity of polyoma virus for C_3H mice, the incidence of mammary tumours in this strain was observed to be higher than that previously found in Swiss mice inoculated with polyoma virus. The virus used in these investigations had been propagated in a cell line derived from a C_3H-mouse mammary tumour[4], and, therefore, a comparison of the oncogenic responses of C_3H and Swiss strains of mice to other preparations of virus was of interest.

Polyoma virus used was strain 1956 *8C* (supplied by Dr. Bernice Eddy, National Institutes of Health, Bethesda, Md.) further passed in this laboratory in cultures of either mouse mammary tumour cells[4] or primary cultures of C_3H or Swiss mouse embryo. Tissue cultures used to propagate viral stocks and to assay for virus infectivity were prepared by methods previously described[4].

Mice used were the Swiss *ICR* strain and the high mammary cancer C_3H strain (descended from C_3H/St) obtained from inbred stocks housed apart from inoculated animals. (Both strains were obtained originally from colonies developed by Dr. T. S. Hauschka, Roswell Park Memorial Institute, Buffalo, New York.) Animals were inoculated within 24 h of birth with 0·1–0·2 ml. of virus, deposited into the subcutaneous tissues of the back and head, as described by Stewart[5], and the sexes were separated. They were weaned when about one month old. To exclude mammary tumours occurring spontaneously in the C_3H strain, experimental observations were limited to virgin animals and were terminated 10 months after inoculation. Animals with tumours were killed, and their tissues removed for histological examination. Sera were tested for hæmagglutinin inhibitors to polyoma virus by the technique and criteria of Eddy *et al.*[6].

C_3H mice showed a higher incidence of tumours and a slightly shorter latent period of tumour development than *ICR* mice, with all virus preparations (Table 1).

The stunted growth and loss of hair reported previously for Swiss mice inoculated with potent virus preparations[2] were observed in some litters of both strains, and were more apparent during the first two to three weeks after inoculation. The stunting was not always seen in mice which later developed tumours; but stunted mice that survived weaning frequently developed early tumours.

Since the apparent difference in susceptibility of the two mouse strains could have been accounted for by the presence of antibodies passed to litters by mothers indirectly contaminated with polyoma virus, mice were selected from normal colonies of each strain and bled by cardiac puncture. When individual sera from old male and female breeders were tested for hæmagglutinin inhibitors to polyoma virus, antibody was demonstrated for 33 per cent of the C_3H mice and only 9 per cent of the *ICR* mice, which suggested that the greater resistance to tumour induction of the *ICR* mice was not due to the presence of maternal antibodies.

In the Swiss *ICR* strain used here, the incidence of polyoma virus induction of tumours is somewhat lower than the 80–100 per cent incidence observed in random-bred Swiss *NIH* strain[2,7]. A lower tumour incidence in *ICR* mice was also found by Mirand *et al.*[8] and by Howatson *et al.*[9]. The latter report attributed this finding to less carcinogenic activity in the variant strain of polyoma used; but it could also reflect genetic variation and differences in susceptibility among Swiss strains of mice.

Table 2 summarizes the numbers of neoplasms of various types revealed by histological examination of the tumour-bearing mice of each strain. Only the totals for each strain are tabulated, since the tumours induced by the different virus preparations did not differ significantly in frequency or type. The high incidence of mammary tumours in the C_3H mice with the virus preparations used in this work resembles our earlier observations when using virus propagated in C_3H-mouse mammary tumour cells. Although some tumour-type specificity was found by Dulaney and Goss[10] with cell-free extracts of tumours induced by polyoma virus, our findings lend some support to those of Winocour and Sachs[1], who showed that the probability of initiating a parotid tumour in mice is the same for polyoma virus recovered from mammary and renal tumour cells *in vitro* as for virus of parotid tumour origin.

In the Swiss *ICR* mice studied here, parotid gland tumours occurred more frequently than any other neoplasm. This has also been reported for $(AKR \times C_3Hf)F_1$ and other strains of Swiss mice[2,7]. However, in the C_3H mice, parotid and mammary gland tumours occurred with equal frequency, except that the frequency of mammary gland tumours was slightly higher in females. Although mammary cancer in C_3H mice has heretofore been limited to females, in the absence of œstrogenic stimulation, and

limited even in virgin females to those at least 10 months old, in this work 53 per cent of the tumours in the tumour-bearing C_3H males were tumours of the mammary gland. The possibility of a relationship between polyoma virus and the mammary-tumour (Bittner) agent present in this mouse strain was suggested by Sachs *et al.*[9].

Parotid gland tumours were found by Stewart *et al.*[5] in 96 per cent of the Swiss and $(AKR \times C_3Hf)\ F_1$ hybrid mice developing neoplasms induced by postnatal injection of polyoma virus, and such tumours exceeded all other types in incidence and extent of glandular involvement. Swiss mice inoculated *in utero*[7] showed a higher incidence of tumours and a shorter latent period than those inoculated as new-borns, but no marked difference in the frequency of histological types of tumour. Thus the selective site of tumour formation did not appear to depend on the state of cellular differentiation and development at the time of inoculation. It was concluded that the cells of the salivary glands either are more susceptible to tumour induction or had been more consistently exposed to the oncogenic inoculum by the method of inoculation used.

The present work, where C_3H mice inoculated by the same route developed mammary and parotid tumours with equal frequency, suggests that the vulnerability of individual host tissues to the oncogenic action of polyoma virus is a genetic feature of the host, and not entirely dependent on the localization of the inoculum.

IMMUNOLOGY

Immunological Investigations of Sheep Prolactin

ZONE electrophoresis on starch revealed that purified sheep prolactin contained, according to Cole and Li[1], three, and, according to Ferguson and Wallace[2], four, components. All these components were found to have biological activity when tested by the crop sac test in pigeons[3]. However, Reisfeld *et al.*[3], testing the biological activity of purified components, found one of these components to be a highly active prolactin, whereas the two further components were biologically less active; these authors considered the latter fractions altered the form of the active hormone.

In the work reported here the immunological properties of whole sheep prolactin (*NIH–P–S–3*) and its electrophoretic components were investigated. The immunological methods used have been described previously in detail[4]. On agar-gel electrophoresis sheep prolactin showed three components (Fig. 1). Component 1 corresponded to the mobility between β- and α-globulin, component 2 to α-2-globulin, and component 3 to α-1-globulin. Whereas components 1 and 2 stained strongly, component 3 was less distinct. As already shown by others[5], using starch electrophoresis, the electrophoretic mobility of the individual components of sheep prolactin resembled that of human growth hormone ($HGH{-}A_3$), but the latter hormone stained less intensively (Fig. 1).

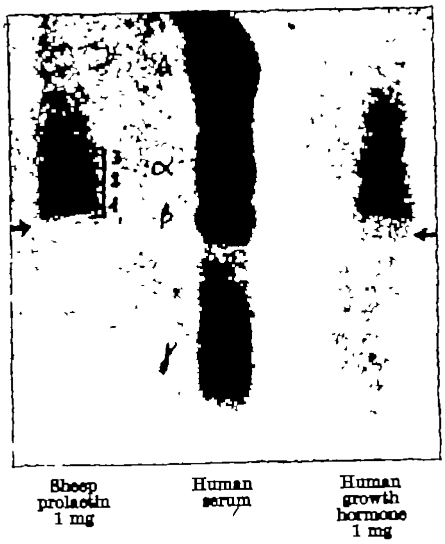

Fig. 1. Agar-gel electrophoresis of sheep prolactin and human growth hormone compared with human serum. Electrophoresis was run for 3½ h at 120 V and 80–90 m.amp. Arrow indicates origin. Stained with amido-black

Antiserum to sheep prolactin was prepared by immunizing rabbits weighing 2 kg in the following manner: 1·5 mg prolactin dissolved in 0·3 ml. sterile and pyrogen-free distilled water and mixed with 0·3 ml. complete Freund's adjuvant (Difco) (the prolactin was added dropwise during constant stirring) was injected intradermally into two foot-pads. Two weeks later the procedure was repeated injecting the two other foot-pads. After a further two weeks, 3·3 mg prolactin in 0·6 ml. water and mixed with an equal volume of complete Freund's adjuvant was injected subcutaneously. Two weeks after this subcutaneous booster, the rabbits were bled and the antiserum

titre was 1/2,500. When tested by agar-gel immunoelectrophoresis against its own antiserum, prolactin formed one precipitation arch (Fig. 2); showing that the preparation used was immunologically uniform and free of antigenically potent contaminants. Bovine growth hormone (*NIH–GH–B*$_2$) tested with the antiserum to sheep prolactin formed one precipitation line, corresponding to the level of prolactin. Bovine albumin (Armour Pharm. Co.) did not react with antiserum to sheep prolactin.

The immunological properties of the individual electrophoretic components of sheep prolactin were examined after their elution from the agar gel by a method described previously[6]. When tested by the agar-gel double diffusion test of Ouchterlony, using antiserum against whole sheep prolactin, the individual components formed one precipitation line. These lines were confluent between themselves and with the precipitation line formed by whole sheep prolactin indicating immunological identity. The bovine growth hormone preparation used formed one precipitation line confluent with the precipitation lines of sheep prolactin or its components. Bovine albumin did not react with the antiserum to sheep prolactin. Using the hæmagglutination technique[7] similar results were obtained. There was no interaction between human growth hormone or its electrophoretic components and antiserum to sheep prolactin or between sheep prolactin and antiserum to human growth hormone.

As shown by immunoelectrophoresis the precipitation line between bovine growth hormone and the antiserum to sheep prolactin occurred at the same level with the precipitation given by sheep prolactin, and not in the area of mobility of bovine growth hormone (midway between β- and γ-globulins), we think that the preparation of bovine hormone used was contaminated with prolactin. Our findings would therefore indicate that the electrophoretic mobility of bovine prolactin is identical to that of sheep prolactin. As a further proof for the immunological identity between the two prolactins is the confluency of the precipitation lines obtained by the Ouchterlony agar-gel double diffusion test (Fig. 3). It is noteworthy that sheep and bovine growth hormone have been found to be immunologically identical[8].

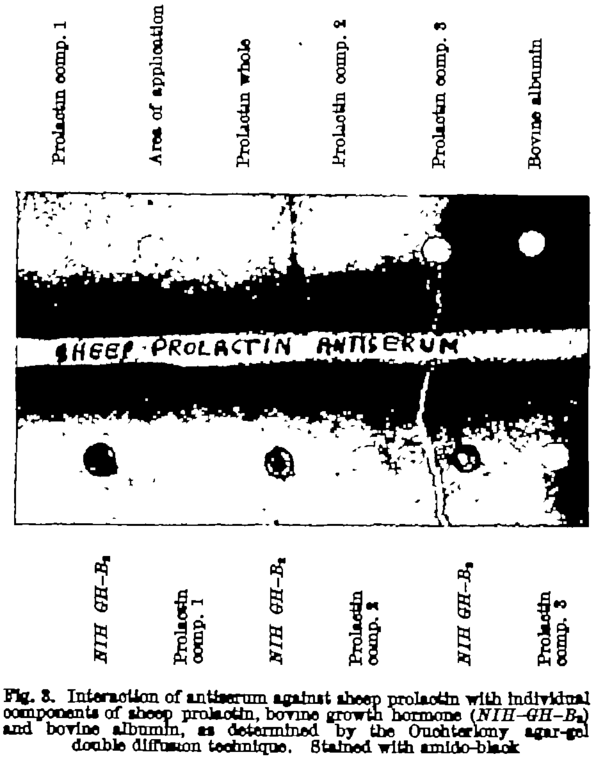

Fig. 3. Interaction of antiserum against sheep prolactin with individual components of sheep prolactin, bovine growth hormone (*NIH–GH–B*$_2$) and bovine albumin, as determined by the Ouchterlony agar-gel double diffusion technique. Stained with amido-black

In conclusion, the present work has shown that sheep prolactin is antigenically potent and that its electrophoretic components, though possibly differing in their biological activity, are immunologically identical. The immunological identity of bovine and ovine prolactins is also discussed.

The sheep prolactin (*NIH–P–S–3*) and bovine growth hormone (*NIH–GH–B–2*) were generously supplied by the Endocrinology Study Section, U.S. National Institutes of Health. The human growth hormone (*HGA–A*$_2$) and its antiserum used in this work were prepared in this laboratory[4].

Influence of Excess of Antigen on Immunological Tolerance in Radiation Chimæras

THE existence of a specific immunological tolerance towards host tissue antigens in radiation chimæras has been clearly demonstrated with different techniques[1-3]. Van Bekkum has shown that this tolerance is lost when the bone marrow of the chimæra is transferred to irradiated mice which carry antigens not related to the first host. A new tolerance was shown to develop towards the antigens of the new host which were not present in the original bone marrow donor. These findings seem to demonstrate that, for a maintenance of the tolerance, a continuous presence of antigens is required.

In this communication, results are given which show that maintenance of tolerance without excess of antigen is possible if not only bone marrow but also lymphatic cells are transferred. For these experiments long-term allogenic chimæras without clinical signs of secondary disease were chosen. In order to remove the antigen excess from the donor type lymphatic tissues in the tolerant chimæras, the bone marrow together with the lymphatic cells were transferred to lethally irradiated mice isogenic to the original bone marrow donor (Table 1). Chimærism was determined by agglutination of peripheral blood erythrocytes[4]. The cells transferred were tested with cytotoxic antisera[5] to ascertain the origin of the cells used (Table 2). After about 40 days the irradiated animals injected with the chimæric cells were grafted with skin, isogenic with the chimæra host strain, together with skin from a non-related strain. In Table 3 the results with different combinations are presented. In all chimæras the skin of the unrelated strain showed a somewhat prolonged survival which is in accordance with the results of Bridges *et al.*[6]. In 12 of 19 *CBA* mice which received $CBA \rightarrow (CBA \times C_{57}Bl)F_1$ chimæra bone marrow together with lymph node cells, tolerance was maintained during the whole observation period (Exp. No. 2). It could not be assumed that antigen excess was present in these animals. A second transfer of bone marrow and lymph node cells from these tolerant animals resulted in a prolonged rejection of the grafted skin, while one animal at the time of writing still carried a graft which showed no signs of rejection (Tables 1 and 3, Exp. No. 3).

No tolerance was observed in mice injected with lymph-node cells from $CBA \rightarrow C_{57}Bl$ chimæras. The cell transfer

‡ Between 116 and 134 days after skin grafting nine animals with normal looking skin grafts were killed for cell transfer. Histology revealed that in 3 grafts a low grade lymphocytic infiltration around the hair follicles was present. At the time of writing, 248 days after grafting, with the three remaining animals the grafts are intact but hairless and scaly.
§ One graft is normal with normal hair growth, two grafts are hairless and scaly.

procedure, however, caused a high lethality of the lymphatic cells from these chimæras.

The effect of chimæric spleen cells as compared with the effect of chimæric lymph node cells was difficult to evaluate because a very weak therapeutic effect against irradiation death could be obtained. In the few surviving animals no tolerance was observed. The exact cause of the failure of these chimæric spleen cells, to prevent irradiation death, is not yet determined.

It is concluded that when the lymphatic system of an irradiated allogenic animal is repopulated with cells from normal bone marrow, tolerance may only develop if sufficient antigens are present[1-3]. Transplantation of even a small number of normal lymph node cells always resulted in an immunological graft versus host reaction and a 'killing effect' of the host[6]. Transfer of bone marrow from a tolerant chimæra to an irradiated animal in which the specific antigens are absent results in a loss of this tolerance, and when excess of another antigen is present tolerance to this antigen may develop[3]. If, however, the lymphatic tissue is re-populated by cells derived from the lymph nodes of a tolerant chimæra, the tolerance in a number of cases is maintained without the continuous presence of the specific antigens. A factor which determines the success of the transfer of tolerance is the dose of lymph node cells. Their number should be far in excess of the bone marrow cell dose. A competition to re-populate the lymphatic tissues seems to exist between bone marrow and lymphoid cells.

In view of these results it is postulated that mouse bone marrow is a source of cells with a still-undetermined immunological function. These cells can develop either into immunologically active lymphoid cells, or into tolerant lymphoid cells when an antigen excess is present. On the other hand, the lymph node cells, which already have an immunological function, do not become tolerant in the presence of antigen excess but remain immunologically active. However, lymphoid cells, once tolerant, pass this tolerant state on to the daughter cells, so no antigen excess is needed to maintain this tolerance. A gradual replacement of tolerant cells in the lymphatic tissues by non-tolerant cells from the bone marrow may be responsible for the gradual loss of tolerance observed in some of these animals.

A part of this work was performed under contract with the European Atomic Energy Commission, 51–53 rue Belliard, Brussels, Belgium.

Immunization against Ehrlich's Ascites Carcinoma with Streptomycin Complexes from Tumour Cells

IT is well known that immunity to transplantable tumours can be produced by pre-treatment of animals with X-irradiated tumour cells[1] or with fractions of tumour cells[2]. Although such experimental observations have little or no direct application to the problem of human cancer[3] there may be some value in recording devices or methods for the preparation of antigenic fractions from transplantable tumour cells. This communication reports the observation that the complexes, which precipitate when extracts of osmotic-disrupted Ehrlich's ascites carcinoma are treated with dihydrostreptomycin, are antigenic.

The antigenic complexes were prepared in the following manner. Packed cells (20 ml.) were obtained by centrifugation (800*g*) of 110 ml. of pooled ascites exudate of 7-day tumour from 21 Swiss albino mice. The cells were washed with 80 ml. of cold water and then re-suspended in 250 ml. of water. After 2 h at 2° C. the suspension was centrifuged (8,000*g*) and the clear supernatant fluid was treated with dihydrostreptomycin to give a final concentration of 1,000 units per ml. The resulting precipitate was collected by centrifugation, and resuspended in 110 ml. of saline to give fraction 1. Fraction 2 was obtained by a second water extraction of the cell residue, followed by precipitation with dihydrostreptomycin and suspension in saline as described for fraction 1. The course of immunization consisted of intraperitoneal injections of 0·2, 0·4 and 0·8 ml. at successive 5-day intervals. One week after the last injection, all mice were challenged by intraperitoneal injections of fresh ascites exudate.

In several experiments, conducted in this manner, the controls invariably showed 100 per cent mortality within 1–3 weeks, whereas one or more treated animals survived. The number of treated animals which survived appeared to be related to the amount of challenging dose. In one

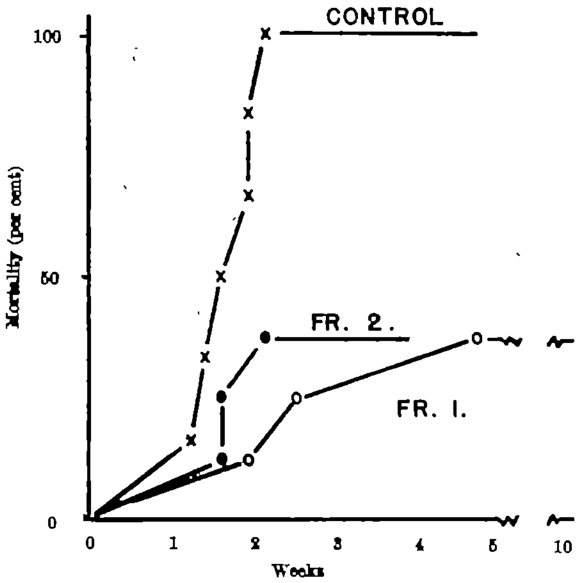

Fig. 1. Percentage mortality of mice receiving 0·2 ml. of a 1/100 dilution of 7-day tumour exudate. ×, Non-immunized controls (6 mice); ●, pre-treated with dihydrostreptomycin-complex, fraction 2 (8 mice); ○, pre-treated with dihydrostreptomycin-complex, fraction 1 (8 mice)

experiment in which all mice were challenged with 0·2 ml. of a 1/100 dilution in saline of fresh ascites exudate from a 7-day tumour, more than 50 per cent of treated mice survived for more than 10 weeks (Fig. 1).

Although the chemical nature of the cell material precipitable by streptomycin (or dihydrostreptomycin) is not known in detail, the work of Cohen[4] permits one to speculate that these fractions would be rich in nucleoprotein.

RADIOBIOLOGY

Retention in the Skeleton of Radiostrontium as Influenced by Tetracycline

SEVERAL recent investigations have directed attention to the influence of tetracycline on the metabolic behaviour of radiostrontium. The results, however, are ambiguous. In contrast to Nakatsuka *et al.*[1], who were not able to observe any significant effect, it was claimed by Ogawa *et al.*[2] that tetracycline administered immediately after radiostrontium injection prevents its skeletal deposition and enhances its urinary excretion. This effect was thought to be due to the chelating properties of the compound. Positive results were also obtained by Richards *et al.*[3]. Repeated daily doses of tetracycline—given 4 days prior until 24 days after the administration of radiostrontium—did not affect the initial deposition of radiostrontium, but rather accelerated its elimination from the bone. The treatment schedule used by the foregoing authors, however, does not permit deciding whether the pre-treatment, or post-treatment, or both, were responsible for the effect.

In order to elucidate this question, albino rats and mice, injected with tracer amounts of carrier-free $^{85}SrNO_3$, were treated with tetracycline hydrochloride (by courtesy of Farbenfabriken Bayer AG, Leverkusen) in different ways. The dosage of tetracycline was the same as that used by Richards *et al.*; it proved, however, to be toxic, and several animals died in the course of the experiment. Both femurs were ashed at 600° C and their activity assayed by use of a sodium iodide (Tl)-scintillation crystal. The strontium-85 content of the whole skeleton was assumed to equal the ten-fold activity of both femurs.

The results (Table 1) show that neither post-treatment nor the simultaneous administration of tetracycline gives rise to a reduced skeletal retention of strontium-85. On the contrary, one experimental series appears to indicate that the elimination of strontium-85 from the bone is inhibited. A significantly reduced deposition was achieved by tetracycline only if given prior to injection of strontium-85.

* Treatment was started 24 h after injection of strontium-85.

These findings make it unlikely that the effectiveness of tetracycline can be attributed to the chelation of radiostrontium. On the other hand, taking into account the pronounced affinity of tetracycline to bone tissue[4-7] (which is thought to be due to the formation of calcium chelates *in situ*[7]), we may tentatively assume that this reaction leads to an impairment of the mechanism(s) responsible for the retention of radiostrontium by bone. As to the mode of action, final conclusions can be drawn only if more detailed investigations on the effectiveness of different tetracyclines, dose dependence, time and duration of treatment, are made available. Such experiments are now under way and will be published elsewhere.

Effect of Thyroid Irradiation on the Release of Labelled Protein-bound Iodine in Rats

THE level of protein-bound iodine in the serum of rats was found to undergo significant changes within 24 h after their thyroids were irradiated internally by iodine-131 at total doses above 150,000 rads[1]. In subsequent studies, it was found that labelled thyroglobulin is released from the thyroid on internal irradiation with doses above 250,000 rads[2] and also at 130,000 rads[3]. No effect was, however, observed after the administration of 100 μc. iodine-131, which deliver to the thyroid a dose of about 15,000 rads[2,3]. Release of radioactivity from thyroids of dogs on external irradiation with 21,000 rads was also reported[4]. In experiments performed on animals so far, there is no evidence for an increase in the level of protein-bound iodine or in the release of thyroglobulin at doses lower than 20,000 rads. On the other hand, certain experimental results were reported which may indicate the release of thyroglobulin on irradiation even at lower

doses. It was shown by bioassay that the thyroxine content of thyroids of mice diminished after doses of total body irradiation as low as 50 rads[5]. A slight increase in the labelled protein-bound iodine was observed in rats at total body irradiation of 450 rads 48 h after irradiation[6]; this effect was, however, interpreted as being due to an enhanced turn-over. On the other hand, it was stated in another investigation[7] that the overall turn-over of the thyroid decreases on irradiation.

In clinical investigations, it was established that thyroglobulin is released into circulation as a result of therapeutic doses of internal irradiation[8]; the doses involved were of the order of 10,000 rads. In a recent clinical investigation, there are indications that some thyroglobulin is released at much lower doses (about 1,000 rads) and it was suggested that the extent of thyroglobulin release is not necessarily proportional to the dose of radiation[9]. It may be concluded that little information is available on the radiobiological behaviour of the thyroid gland on absorption of doses lower than 10,000 rads.

It was of interest to determine whether any increase in the rate of production of labelled protein-bound iodine occurs after local irradiation at doses lower than those cited here. It was possible to carry out this examination by the administration of repeated doses of iodine-132 and determining the protein-bound ^{132}I/protein-bound ^{132}I + iodine-132 at intervals. When the determinations were carried out at 24-h intervals, it was possible to determine the protein-bound ^{132}I level without interference of the labelled protein-bound iodine formed before. Next, it was possible to use a strontium-90 – yttrium-90 source for local external irradiation and iodine-131 as an internal source of radiation, and to determine by aids of iodine-132 the protein-bound ^{132}I level in serum. The iodine-131 present in the organism does not interfere with the radioassay of iodine-132 when carried out with a scintillation counter provided with an appropriate energy discrimination.

The experiments were carried out on groups of rats (5 rats per group). The rats were injected intraperitoneally 'carrier-free' iodide-131 or iodide-132 as necessary (iodine-132 was separated from an alumina column loaded with tellurium-132). One hour after injection of the iodide, blood samples were drawn from the tail. The serum was separated and the protein-bound iodine was precipitated by trichloroacetic acid. The iodide was then precipitated by silver nitrate and both protein-bound iodine and free iodine were radioassayed consecutively in a well-type scintillation counter. The butanol non-extractable fraction in the protein-bound iodine was determined by the conventional method, counting the protein-bound iodine first and the residual activity, after consecutive extractions with water-saturated *n*-butanol, thereafter. Wherever necessary, the measured activity was corrected for the decay of iodine-132. When the experiment was performed on rats containing iodine-131, care was taken to adjust the energy discrimination of the counting system so as to cut off any iodine-131 activity. The doses absorbed from iodine-131 and iodine-132 accumulated in the thyroid were calculated using the formulæ of Feller *et al.*[1]. External irradiations were carried out with a strontium-90–yttrium-90 source plated on a silver foil (8 × 8 mm); the foil was attached to the rats' necks by an adhesive tape for a pre-determined time. The source was calibrated by low-geometry β-counting and the absorbed dose rate at 5-mm depth was calculated to be 40 rads/h.

The experimental results presented in Table 1 show the protein-bound iodine-level in rats at different time-intervals after absorption of different doses of radiation. In the first two groups of experiments, iodine-132 was used both as an internal source of radiation and as an indicator of the extent of production of labelled protein-bound iodine within 1 h of injection. The fourth group of experiments summarizes the effect of external irradiation, whereas in the fifth group the thyroids were internally irradiated with an iodine-131 at a much lower dose rate than that of the external irradiations. It may be seen that previously intact animals form in 1 h about 3–5 per cent protein-bound iodine (Exps. 1, 6, 9, 12, 18) in the range of 20–2,000 rads, irrespective of the immediate dose absorbed (cf. Exps. 6, 12, 18 with Exps. 1 and 9). When examined 24 h after initial irradiation, a sharp rise in the labelled protein-bound iodine production rate is observed (Exps. 2, 7, 10). When the same rats were examined at 48, 72 and 96 h after irradiation, and the accumulated dose increased up to 21,000 rads (Exp. 5), there was no further increase in the rate of protein-bound iodine production. An almost analogous behaviour is observed at lower accumulated doses up to 3,000 rads (Exps. 7, 8; 10, 11; 16, 17).

At much lower doses (less than 1,000 rads), the increase in the rate of protein-bound iodine production depends on the administered dose; a similar effect is obtained whether the dose is given externally at a high dose rate (40 rads/min) or internally (less than 5 rads/h) (Exps. 13–16, 19–21). The extent of protein-bound ^{131}I production in 24 h, which was examined simultaneously with the protein-bound ^{132}I produced within 1 h, showed also a slight increase with absorbed dose (Exps. 19–21); this increase, however, is much less conspicuous, because a major part of the protein-bound ^{131}I present in blood at

24 h has been formed during the first hours after administration, that is, before any radiological changes have occurred.

The lowest dose of radiation which still was found to affect the rate of labelled protein-bound iodine production is less than 5 rads (Exp. 19; 50 rads is the accumulated dose over 24 h, but it should be remembered that the effects of radiation manifest themselves only a few hours after irradiation). This is of the order of magnitude of doses delivered to patients when determining the rate of formation of protein-bound iodine.

In one series of experiments (group 4) the butanol non-extractable fraction of the protein-bound iodine has been determined, and it was found to increase rapidly with the increase of absorbed dose (Exps. 12–16). This has been previously observed, but at one hundred-fold doses[8,9]. The question remains whether this observation is true also of the human thyroid; a clinical investigation has been undertaken in this laboratory to examine this possibility.

It may be concluded that a certain radiological damage is caused to the thyroid gland of rats at relatively low doses of radiation, of the same order of magnitude delivered by diagnostic tracer doses. This damage manifests itself by an increased production rate of protein-bound iodine which is of abnormal composition, containing substantial amounts of a butanol non-extractable component.

Genetic Effects of Strontium-90 Injected into Male Mice

IN estimations of the genetic risks from the fall-out after bomb-tests little attention has been paid to strontium-90. This is in fact remarkable since Mazia[1], as early as 1954, suggested that bivalent metallic ions are bound in the chromosomes. Steffensen and LaChance[2] have shown that strontium-90 is incorporated into chromosomes in *Lilium* and *Habrobracon*. Therefore it is desirable to examine the possible genetic consequences. As a first step to study the effects of strontium-90 on the chromosomes we have analysed the rate of intra-uterine death among offspring to male mice, which received intraperitoneal injections of strontium-90. Strontium could cause chromosome breaks in spermatozoa and spermatids due to the radiation emitted from the strontium circulating in the blood and the lymph. Furthermore, strontium-ions could be incorporated into the chromosomes and could there, also through the disintegration process, cause chromosome breaks which afterwards cause the death of a zygote.

In order to distinguish between these two processes, which are not mutually exclusive, we also examined the effects of injections with caesium-137, which within the animal emits most of its radiation energy through β-radiation, as does strontium-90. If at first the time that the isotopes are in the circulatory system is ignored one would expect about similar effects from caesium-137 and strontium-90. Since about half the amount of strontium-90 injected is incorporated into the bones within a rather short time, the dose delivered from the isotopes in blood and lymph would probably be reasonably higher for caesium-137 than for strontium-90. Hence, one would *a priori* expect a stronger effect of caesium-137 than from strontium-90 on the rate of intra-uterine deaths.

Table 1. EFFECT ON INTRA-UTERINE DEATH AFTER INJECTION OF CAESIUM-137 AND STRONTIUM-90 IN 4 AND 5 WEEKS RESPECTIVELY AFTER INJECTION

Treatment		No. of Dead	No. of Implants	% dead
^{137}Cs	18 μc.	216	2,161	10·0*
^{137}Cs	38 μc.	55	703	7·82
NaCl		188	2,078	9·05
^{90}Sr	18 μc.	987	8,051	12·26†
NaCl		690	8,848	7·80

* Caesium-137 18 μc. versus NaCl $\chi^2 = 1·1$; d.f. 1
† Strontium-90 versus NaCl $\chi^2 = 91·4$; d.f. 1

In these experiments animals from inbred *CBA* strain were used. The males were injected intraperitoneally with either 18 μc. caesium-137 or strontium-90. In one small series some males were given 38 μc. caesium-137. Each male was mated to three females within 1 h after the injection. Every 7th day the females were replaced by new virgins. After the mating period the females were stored until the 19th day following the start of mating and were then killed and the uterine content examined. Here only the results from the first 5 matings are presented. In the case of caesium-137 only 4 matings were performed. In all cases there were simultaneous controls where the males were given saline injections.

The results are given in Table 1 wherein the data are combined for all mating periods. From Table 1 it is evident that the injections with caesium-137 had no demonstrable effect as regards intra-uterine death. On the other hand, the material in the strontium series shows a marked increase compared with its control. Separation of the material into mating periods is presented graphically in Fig. 1 for caesium-137 and Fig. 2 for strontium-90. This reveals in both cases a peak in the 3rd week after

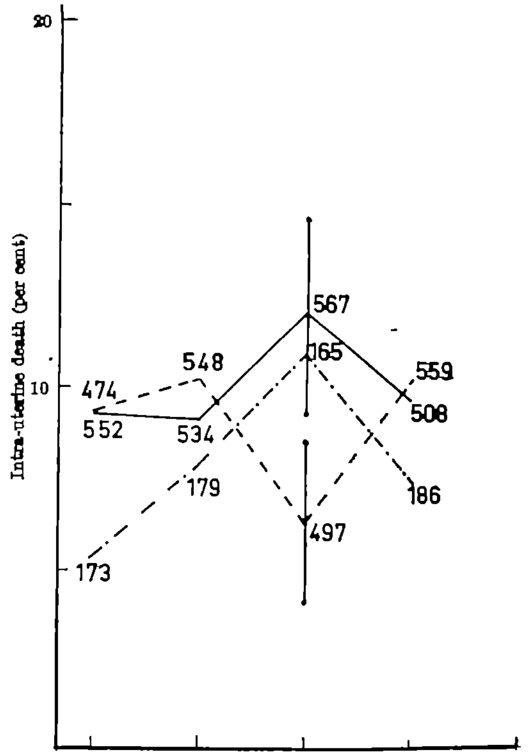

Fig. 1. Intra-uterine death in weeks after injection of caesium-137. Number of implants are given on the graphs. —, 18 μc. caesium; —·—, 38 μc. caesium; - - -, sodium chloride

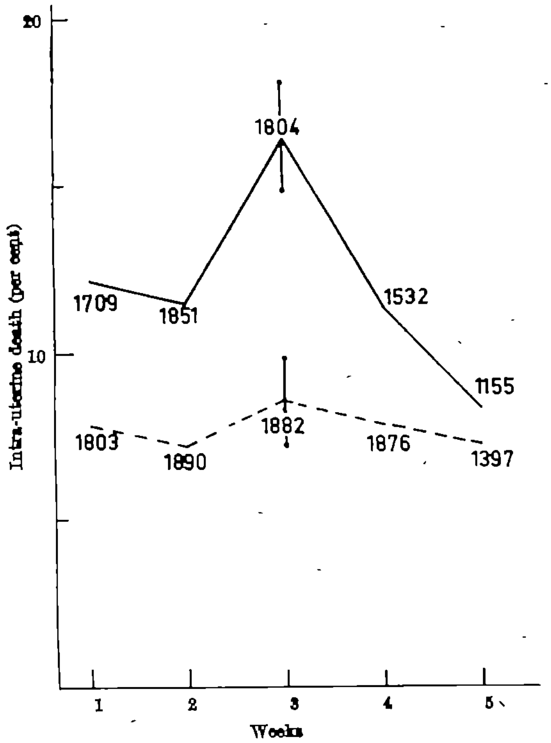

Fig. 2. Intra-uterine death in weeks after injection of strontium-90. Number of implants are given on the graphs. ——, 18 μc. strontium; – – –, sodium chloride

injection. This is similar to the results from X-ray experiments[3] when the peak also appears in the third week after treatment. It is supposed that this corresponds to the spermatid stage, which in *Drosophila*, too, is a very sensitive stage[4].

The aforementioned hypothesis about equal or stronger effect of injected caesium-137 compared with strontium-90 is not supported by the results presented here; rather the reverse. The effect of strontium-90 is much stronger than that of caesium-137. This could be explained if strontium-90, in agreement with Mazia's idea about divalent metallic ions, were incorporated into the chromosomes and, hence, could more easily cause chromosome breaks.

Since sperm used as early as the first week after the injection had a markedly increased rate of intra-uterine death, one would suppose that strontium-ions could penetrate the sperm and exchange with calcium-ions. If the process can go in that direction it may also revert. When the concentration of strontium in blood decreases due to incorporation of this element into bones and due to excretion in urine and faeces the strontium-ions in chromosomes could be replaced by calcium-ions.

In favour of this tentative hypothesis are the results from the fourth and the fifth weeks. During these weeks germ cells are used which at the time of the injection were in meiosis or prior to meiosis; in other words, stages where the chromosomes to be included in sperm are synthesized. If strontium-90 were incorporated stably in the chromosomes one would expect that during spermatid and spermatozoon stages disintegration would cause chromosome breaks that would cause zygotic death. The results show rather that during these periods the rate of intra-uterine death in the strontium-90 series is approaching that of the control.

If the incorporation of strontium-90 into the chromosomes were for a short time only, chromosome breaks induced in meiotic and pre-meiotic stages would be eliminated before being included in sperm. Hence, one would not expect any considerable effect of strontium-90 in sperm from weeks 4 and 5 after injection.

In order to examine further the effects of strontium-90 we have started one experiment with injections into females and in another we shall analyse the possible occurrence of recessive lethals in spermatogonia after injections of strontium-90.

Protein Nutrition and Radiation Damage in Mice

In the case of protein nutrition and irradiation, a few experiments have been reported but are not all in agreement. In the work reported here, experiments were performed to test the influence of protein content in the diet on the survival rate of γ-ray irradiated mice. The effect of protein was examined both before and after irradiation.

The experimental animals were young *d–d* colony male mice. Some animals were fed the basal standard diet (including 18 per cent of casein, 69 per cent of α-starch, 6 per cent of corn and liver oil, 1 per cent of Macoollum's salt mixture, 1 per cent of vitamin mixture and 2 per cent yeast powder), and others were fed the protein-deficient diet (casein was replaced with α-starch) for two or three weeks before radiation. Diets and water were given *ad libitum*. At the end of the period they were exposed to a single dose of 1,000 r. of whole-body γ-irradiation. The nutritional conditions afterwards were kept the same as before radiation. The control groups without irradiation served as references. The survival rate for two weeks after irradiation is given in Table 1.

Table 1. Effect of Protein Diet before Irradiation on the Survival Rate of Mice

Group No.	Diet groups Protein content of diet (%)	γ-ray radiation	No. of animals before irradiation	No. of animals survived two weeks after irradiation
1	6	+	25	0
2	6	—	24	24
3	18	+	25	3
4	18	−	25	25

In other separate experiments the effects of protein diets after radiation were examined. Mice were fed and irradiated as already described. Directly after irradiation, the diets were switched from low protein to standard and vice versa. The results are given in Table 2. Those of the control groups without change of diet as well as without irradiation are also shown in Table 2.

Table 2. Effect of Protein Diet after Irradiation on the Survival Rate of Mice

Group No.	γ-ray irradiation	Diet groups Protein content of diet before radiation (%)	Protein content of diet after radiation (%)	No. of animals before irradiation	No. of animals survived three weeks after irradiation
1	−	6	6	11	10
2	−	6	18	12	11
3	−	18	18	18	18
4	+	6	6	20	4
5	+	6	18	20	11
6	+	18	18	20	11

A favourable effect of protein enrichment after irradiation was demonstrated.

In the next series of experiments, the optimum amount of protein necessary after irradiation was studied. Experimental conditions were the same as described here.

Table 3. OPTIMUM AMOUNT OF PROTEIN NECESSARY FOR THE RECOVERY FROM RADIATION DAMAGE

		Diet groups

6	+	6	6	20	7
7	+	6	12	20	8
8	+	6	18	20	14
9	+	6	24	19	4
10	+	6	30	19	4
11	+	18	6	20	5

The results are given in Table 3. The 6–8 group showed the most favourable effects.

From these results it may be concluded that protein diet after, as well as before, irradiation had a pronounced influence on the mortality of whole-body irradiated mice, and that excessive supplement of protein after radiation produced unfavourable effects. Jennings[1] reported high susceptibility of protein-depleted rats to whole-body X-irradiation. His results were essentially in accordance with ours. Smith[2] observed little effect of protein reduction or enrichment after radiation, which was contrary to our results.

BIOLOGY

Occurrence of *Discocotyle sagittata* on Sea Trout

Discocotyle sagittata Leuckart is a well-known monogenetic trematode found on the gills of European salmonids[1–3]. So far as I am aware it has previously only been found on hosts caught in fresh water, and it is therefore of interest to record it from sea trout (*Salmo trutta* L.) caught in the sea.

During 1953–61 inclusive, sea trout caught by beach seine in Port Erin bay were examined for their ectoparasites. The gills of each fish were removed soon after capture and examined under a binocular microscope. The numbers infested with *Discocotyle* are given in Table 1.

Table 1. NUMBERS OF SEA TROUT INFESTED WITH *Discocotyle sagittata*

Sea trout examined		No. infested
Males	30	6 (20·0%)
Females	132	32 (24·2%)
Total	162	38 (23·5%)

The number of worms varied between 1 and 14 per infested fish with a mean of 4·2. Out of 151 worms, 117 (77·5 per cent) were on the first gill arch, 15 (9·9 per cent) on the second, 11 (7·3 per cent) on the third and 8 (5·3 per cent) on the fourth gill arch. Compared with the data given by Llewellyn and Owen[4] for *Discocotyle* on trout from fresh water, the percentage infestation is much lower, although the mean number of parasites per infested fish is much the same. Furthermore, at Port Erin a much higher proportion of parasites was found on the first gill arch.

There are insufficient data to distinguish definit seasonal fluctuations in the incidence of *Discocotyle*. Se trout were caught in all months of the year with a peak i spring, and although *Discocotyle* was recorded in al months except December–February inclusive, its absenc at that time may have been due to low fishing effort Specimens of *Discocotyle* were usually producing egg whenever they were found. The eggs appeared normal but attempts to hatch them in salt water or fresh wate were unsuccessful.

As it has now been found on hosts in both marine an fresh waters, it would appear that *Discocotyle* possesse osmoregulatory powers. It is also possible that we ar dealing with two closely related species, but I could fin no differences in whole mounts of *Discocotyle* from se trout caught in the sea and brown trout from fresh water Furthermore, Frankland[5] notes an instance of a rainbo trout which had been gradually acclimatized to sea water and which was found to harbour healthy specimens o *Discocotyle sagittata*.

Some simple experiments showed that *Discocotyle* i capable of osmoregulation. *Discocotyle* from sea trou survived for at least 48 h after direct transfer from se ($S = 34$ parts per thousand) to fresh water. In the revers case, however, a period of acclimatization may be necessary, for specimens of *Discocotyle* from fresh water brown trout did not survive transfer to full sea water, although they would tolerate 50 per cent sea water for at least 48 h.

Daily Age Markings on the Shell of Cuttlefishes

MUCH information concerning the growth of the shell in mollusca is available, and this indicates the close relation between growth of shell and physiological periodicity of the living body[1].

As was pointed out by Appellöf[2], Naef[3] and Yasuda[4], the formation of the stripe pattern on the shell of cuttlefishes shows a set periodicity. Yagi[5], who followed the growth of the shell stripe pattern of *Sepia esculenta* Hoyle, contends that, although the shell stripe pattern increases with the age, a double resultant sigmoid growth-curve holds (with age as the basis) good to this case, that is, that the periodicity of formation of shell stripe pattern is about 2 days at the stage immediately after hatching, 1·5 days at the most rapid growth stage and about 9 days at the latter stages of growth with less formative force. This gives an average of about 3·5 days throughout the whole period of growth. However, since Yagi's results are based on the assumption that the hatching date is July 1 for *Sepia esculenta* and that the environmental conditions are the same for all individuals, certain errors become involved.

Immediately after hatching, the cuttlefish has a frail shell. On the dorsum of the shell, there are observed a distinct Wurstlamellen, and, in the striated area of the ventrum of the shell, there are as many stripe-lines as Wurstlamellen are formed. The number of the shell stripe-lines is 7–8 for *Sepia officinalis*[2] just hatched, 6–8 (7 average) for *Sepia esculenta*, 7–9 (7·8 average) for the *Sepia subaculeata*, and 7–8 (8 average) for *Sepiella maindroni* (Table 1). These numbers of stripe-lines increase with growth.

The periodicity of formation of the stripe-pattern of the shell of *Sepia esculenta* is affected by nutritive and environment conditions such as deficiency in feed, lower salinity of the surrounding sea-water, lower oxygen content, lower

Table 1. Relation between the Day-Age and the Number of Stripe-lines of the Shell in the Cuttlefish

* The original mean number of stripe-line of the shell in the newly hatched *Sepiella maindroni*.

† Since the rear end of the shell was broken, the number of stripe-lines could not be counted exactly.

temperature of the water, etc. Table 1 shows the relation between the day-age and the number of stripe-lines for three species of cuttlefishes (*Sepia esculenta* Hoyle, *Sepia subaculeata* Sasaki and *Sepiella maindroni* de Rochebrune) reared under sufficient feeding and environmental conditions at a water temperature of 19°–30° C. As with *Sepia esculenta* and *Sepia subaculeata*, the number of stripe-lines, including those observable at the time of hatching, approximates well to age in days; in *Sepiella maindroni*, the number is equal to the age in days plus the lines at the time of having been hatched. In other words, it can be said that the shell stripe-lines are formed at the rate of one each day. Between *Sepia esculenta* or *Sepia subaculeata* and *Sepiella maindroni*, however, there is a difference in periodicity of stripe-line formation: the *Sepiella maindroni* is seen to start forming its stripe-lines at the rate of one per day from the very date of hatching, whereas the other two species are presumed to be dull in their stripe-line formation at the earlier period after hatching. Noteworthy in this connexion is that the resistance against fasting of *Sepiella maindroni* is 6–7 days, whereas it is 10–11 days in *Sepia esculenta* and 12–15 days in *Sepia subaculeata*.

Table 1 gives results obtained under sufficient nutritive and environmental conditions at a water temperature of 19°–30° C. When amount of food is insufficient or feeding does not go smoothly owing to unfavourable changes in the sea-water for rearing, the formation of stripe-pattern becomes disturbed and the periodicity of one stripe-line per day is no longer exact. With insufficient feeding especially, the stripe-lines either do not appear or are indistinct with a reduced distance between each. The locular index for this sort of shell is likely to be decreasing. The shell locular index of the cuttlefishes is one of the most significant characteristics for diagnosis of species[4], so it must be recognized that this characteristic within a somewhat wider range, depending on conditions for growth, varies.

The fact that the number of stripe-lines for *Sepiella maindroni* which were reared for 127–133 days or until October 31 averages + 95·5 (Table 1) is thought to be ascribable to the lowering of the water temperature to below 19° C during mid-October and afterwards, that is, to the consequent disturbance of the periodicity of formation of the stripe-line.

The shell stripe-line of cuttlefishes is therefore shown to be formed one per day as a rule under good conditions of nourishment, but this does not hold in cases where the nutritive and environment conditions become disturbed so that physiological periodicity is upset.

Rearing of Cuttlefishes and Squids

We have succeeded (through improving the feed during the earlier stages after hatching) in rearing three species of the cuttlefish (*Sepia esculenta* Hoyle, *Sepia subaculeata* Sasaki and *Sepiella maindroni* de Rochebrune) and two species of the squid (*Sepioteuthis lessoniana* Lesson and *Euprymna beryii* Sasaki)[1]. The main points to note in rearing these animals are as follows:

Great care should be taken of eggs over a fairly long period until hatching. The vital point in the care of eggs is always to arrange that they are in contact with fresh-water, thus preventing the lowering in salinity of the storage sea-water.

If the eggs are exposed to too much light, diatoms or green algae tend to adhere to their surface, thus affecting adversely the development of the eggs. Eggs are better kept in the dark.

The five species of the cuttlefish and the squid mentioned here start feeding 16–48 h after hatching.

At the earlier stages, when about 2–10 mm long, considerable motility, though not too much, should be allowed. Suitable food are *Mysis*, larvae of the shrimp and other small crustacea.

A glass water tank is best for rearing. Flowing sea-water containing dissolved oxygen at saturation point encourages feeding.

Having grown to 20 mm mantle-length (four species except *Euprymna beryii* achieve a mantle-length of 20 mm in about 30 days after hatching), the animals begin to prey on small-sized shrimps or fishes.

Following these requirements, 80 per cent survival can be expected, and provided that the supply of food is satisfactory even after the animals begin to prey on large-sized food, they may reach adult size 3–4 months after hatching.

Estimation of Dry-Matter Intake in Wild Herbivores

For some years now, I have been studying nutrition in the wallaby, *Setonix brachyurus*, on Rottnest Island, Western Australia. A technique[1] was developed for estimating the relative abundance of various food items in the diet. To convert these data to absolute quantities, total daily intake of dry matter was required. The methods at present used in estimating dry-matter intake by freely grazing livestock may be classified according as they make use of: (1) pasture productivity assessments; (2) consumption-defæcation ratios; (3) indigestible markers; (4) fæcal nitrogen. For various reasons none of them is applicable to a wild herbivore feeding on natural vegetation.

It seemed axiomatic that the quantity of dry matter ingested each day should be equal on average to that leaving the stomach either by local absorption or by passage into the duodenum. In other words, to obtain the daily rate of ingestion, all that was needed was the daily rate of loss from the stomach. It was believed (wrongly, it was learnt later) that the wallabies fed all night and that their stomachs would consequently be most full at dawn. If a large number of wallabies were caught before sunrise and divided into batches which were dissected at regular intervals throughout the following day, comparison between batches in mean weight of dried stomach contents should reveal the rate of loss from the stomach for all possible weights of contents (Calaby[2] had suggested that the rate of passage in *Setonix* was affected by degree of fill). This would cover the period of fasting, sunrise to late afternoon. For the remainder of the day the loss would be computed by applying to weights of stomach contents observed at various times in the night the rate of loss obtained at those weights in fasting animals.

Seventeen adult wallabies were caught early in the evening of November 16, 1960, and another 11 before midnight, both batches being dissected within an hour of capture. On the following morning, between 3 and 4.30 a.m., a further 55 animals were caught and divided into 5 batches. The stomachs from one batch were immediately dissected out, the remainder at approximately 4-hourly intervals. Stomachs were preserved in a drum of 70 per cent alcohol; their contents were later scraped into enamel dishes, oven-dried at 100° C for 36 h, and weighed. Mean weight of wallabies was 3·05 kg for males, and 2·51 for females.

When the results were graphed, stomach contents against time of dissection, a straight line could be fitted through the means of batches 2–7. This suggested: (1) that feeding had virtually ceased by 11 p.m.; (2) that loss from the stomach was proportional only to time. Both discoveries were contrary to the preconceived ideas with which the investigation was designed. The second, however, greatly simplified the analysis. Instead of having to integrate changing rates of stomach loss through 24 h, all that was required now was the slope of the best fitting line through the means of batches 2–7.

Table 1. ADULT MALE WALLABIES, SHOWING BY BATCHES AVERAGE TIME OF CAPTURE AND DISSECTION AND MEAN DRY WEIGHT OF STOMACH CONTENTS (FEMALE DATA IN BRACKETS)

Batch	No.	Time Caught	Time Killed	Dry weight of stomach contents (g)
1	10 (7)	19.48	20.42	88·8 (71·7)
2	4 (7)	23.17	23.56	95·8 (87·2)
3	9 (4)	03.35	05.41	82·9 (79·3)
4	6 (5)	03.37	09.05	77·1 (74·9)
5	3 (8)	03.47	12.37	73·9 (70·8)
6	5 (4)	03.39	15.54	64·2 (65·5)
7	4 (7)	03.55	20.29	54·2 (58·0)

The line through the means of batches 2–7, weighted for number of animals in batch and fitted by the method of least squares, had an equation of $y = 96{\cdot}1 - 1{\cdot}86\,x$ for males and $y = 87{\cdot}9 - 1{\cdot}39\,x$ for females, where y is the dry weight of stomach contents in grams and x is the time elapsed in hours since the dissection of batch 2. Thus the rate of loss of dry matter from the stomach of adult males fasting for at least 20 h was constant at 1·86 g/h, and in adult females at 1·39 g/h. Although the investigation could not give information on the rate in feeding animals, there is no obvious reason why it should differ from that in fasting wallabies. Material cannot pass through the pylorus until it attains a certain degree of maceration, and it seems unlikely, on reflexion, that the process should be hastened by feeding or other activity. The hourly rates have therefore been extrapolated to give daily rates of loss of dry matter from the stomach of 44·7 g in males and 33·4 g in females.

Strictly, observation of the rate of loss from the stomach yields an estimate of the food required for 'topping up', rather than a prediction of how much would have been eaten in the following evening. Financial assistance was granted by the C.S.I.R.O. and the University of Western Australia.

Termination of Pregnancy in the Rat with Norethynodrel

CLEAR indications that norethynodrel diminishes the chances of survival of the conceptus have been obtained in the rat[1,2]. It was therefore conceivable that post-coital administration of the steroid could induce sterility in this species. The possibility seemed well worth investigation, as a similar action in humans would appear to offer efficient alternatives to the present contraceptive application of norethynodrel.

Data are presented that demonstrate the effectiveness of norethynodrel in terminating pregnancy in rats before and after nidation.

Rate of Nidation. Adult female white rats detected in procestrus or cestrus from daily vaginal smears were mated with fertile males. Mating was allowed to occur during a 24-h period. Thereupon, the female rats were randomly allocated to treatment groups. Soon after fertilization was presumed to have occurred, and before the sixth day post-coitum when nidation usually takes place in the rat, norethynodrel in sesame oil was administered subcutaneously either by single injection or daily injections for 3 days in the quantities shown in Table 1. The rate of nidation was ascertained at autopsy 10–12 days after mating (all intervals are taken from the initial day of mating). With the aid of a dissecting microscope the number of mature corpora lutea was counted. The number of corpora lutea was assumed to be an estimate of the number of ova shed. Thus, the rate of implantation in a group represented the proportion of fœtuses to corpora lutea. In Group III (Table 1) the rate of nidation was based on only four rats because corpora lutea present in the ovaries of one rat had not been counted.

A glance at Table 1 reveals that norethynodrel prevented the occurrence of nidation in Groups I, II and IV. A possibility of delayed implantation was checked by flushing the uteri with saline. No blastocysts were found to be present.

Fœtal Resorption. As in the previous experiment, adult female rats were mated when in procestrus or cestrus. Norethynodrel was administered by gavage in doses of 10 mg per day for 3–5 days as shown in Table 2. Control animals were given 1 ml. of sesame oil for 5 days by gavage. Pregnancy was permitted to go to term, and the frequency and size of litters were recorded. The incidence of resorption was determined from signs of blood in the vagina at the time of treatment and from examination of the uterine contents at autopsy 21–27 days after mating.

Clearly, norethynodrel induced extensive fœtal resorption. The treatment of longer duration proved completely effective in terminating pregnancy. Included in the litter-size data for Group II are at least five stillbirths, on the grounds that they represented failures to resorb. In two rats, stillbirths were associated with delays in parturition of about 4 and 6 days.

These data show that post-coital administration of norethynodrel can suppress fertility in the rat. The

Table 1. EFFECT OF SUBCUTANEOUS ADMINISTRATION OF NORETHYNODREL ON THE RATE OF NIDATION IN RATS

* Includes stillborn; less than control, $P < 0·01$.

treatment proved to be most effective before implantation; 0·9 mg norethynodrel given subcutaneously on the second day post-coitum completely abolished pregnancy, while daily 10 mg doses by gavage from day 10–12 allowed some fœtal development to proceed unimpaired, though litter size was very significantly depressed. Hence, previous reports[3,4] that in ovariectomized rabbits as much as 2 mg per day of norethynodrel post-coitum fails to induce implantation are most probably explained by its potent inhibitory action on this phase of pregnancy, rather than a simple lack of progestational activity. It is known that nidation of the rabbit blastocyst can be prevented by administration of the steroid prior to coitus[4].

How norethynodrel terminates pregnancy is a pressing question. There is some indication that the steroid exerts an effect during tubal passage of the zygote. From Table 1 it can be seen that 0·9 mg norethynodrel completely suppressed fertility when given on the second day post-coitum, but when 0·5 mg of the same total dose was given on day 4 (Group III), by which time the rat blastocyst is usually in the uterus, the treatment was ineffective. It is possible that norethynodrel may interfere with tubal transport, but its ovacidal effects[4] clearly suggest a direct effect on the fertilized egg. These considerations minimize the importance of any influence norethynodrel may have on the uterus. However, the failure of large doses of norethynodrel to induce deciduomata in rats[3,4] together with its œstrogenic activity may lead one to suspect the steroid of an antidecidual property that could impede nidation. A disturbance of the developmental synchronization between the endometrium and blastocyst by the steroid may also contribute to preventing implantation[5]. The induction of fœtal resorption is probably the result of a specific action by norethynodrel; certainly it would not seem to result from an unmodified œstrogenic action by the steroid as the equivalent of 2·5 mg/kg/day œstrone (that is, 10 mg norethynodrel to 200-g rats, with norethynodrel possessing 5 per cent of the œstrogenic activity of œstrone) for 3 days was required to reduce mean litter size to 2·4. However, it is known that 0·4 mg œstrone/kg on day 10 can produce such a response[6]. If Sammelwitz *et al.*[7] are correct in asserting the hypophysis of the rat during pregnancy is responsible for only a single release of luteotrophin at the time of mating, then obviously a mediated effect via the hypophysis, similar to that involved in blocking ovulation with norethynodrel, cannot be invoked to explain the termination of pregnancy. Moreover, the steroid seems to have no direct influence on the ovary[4,5]. Consequently, the present effects on the conceptus appear to result from a direct action of norethynodrel or a metabolite. It should be pointed out that these observations are in no way incongruous with norethynodrel exerting an inhibitory effect on ovulation.

This work was supported by the grant of a Population Council fellowship. Norethynodrel was a gift of G. D. Searle and Co., Chicago, Illinois.

Armillaria mellea: an Ozonophilic Basidiomycete

OZONE is a strong oxidizing agent and in very low concentrations is generally toxic to both micro-organisms and higher plants and animals. Davis[1] and others[2] have examined the bactericidal effects of ozone by growing *E. coli* in ozonated water solutions and found that 30 p.p.m./vol. caused 99 per cent lethality in 1 min or less, while 1 p.p.m./vol./8 h-day is considered toxic to man[3]. It was therefore surprising to find that *Armillaria mellea*, a luminescent basidiomycete grown in culture, had its light emission stimulated by high ozone concentrations and that it survived long ozone exposures without apparent lasting ill-effect.

I used both a commercial negative ion generator which produces ozone by ultra-violet light and a Wellsbach *T*-23 ozonator with either an air or an oxygen source. The concentrations were determined iodometrically[1,4] and by using a Wellsbach ozone meter with good correlation between the two methods. Changes in the light emission were used as an index of the respiration[5]. The general physiology of the organism and the culture and photometric methods have been previously described[5]. For these experiments the ozone was drawn through a flowmeter and into a glass experimental chamber with a light-tight metal jacket. Between the ozone source and the flow meter there was a by-pass system for sampling and calibration. Since there is a drop of approximately 50 per cent in ozone concentration across the jar which encloses the sample, the values given are those at the entrance of the experimental chamber. Concentrations were varied by changing both the source output and the rate of flow. The 7–10 day old cultures in small Petri dishes were mounted upright against the glass wall of the jar and the light emission was monitored continuously through an aperture in the metal shield. It was also determined that the uninoculated agar on which *A. mellea* was grown does not absorb or decompose ozone at a faster rate than an actively growing culture.

At all concentrations tested (75–500 p.p.m./vol.) there was an initial and usually transient rise in the light emission intensity (Fig. 1). At 75 p.p.m. it took 3 h for this peak to be reached while at 500 p.p.m. it took 3 min. At concentrations of 200–500 p.p.m. it took 3–6 h for this gain to be lost and the light-level to return to the

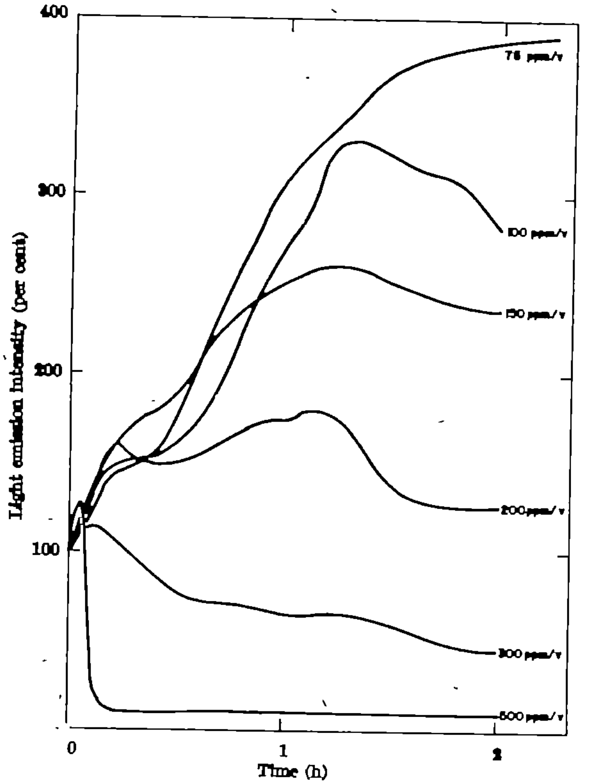

Fig. 1. Changes in light emission intensity of *Armillaria mellea* during exposure to various concentrations of ozone

original steady state. A 3-h exposure at all concentrations did not kill any of the samples. When removed from the ozone atmosphere all recovered to light emission levels at least equivalent to the pre-exposure value (100 per cent) within 3 days. When *A. mellea* was grown in an ozone atmosphere of 100 p.p.m. for 5 days the light intensity declined about 50 per cent in the first 24 h. After 5 days under these conditions the light-level was extremely low but measurable. Part of this low intensity is undoubtedly due to drying of the agar.

At concentrations of 200 p.p.m. and higher there was distinct bleaching of the brown melanin-type pigment found in normal hyphæ of *A. mellea*. During recovery there was no reducing of the pigment of exposed cells back to the original brown colour. Hyphæ growing out of the exposed mycelium have the usual brown pigmentation. There is thus a strong possibility that this pigment acts as an ozone protecting substance by preventing the formation of free radicals and peroxides. Ozone damage has usually been attributed to these causes[6,7]. This is particularly likely since we have found that *Panus stipticus*, another luminescent basidiomycete with no pigment, is killed within 10 min in 100 p.p.m. of ozone. Also, young cultures of *A. mellea* which have little or no pigment are much more affected by equivalent concentrations than more mature samples. This unusual ozone protection mechanism is under continued investigation.

Increased Tolerance of Bean Plants to Soil Drought by means of Growth-retarding Substances

In experiments with *Chrysanthemum morifolium*[1] plants treated with (2-chloroethyl) trimethyl ammonium chloride ('CCC') and *Petunia hybrida*[2] plants treated with 2,4-dichlorobenzyltributyl phosphonium chloride ('Phosfon') it has been observed that treated plants seemed to be less susceptible to water stress than untreated ones. High temperatures following periods of low light intensities caused wilting in control plants, while treated plants remained turgid. These substances are growth-retarding materials[1,2], and some of their physiological activities have been reported[3].

In recent work on drought resistance it was found that it is possible sometimes to increase the tolerance of plants to drought by means of chemical treatment[4]. The foregoing observations prompted us now to include these chemical groups in studies on drought responses of plants, and this report summarizes two typical experiments using 'CCC' and 'Phosfon'.

Experiments were carried out with *Phaseolus vulgaris* L. var. Brittle Wax. Plants were grown in half-gallon cans, containing a loamy-sand soil (field capacity 14·7 per cent, wilting point of sunflowers 4·3 per cent). Ten seedlings were grown in each can. When the first pairs of leaves were fully expanded in most seedlings, 250 ml. of aqueous solutions were applied to each can containing 50 mg 'Phosfon' and 500 mg 'CCC', respectively. Each treatment was replicated 4 times (cans). Routine irrigation of the cans was continued until the expansion of the third leaf, after which the supply of water was stopped.

Five days after the last watering the leaves of the control (untreated) plants started wilting, and the growth of these plants ceased. Nine days afterwards leaves of the untreated plants began to dry and dropped. Most of the control plants were completely desiccated 30 days after the last irrigation. Fig. 1 represents the situation at the time when only a few of the youngest leaves of some of the control plants remained attached at a wilting stage.

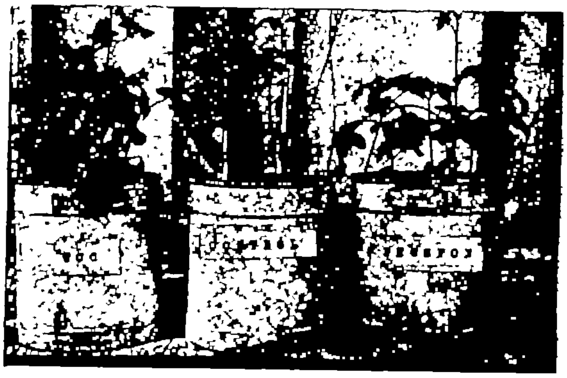

Fig. 1. Effect of 'Phosfon' and 'CCC' on bean plants, 30 days after last irrigation

In contrast, the treated plants remained turgid in these 30 critical days (Fig. 1). They continued growing for 22 days after the last irrigation. A few of the oldest leaves started showing signs of wilting on the twenty-eighth day after irrigation in case of 'CCC'-treated plants. In 'Phosphon'-treated plants some wilting was noticed only after 33 days. Nine days afterwards (42 days after last watering) leaves of the treated plants began to drop and the plants to dry up. At this stage soil moisture was determined in each can and is given in Table 1.

As seen from Table 1, the moisture percentage in the control soil was at the wilting point (4·36 per cent), while in the treated soil it was below wilting point (3·98 and able 1. SOIL MOISTURE OF CONTROL AND TREATED SOILS (42 DAYS AFTER IRRIGATION)

Treatment	Soil moisture (%)
Control	4·36
'Phosfon'	3·98
'CCC'	3 62
L.S.D. 0 05	0·31

3·62 per cent for the 'Phosfon' and 'CCC' treated soil, espectively).

In a second experiment, beans were sown in clay pots ontaining 500 g of soil (19 per cent field capacity, 7 per ent wilting point), 1 plant per pot. After emergence half he pots were watered with an aqueous solution of 'Phos-on' (12 mg/plant/pot). Routine irrigation was followed until the plants reached a stage of two fully expanded eaves, after which they were subjected to three different water régimes. This experiment was designed as a randomized block experiment, including four replicates per reatment, each of which was composed of five plants (pots). The soil moisture was determined by daily weighing of the pots. In the water treatments the plants were irrigated at different levels of soil moisture, as follows: *A*, 95 per cent available water; *B*, 20 per cent available water; *C*, near wilting point.

As the plants of treatment *A* reached a stage of six leaves all the plants were collected and their fresh and dry weights were determined (Table 2). As seen from Table 2, both the fresh and dry weights of 'Phosfon'-treated plants were considerably higher in the 'dry' treatments (*B* and *C*) than the untreated plants.

Table 2. EFFECT OF 'PHOSFON' ON THE GROWTH OF BEAN PLANTS GROWN AT DIFFERENT WATER REGIMES

Watering treatment	Control Fresh weight (g)	Control Dry weight (g)	'Phosfon' Fresh weight (g)	'Phosfon' Dry weight (g)
A) 95% available water	13·76	1·93	13·52	1·94
B) 20% available water	11·31	1·52	13·40	1·85
C) Wilting point	7·93	0·94	12·00	1·60

These results suggest that both 'CCC' and 'Phosfon' evidently increase the drought tolerance of plants.

'Phosfon' was supplied by Virginia-Carolina Chemical Corporation and 'CCC' by the Cyanamid Co., whom we thank.

ENTOMOLOGY

Fatty Acid Characteristics of Some Insect Taxa

As a prelude to a study of fat metabolism in the parasitic dipteron *Agria affinis* (Fall.) 30 species of insects and 2 of spiders were surveyed for fatty acids by gas chromatography. Because *A. affinis* has peculiar nutritional requirements[1] it was supposed that it had a peculiar fat metabolism which would produce some equally peculiar fat composition.

The survey not only showed that such a peculiarity exists, but also that some broad similarities exist within taxa. Thus, among the 30 species of insects, representing 23 families and 8 orders, the 5 species of Diptera were characterized by a relatively high proportion of palmitoleic acid, a proportion approached by only the single neuropteron examined. Furthermore, among the 9 species of Homoptera, the 5 members of the family-group Aphidoidea had a proportion of myristic acid much greater than any other of the 30 species. No obvious characteristics of the orders were found among the 7 species of Coleoptera and 4 of Lepidoptera. The remaining orders and families were represented by too few species to permit any inferences.

Thus a biochemical property probably characteristic of an order has been shown in Diptera and of a family-group in Aphidoidea. These observations indicate that chromatography of the fatty acids may prove more useful than other techniques used so far in showing biochemical characteristics of insect taxa.

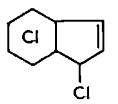
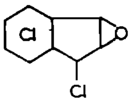
Significance of the Epoxidation of the Isomeric Insecticides Aldrin and Isodrin by the Adult Housefly *in vivo*

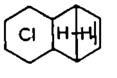
PERRY[1], commenting on the latent period between application of heptachlor (I) to susceptible houseflies and onset of signs of poisoning, pointed out that although there is an adequate amount of heptachlor in the insect tissues during this period, onset of signs of poisoning seemed to coincide with the appearance of heptachlor epoxide (II) in the tissues. These observations apply also to aldrin (III) and isodrin (IV)[2].



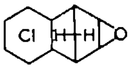
I



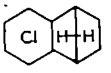
II



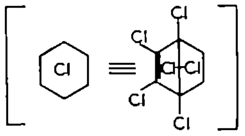
III or IV



V or VI



VII or VIII



Winteringham[3] suggested that the remarkable ability of houseflies to survive long periods of anoxia[4] might be exploited to determine the rôle of atmospheric oxygen in epoxidation *in vivo* and its toxicological significance. That epoxidation of III or IV by the adult housefly *in vivo* requires the presence of atmospheric oxygen was demonstrated by the failure to detect the formation of the corresponding epoxides (V or VI) when the insects were dosed and kept in oxygen-free nitrogen. Penetration of the applied insecticides through the cuticle was, however, unaffected by anoxia.

Compounds III, IV, V or VI were applied topically in acetone (2 µl.) to groups of ten susceptible adult female houseflies, *Musca domestica*, at a dose of 1·1 µg per insect. Groups were treated and observed in air at 25° C. Alternatively, groups were similarly treated after immobilization in oxygen-free nitrogen and held in nitrogen at 25° C for 60 min after treatment. These groups were then transferred to fresh air at about 25° C. The times of appearance of signs of poisoning and later knockdown effects are summarized in Table 1. The results show that anoxia has delayed by about 60 min the onset of signs of poisoning in the insects treated with aldrin or isodrin. The interval between appearance of signs of poisoning and complete knockdown was somewhat shorter than that observed in insects kept entirely in air. The knockdown effect in the dieldrin- or endrin-treated groups could, however, be recognized when they recovered from anoxia.

(95 min) and so was not delayed by more than about 15 min; the failure to observe the earlier signs of poisoning suggests that this stage was actually reached during anoxia. Moreover, aldrin- or isodrin-treated insects actually recovered and behaved normally between the times of removal from nitrogen and the times of appearance of first signs of poisoning (that is, between 60 and 133 min). One conceivable explanation was that anoxia had delayed penetration of compounds III and IV through the insect cuticle considerably more than that of compounds V and VI. However, gas-chromatographic analysis of tissue extracts showed that following a dose of 1·1 μg of endrin in air, 0·14 μg of the unchanged insecticide was recovered from the tissues within the hour, and following a dose of 1·1 μg of isodrin in nitrogen, 0·13 μg of unchanged insecticide was recovered after 1 h. This shows that the delays indicated in Table 1 are not due to delayed penetration of the insecticide through the cuticle.

Table 1. APPEARANCE OF SIGNS OF POISONING IN ADULT HOUSEFLIES EXPOSED TO INSECTICIDES IN AIR OR IN OXYGEN-FREE NITROGEN

	Insects dosed and kept in air at 25° C		Insects dosed and kept in nitrogen for 60 min and then observed in air at 25° C	
Compound	Time (min.) after treatment of first positive signs of poisoning, 'flight convulsions', etc.	Time (min) after treatment of 'knockdown' effects	Time (min) after treatment of first positive signs of poisoning, 'flight convulsions', etc.	Time (min) after treatment of 'knockdown' effects
Aldrin (III)	70	120	133	176
Isodrin (IV)	80	135	136	175
Dieldrin (V)	45	78	—	96
Endrin (VI)	45	80	—	90

These results show that aldrin and isodrin possess lower intrinsic toxicities than the corresponding epoxides. The higher polarity of the epoxides (as indicated by their higher R_F values under conditions of reversed-phase paper chromatography) may favour a more rapid penetration of these insecticides to the sites of action *in vivo*, possibly by permitting a more favourable partition between aqueous and lipid phases. Relevant is the observation that isodrin (0·37 μg), injected in 1 μl. of liquid paraffin, produced no signs of poisoning for 5 h in air, while with this dose of endrin signs of poisoning appeared in 2 h. This suggests that the more polar epoxide was released more rapidly into the hæmolymph from the injected oil. The insecticidal properties of aldrin or isodrin seem unlikely to be due entirely to epoxidation since the related dihydro-compounds (VII or VIII), which do not undergo epoxidation *in vivo*, are moderately toxic on their own account.

These experiments are connected with an investigation supported in part by a grant from the World Health Organization.

Probable Mechanism regulating Water Economy of *Rhodnius prolixus*

FIFTH-STAGE larvæ of *Rhodnius prolixus* decapitated immediately (10–20 min) after feeding have been shown[1] to excrete less urine than normal controls. These results apparently contradict the report of Maddrell that "ligating the fed insect anterior to the ganglionic mass has no effect on urine production".

To decide between these alternatives the amount of urine produced by three groups of animals was measured: (a) with all the abdominal nerves (originating at the large fused ganglionic mass situated in the mesothorax) sectioned (the leg nerves were not sectioned); (*b*) with th connectives between the prothoracic ganglion and th mesothoracic fused ganglionic mass sectioned (the animals lose control over the two pairs of posterior legs (*c*) controls operated without neurotomy.

20 h after the operation all animals were fed wit oxalic (1 part per thousand) blood; their ani wer previously plugged to avoid loss of excreted urine. 3–5 after feeding they were dissected; the success of the opera tion was verified and the amount of urine produced we determined. The weight of the rectal contents we measured by difference with non-fed controls.

The values given in Table 1 confirm the earlier result obtained by decapitation in showing inactivity of th Malpighian tubes in all operated animals if operation i performed before feeding.

Table 1

	Weight of rectum (mg)		Weight of rectum contents (mg)	Weight animals (mg)
Non-fed controls	3	(*n* = 5)*		40
Fed controls	14	(*n* = 12)	11	197
Group (*a*)	4·8	(*n* = 18)	1·8	155
Group (*b*)	4·9	(*n* = 7)	1·9	250

* *n* = No. of animals

The absence of diuretic hormone in operated animal (judged from the amount of urine accumulated in th rectum) may be attributed, according to preliminary observations, as follows: In animals of group (*a*), to th interruption of the neurosecretory pathway caused by sectioning of the axons of the neurosecretory cells (responsible for the production of the diuretic hormone) in the fused ganglionic mass (the absence of neurosecretion in these cells resembles that described by Scharrer[3] after section of the n.c. allatum). In animals of group (*b*), to the interruption of the central nervous efference (efference which is due, probably, to dilatation of the gut[4]).

Furthermore, unpublished results show in normal animals the existence of a peripheral inhibition of central origin which is exerted on the abdominal wall and which can be demonstrated on sectioning the abdominal nerves on one side. This inhibition, probably related to that found by Dethier[5] in *Phormia*, could serve as a feed-back mechanism (via the hydrostatic pressure in the gut) for the regulation of the time of ingestion in *Rhodnius*.

The apparent contradiction with Maddrell's results may be due to the fact that already during ingestion there is liberation of some diuretic hormone since urine production starts in the first 15 min from the beginning of feeding.

It remains to be decided whether in the input of the regulating circuit there operate signals of abdomen volume apart from those signals which arrive through the prothoracic-mesothoracic connective.

Mating Behaviour of *Anopheles stephensi*

THE successful eradication of screw worm fly from Curaçao and from the southern United States has created a great interest in the possibility of insect eradication by release of sterile males[1]. Even where complete eradication cannot be achieved, the method can still be used for limiting the population density of harmful species to a level where it ceases to be of importance. If this can be done for a certain length of time in the case of vectors of diseases, it is possible that the disease-cycle may be completely interrupted and the disease itself eradicated.

With this in view, we examined the possibility of the radication' of *Anopheles stephensi*, the main vector of alaria in southern Iran. This species has shown a marked sistance to DDT, BHC and dieldrin[2], thereby making alaria eradication by the use of residual insecticides lmost impossible. The use of sterile males, we thought, ay yield encouraging results and seemed feasible ecause: (1) they can be easily reared in the laboratory;) the males and females can be easily separated in the upal stage by the mechanical separating device of Fay nd Morlan[3]; (3) the males are completely harmless; (4) e males are powerful fliers—a flight-range of up to 4·3 m has been recorded (Quraishi *et al.*, 1962, data npublished)—and form big swarms for mating; (5) the ngevity of the male seems to be quite comparable with hat of the female[4].

The mating behaviour of the female was examined first. abelling' the male with phosphorus-32 was found very onvenient for such investigations. This was done by earing the third and fourth instar larvæ in water containing 10–20 μc. phosphorus-32/l. The emerging male osquitoes were counted in the top shelf of an Ericsson caling unit type 1221*C*. Their counts varied from 2,500 o 38,000 c.p.m. The mosquitoes were then dissected and heir reproductive organs counted. Table 1 summarizes he counts of males and their reproductive organs.

Table 1

Males (c.p.m.)	Reproductive organs (c.p.m.)
2,500—4,000	75—147
4,000—6,000	120—230
6,000—8,000	197—308
11,000—13,000	327—373
30,000—38,000	541—741

Males giving a count of 7,000–13,000 were chosen for his experiment and were kept with virgin females and emales which had oviposited once. Similar females were ept with 'unlabelled' males. After 24 h the spermathecæ f all the females were dissected. The spermathecæ of emales (both virgin and those which had completed one onotrophic cycle) kept with 'labelled' males showed a ount of about 1½–2 times the background. Background n this case was 12 c.p.m. The counts of the spermathecæ aried from 17·5 c.p.m. to 25 c.p.m.

The spermathecæ of the females kept with normal males id not show any increase in count rate above the background.

This clearly indicates that female *Anopheles stephensi* ates more than once and that mating can be investigated asily by the use of 'active' males.

We are carrying on further investigations on the easibility of using this method.

We thank Mr. H. A. C. McKay and Dr. M. L. Smith, ormer director and present director, respectively, of the ENTO Institute of Nuclear Science, for help and advice, nd Dr. Ch. M. H. Mofidi for providing the adults and arvæ of *Anopheles stephensi*.

Note. After having completed this communication, we ead with interest the article, "Chemical Sterilization of osquitoes", by Dr. Donald E. Weidhaas[5], and feel that elease of sterile males coupled with spraying structures ith 'Tepa' (provided the cost is reasonable and no health azards are involved) may provide an answer for the eradication[1] of the species.

MICROBIOLOGY

Identification of Early Labelled Products of CO_2-Fixation by Hydrogen Bacteria accumulating Poly-β-hydroxybutyric Acid

THE effect of the reductive pentose phosphate cycle in hydrogen oxidizing bacteria has already been established[1,2]; the detection of early labelled organic acids[3] and of an unknown compound, situated beyond the area of phosphate esters on chromatograms[4], led to the assumption that other carbon dioxide fixation reactions might occur under certain conditions.

Since poly-β-hydroxybutyrate (PHBA) is synthesized from carbon dioxide and water in hydrogen-oxidizing bacteria[5], it became possible to investigate the fixation of carbon dioxide into this storage material by *Hydrogenomonas spec. 16* under controlled physiological conditions and excluding all side-reactions.

The incorporation of $^{14}CO_2$ into different cell fractions was investigated with autotrophically grown, washed cells, suspended in a dilute, nitrogen-free mineral buffer solution. After the incorporation time of 20 sec (30° C), 84 per cent of the totally fixed radioactive carbon was found in the ethanol-soluble extracts. About an equal amount of radioactivity of this ethanol extract (11 per cent) was observed in both the steam-volatile and the ether-soluble fractions, while the bulk of radiocarbon (73 per cent) was contained in the extract after removal of the fractions mentioned here (in P-esters, amino-acids and sugars).

The most intensively labelled compounds of the steam-volatile and ether-soluble acids of a 1-min experiment were identified by paper-co-chromatography and by conversion into and separation of the corresponding hydroxamic acids: acetate, lactate, pyruvate, succinate, malate, fumarate, β-hydroxybutyrate, citrate, glutamate and α-alanine. Lactate evidently was an artefact, formed from dihydroxyacetone phosphate, when the extracts were alkalized before concentrating them *in vacuo*.

Organic acids, amino-acids, sugars and phosphate esters have been separated by two-dimensional paper chromatography (Schleicher and Schüll 2043 *a*, washed paper) using the solvent system *n*-propanol–ammonia–water (6 : 3 : 1 by vol.) and *sec* butanol–formic acid–water (6 : 1 : 2 by vol.) according to Metzner[6]. Labelled products of carbon dioxide-fixation were identified by R_F-values or positon constants, by co-chromatography with reference substances, and by comparing extracts of *Hydrogenomonas 16* labelled with carbon-14 and phosphorus-32 with extracts of *Chlorella pyrenoidosa* labelled with carbon-14. In *Hydrogenomonas 16* phosphoglyceric acid and hexose monophosphates dominated; ribose-5-phosphate, dihydroxyacetone phosphate, nucleotides and phosphoglycolic acid were also found to be labelled. *Chlorella* showed considerably more activity in phosphoenolpyruvate, triose phosphates and hexose diphosphate.

When ^{14}C-acetate was given instead of $^{14}CO_2$ under storing conditions, the P-esters were not labelled, but β-hydroxybutyric acid and some other organic acids were found to be radioactive.

However, in autotrophically grown, washed cells under air incubated with $^{14}CO_2$ in the presence of succinate for 8 sec, the radioactivity first appeared in P-esters with a pattern typical for the Calvin cycle. Therefore we have to assume that even under heterotrophic conditions C-autotrophically grown cells assimilate limited amounts of carbon dioxide via the Calvin cycle.

When washed cells grown on succinate were exposed to $^{14}CO_2$ under oxy-hydrogen atmosphere for 9 sec, phosphoglyceric acid, hexose mono- and di-phosphates, and aspartic acid were very intensively labelled. The same cells under air, exposed to $^{14}CO_2$ in the presence of succinate, incorporated $^{14}CO_2$ mainly into malate, succinate and citrate, and, to a limited extent still, into phosphate ester compounds. These observations show that even cells grown heterotrophically on succinate, but which were derived from a 0·1 per cent autotrophically grown inoculum, contain a carbon dioxide fixation system identical with or similar to the reductive pentose phosphate cycle.

Effects of Incorporation of Iododeoxyuridine on *Escherichia coli*

A variety of base analogues which are incorporated into deoxyribonucleic acid (DNA) affect the growth of mammalian cells, bacteria, plant and animal viruses. It has been shown[1,2] that thymine substitution by halogenated analogues is higher in thymine-less than in wild bacterial strains. To increase the incorporation in wild-strains, inhibitors of thymidylic acid synthesis were used (aminopterin or sulphanilamide). The substitution of the natural base by the brominated analogue produces some physiological and genetical effects. It was demonstrated[3] that bacteria labelled with bromouracil are highly sensitive to ultra-violet irradiation. In some cases the replacement of thymine in DNA produced a significant increase of the frequency of mutations at specific locations of phages T_4 or T_2 (refs. 4 and 5) or in *Salmonella typhimurium* at the tryptophan *D* locus[6]. In contrast to the brominated analogues, the iodinated analogues of thymine were not thoroughly examined until now.

To enhance the incorporation of iododeoxyuridine (IUdR) into a wild-strain of *Escherichia coli* I used fluorodeoxyuridine (FUdR), a specific inhibitor of thymidylate synthetase. Bacteria propagated in nutrient broth in log-phase were transferred into a minimal medium supplemented with 200 μg/ml. IUdR and 1 μg/ml. FUdR and grown for 3 h. In the presence of the fluorinated analogue, 43 per cent of thymine was substituted by IUdR, while without FUdR only 18 per cent. Bacteria containing IUdR showed an increased sensitivity to ultra-violet light. This sensitization of micro-organisms labelled with IUdR to ultra-violet light was significantly lower than that of bacteria containing bromodeoxyuridine.

The resulting radiosensitization, expressed as ultra-violet dose ratio for identical survivals of normal and analogue-labelled cells (dose reduction ratio), amounted to as much as 2·2 (43 mol per cent IUdR substitution) or 3·4 (46 mol per cent BUdR substitution). At the same time the rates of mutation were estimated in the system from streptomycin dependent to streptomycin independent. In bacteria containing a large amount of IUdR (about 50 per cent) the frequency of mutations increased 20 times, whereas in micro-organisms containing 15–20 per cent of the analogue the number of mutants was increased only three times. After ultra-violet irradiation, the frequency of mutation increased significantly, but the rate of the increase was higher in the control culture than in that containing IUdR. After irradiation with a dose of 2,000 ergs/mm^2 the number of mutants per survivals in the normal culture was even higher than in IUdR-labelled bacteria. This was presumably connected with the selection by ultra-violet light of IUdR labelled bacterial mutants. DNA isolated from bacteria containing IUdR showed a broadening of the profile of hyperchromasis after heating in comparison with the normal DNA.

Utilization of Amino-Acids during Metabolism in *Escherichia coli*

While engaged in the examination of metabolism and hydrolysis by soil bacteria of benzoic acid derivatives, amino-acids, and acylated amino-acids[1-3], we have shown that there was a significant difference in strains of soil bacteria in their capability of metabolizing organic substances of different structures. We have now examined the metabolic activities of twenty-five strains of *Escherichia coli* standard *O* group on the following nineteen amino-acids to be used as a sole source of carbon: L-glutamic and DL-aspartic acids, DL-alanine, DL-serine, glycine, DL-valine, DL-leucine, L-isoleucine, DL-phenylalanine, L-tryptophan, DL-threonine, L-lysine, DL-methionine, L-cystine, L-arginine, L-histidine, L-tyrosine, L-proline, L-hydroxyproline.

The constituents of the culture medium used were: ammonium chloride, 0·1 gm; dipotassium hydrogen phosphate, 0·1 gm; crystalline magnesium sulphate, 0·05 gm; 1 per cent crystalline calcium chloride, 2 drops; 1 per cent crystalline ferric chloride, 1 drop; DL-amino-acid to be tested, 0·2 gm (L-amino-acid, 0·1 gm; L-cystine and L-tyrosine, 0·02 gm); distilled water, 100 c.c.; *p*H 7·4–7·6 (adjusted with 10 per cent sodium hydroxide).

Special attention may here be directed to the following points: (1) All 25 strains grew luxuriantly in the synthetic medium containing alanine, aspartic and glutamic acids or proline as the sole source of carbon at 37° within four days. This cultivation experiment was repeated three times in succession. (2) Of 25 strains, 19 were able to utilize serine as well as alanine. (3) The following 14 amino-acids could not or only just be utilized by any of 25 strains at 37° in four days: glycine, valine, leucine, isoleucine, phenylalanine, tryptophan, threonine, lysine, methionine, cystine, arginine, histidine, tyrosine, hydroxyproline. (4) The response of *E. coli* to histidine is worth noting from the point of view of phylogeny for Enterobacteriaceae when considered together with the fact that some strains of *Klebsiella*, *Cloaca*, *Citrobacter*, *Hafnia* and *Proteus* could utilize histidine as a source of carbon in our preliminary experiments. (5) 8 essential amino-acids such as tryptophan, lysine and methionine could not be utilized by *E. coli*.

We thank Dr. H. Fukumi and Dr. R. Nakaya, of the National Institute of Health, for kindly supplying strains of *E. coli*.

VIROLOGY

Guanidine Conditioned Infectivity of Ribonucleic Acid extracted from a Strain of Guanidine-dependent Polio-1-Virus

We have previously shown that polio-1-virus, when ropagated in HeLa cells in the presence of guanidine ydrochloride, can become resistant to guanidine, and, fter a number of additional transfers, will become lependent on guanidine[1-3].

The work recorded here attempts to evaluate: (*a*) the nfectivity of RNA extracted from either guanidine-ensitive or guanidine-dependent strains of polio-1-virus; *b*) the influence of guanidine on the infectivity of such ₹NA preparations.

The RNA was prepared essentially according to the nethod of Gierer and Schramm[4], except that the extracion was performed at 56° C. The infectivity of such reparations was tested on cells pretreated with hypertonic aline solutions. Virus preparations, as well as viral ibonucleic acid, were prepared as follows: three-day culures of HeLa cells were infected with 10^{8} cytopathogenic mits (CPU) of either guanidine-sensitive polio virus or irus which had become guanidine-dependent by 77 transers in the presence of 200 μg guanidine hydrochloride per nl. After incubation at 37° C for 2 h, 10 ml. of maintennce medium[5] were added to each flask. In some cases, the naintenance medium also contained 200 μg guanidine ıydrochloride per ml. The cultures were incubated at 7° C until cytopathogenic lesions were clearly evident. They were then submitted to three cycles of freezing at − 30° C, and thawing at + 20° C. Each preparation was livided into two portions. One portion was centrifuged at ,000 r.p.m. for 5 min, and the supernatant utilized for the letermination of complete virus by CPU titration. The econd portion was shaken for 10 min in a 56° C water bath vith an equal volume of phenol (Merck; peroxide free, aturated with water at 4° C). The mixture was briefly ooled in ice and centrifuged. The upper layer was xtracted 5 times with peroxide-free ether, and stored at − 30° C in small open Petri dishes.

HeLa cell monolayers were pretreated prior to infection y successive washes with 0·3 M sodium chloride, and hen 0·6 M sodium chloride. Immediately before infecion, the RNA preparations were thawed, diluted into volumes of 1·2 M sodium chloride, and incubated for 3 nin at room temperature in the presence or absence of μg RNase per ml. (RNase: BDH, Chemical Division, Poole, England). 1 ml. of decimal dilutions in 1·2 M odium chloride were used to infect the pretreated cell ayers. After 20 min at room temperature, unabsorbed RNA was removed with 2 washes of 0·6 M sodium chloride; 0 ml. of maintenance medium (minus serum) were added. The cultures were scored for cytopathogenic lesions after days at 37° C. All the cultures were disrupted by 3 ycles of freezing and thawing as before, and cell débris removed by centrifugation. Virus production in each of the cultures was assayed by determining the CPU in each of the supernatants. As shown in Table 1, RNA extracted from guanidine-sensitive polio virus was able to infect cell cultures and produce whole virus, as shown by the appearance of CPU. Guanidine hydrochloride inhibited the ability of this RNA to produce whole virus. On the other hand, RNA obtained from guanidine-dependent virus induces whole guanidine-dependent virus only when guanidine is present in the maintenance medium. The lack of infectivity of phenol extracts treated with RNase confirms the RNA nature of the infective materials.

Table 1

Inocula	CPU produced in three days by HeLa cells cultured in absence of guanidine	CPU produced in three days by HeLa cells cultured in presence of guanidine hydrochloride (200 μg/ml.)
Polio 1 guanidine-sensible	10^{6}	10^{5}
dem + RNase	10^{5}	10^{6}
RNA from polio-1 guanidine-sensitive; maintenance medium without guanidine	10^{5}	<10
dem ; maintenance medium with guanidine hydrochloride 100 μg/ml.	<10	<10
dem ; in presence of RNase; maintenance medium without guanidine	<10	<10
Polio 1 guanidine dependent	$<10^{4}$	10^{6}
dem + RNase	$<10^{4}$	10^{6}
RNA from polio 1 guanidine dependent; maintenance medium without guanidine	<10	<10
dem ; maintenance medium with guanidine hydrochloride 100 μg/ml.	<10	10^{5}
dem ; in presence of RNase; maintenance medium with guanidine hydrochloride 100 μg/ml.	<10	<10

These experiments clearly show that the guanidine-dependence of polio virus is a character assumed by viral RNA.

Experiments with guanidine labelled with carbon-14 are in progress to ascertain the possibility whether or not guanidine-dependent viruses incorporate guanidine.

Immunological Response of an Elasmobranch to Human Influenza Virus

Investigations here concerning virus infections of marine animals and of their cells in tissue culture indicated the need for an understanding of the immunological responses of such animals. To our knowledge there are no published reports on antibody production in marine fish (elasmobranchs or teleosts), although such investigations have been reported for fresh-water fish[1-4]. This paper represents a preliminary report on the production of viral antibodies in sharks.

Three female 10–15 lb. lemon sharks, *Negaprion brevirostris*, were injected with the *PR* 8 strain of influenza *A* virus (chick allantoic fluid, hæmagglutinin titre of 6,400 units/ml.) according to the schedules seen in Table 1. The results of hæmagglutination inhibition tests with sera from these animals, performed at room temperature (approximately 27° C) and using guinea pig red blood cells, are also shown in Table 1. They clearly indicate that sharks are capable of forming antibodies to a mammalian virus. Heating these immune sera to 56° C for 30 min failed to reduce the hæmagglutination inhibition activity. Both normal and immune shark sera contained hæmagglutinins for guinea pig red blood cells as well as non-specific inhibitors in low concentration for influenza *A*–2 (Asian strain) and influenza *B* (Lee strain). The former could be removed by adsorption with guinea pig red blood cells and the latter by adsorption with kaolin without reducing the immune hæmagglutination inhibition titre to *PR*8 virus. Immune shark sera also neutralized *PR*8 virus infectivity for chick embryos, as seen in the corresponding part of Table 1. However, complement fixation tests with *PR*8 antigen indicated that shark sera did not fix guinea pig complement. Indirect complement fixation tests have not yet been done.

These investigations indicate the elasmobranchs can form specific heat-stable antibodies to influenza virus. Work is at present in progress to determine the effects of

different routes, dosages and schedules of injection of *PR*8 as well as other antigens. In addition to serological investigations, the present work includes chemical characterization of shark antibodies.

Part of this work was carried out at the Lerner Marine Laboratory, Bimini, British West Indies. We wish to thank Dr. Robert F. Mathewson and his staff for their help. The work was supported by a contract from the Office of Naval Research, U.S. Navy.

Note added in proof. Recent results indicate that the lemon shark is capable of producing hæmagglutination-inhibition titres of from 1 : 5,000 to 1 : 40,000 under certain conditions of dosage and route of injection. This work will be published elsewhere.

An Anti-Virus Action of Azaserine-Thioguanine *in vivo*

RECENT work on the tumour-inhibiting action of 6-thioguanine (TG) has suggested strongly that growth inhibition is correlated with the incorporation of TG into the tumour nucleic acids, and particularly into DNA. Pre-treatment of tumour-bearing mice with azaserine (AS), an inhibitor of *de novo* purine synthesis, greatly enhanced the inhibitory action of TG, and this was associated with an increased incorporation of TG into the tumour nucleic acids[1,2].

From these results it seemed possible that TG, with or without AS, might have anti-virus activity, and some preliminary observations are reported in this communication. As a test system it was decided to use the virus dis covered by Riley *et al.*[3], which causes an elevation of plasm lactic dehydrogenase (LDH) activity by a factor of abou 6-fold in infected mice. These authors showed that th virus was present in many varieties of transplantabl mouse tumours and that it was readily transmitted b inoculation of small amounts of blood or plasma take from tumour-bearing mice. The inoculated animals ma in turn be used as sources of virus. These observation have been confirmed and extended by many investigators[4]

One important reason for using the Riley virus-plasm LDH system in the present work was the readiness wit which virus activity can be assayed by using the rise i plasma LDH activity which occurs after the inoculation o an infective dose. After inoculation, Riley virus builds u very rapidly in the plasma after a short lag phase. Rowso and Adams[5] showed that the plasma of mice inoculate with about 10^4 infective doses contained little virus 5 h afterwards, but that during the next few hours the plasm virus titre rose to about 10^8 infective doses/ml.

Experimentally, groups of four mice were inoculated with 0·01 ml. of plasma taken from a mouse which had been infected four weeks previously with Riley virus. Fifteen minutes before the inoculation one group of mice was injected intraperitoneally with 10 mg/kg AS. One hour after inoculation this group was injected with 10 mg/kg TG, repeated at hourly intervals for 6 h, and finally with two similar doses of TG at 90-min intervals. Blood (0·03 ml.) was withdrawn from the tails of the control and treated mice at intervals, and the blood from each group pooled, diluted in heparin saline, and centrifuged. Serial dilutions of plasma were then injected into groups of three mice. After seven days their LDH activity was determined[4] and the results are given in Table 1 as high (infected) or low (normal). Five hours after infection the plasma of both groups of mice contained less than 10^2 infective doses/ml. After a further 2 h the titre of the untreated group had risen to approximately 10^5 infective doses/ml. of plasma, while that of the treated group was between 10^3 and 10^4 infective doses/ml. Eleven hours after infection the titre of the untreated group had risen to between 10^6 and 10^7 infective doses/ml. while that of the treated mice remained at around 10^4 infective doses/ml. Twenty-four hours after infection the titre of both groups was at least 10^{11} infective doses/ml., which is considerably higher than the maximum titre obtained by Rowson and Adams[5]. This may be due to the use of a different strain of mice, or a higher initial infective dose.

The results show that over the period during which the injections were given there was a large reduction in plasma virus titre in the treated animals. By analogy with the mechanism of the inhibition of tumour growth resulting from treatment with an AS–TG combination it seems reasonable to suggest that TG is being incorporated into the virus nucleic acid to produce a non-infective molecule. Further experiments are in progress to test this hypothesis.

The nine doses of 10 mg/kg TG given to the mice during the course of treatment caused a loss in body-weight of about 5 per cent, which was regained rapidly, and the mice appeared healthy and active at all times.

Table 1. RILEY VIRUS CONTENT OF SERUM FROM NORMAL (N) AND AS–TG TREATED (TG) MICE AFTER INFECTION WITH 0·01 ML. OF PLASMA FROM A PREVIOUSLY INFECTED MOUSE

Ml. of plasma injected	Time of withdrawal of blood samples (hours after infection) 5 N	5 TG	7 N	7 TG	11 N	11 TG	24 N	24 TG
10^{-11}							+++	+−−
10^{-10}							+++	+++
10^{-10}							+++	+++
10^{-9}							+++	+++
10^{-8}					−−−	−−−		
10^{-7}			−−−	−−−	−−−	−−−		
10^{-6}			−−−	−−−	+++	−−−		
10^{-5}			++−	−−−	+++	−−−		
10^{-4}	−−−	−−−	+++	−−−	+++	++−		
10^{-3}	−−−	−−−	+++	+++	+++	+++		
10^{-2}	−−−	−−−	+++	+++				

Blood was withdrawn at intervals and serial dilutions of plasma were inoculated into groups of three mice. The plasma LDH activity of these animals was determined seven days after inoculation. LDH activities in the individual mice are given as normal (−) (non-infected) or raised (+) (infected).

Very recently a report has appeared suggesting that ioguanosine reduces by a factor of 10 the infective Rous rcoma virus in a chick embryo tissue culture[6].

This work was supported by contract No. *SA-43-ph-*)68, Cancer Chemotherapy National Service Center, ational Cancer Institute, National Institutes of Health, id grant No. *CY*-4551, both from the U.S. Public Health ervice.

SOIL SCIENCE

Reaction between Monocalcium Phosphate and Calcium Carbonate

WHEN an acid phosphate is applied to a soil containing alcium carbonate or mixed with liming material a reaction rill occur leading to the formation of more basic phoshates such as dicalcium phosphate, octocalcium phoshate and hydroxyapatite.

In order to investigate what phosphate may initially be ormed and at what rate when triple superphosphate eacts with calcium carbonate, the following simple xperiments were conducted.

In the first experiment, which was performed at room emperature, a 5-cm layer of dry calcium carbonate was laced in a glass tube and a 2·5-cm layer of monocalcium hosphate (analytical grade) was placed on top. Air aturated with water vapour was then passed down the olumn for 10 days. During this experiment the layer of alcium phosphate was seen to absorb moisture and a hard –10-mm thick cake was formed at the top of the calcium arbonate column. After separation of this cake from the alcium carbonate column it was found (by X-ray diffracion analysis) to consist mainly of dicalcium phosphate lihydrate (about 80 per cent) and some calcite.

The experiment was repeated with commercial granular riple superphosphate (49 per cent phosphorus pentoxide, article size 2–4 mm) instead of pure monocalcium phoshate and the result was similar to that with the pure hosphate.

able 1. RATE OF REACTION BETWEEN DRY TRIPLE SUPERPHOSPHATE (TSP) ND DRY CALCIUM CARBONATE WHEN ABSORBING WATER FROM MOIST AIR

Amount of TSP used (g)	ml. N/10 Ba(OH)$_2$ consumed per g triple superphosphate			
	1 day	2 days	3 days	8 days
0·0477	38·2	62·0	69·7	74·3
0·0808	40·0	64·8	68·3	70·1
0·0992	38·6	60·6	63·1	66·0
fean	38·9	62·2	67·0	70·1
		Theoretical: - 69·0		

In a second experiment the evolution of carbon dioxide esulting from the following reaction between monocalcium hosphate and calcium carbonate $Ca(H_2PO_4)_2 + CaCO_3 + H_2O \rightarrow 2CaHPO_4.2H_2O + CO_2$ was measured as a function f time, using Cavett micro-diffusion flasks[1]. The small essels were half-filled with dry calcium carbonate and a nown weight of dry triple superphosphate (49 per cent hosphorus pentoxide, particle size 2–4 mm) was placed on he surface of the calcium carbonate. 5 ml. N/10 barium hydroxide was measured into each of the flasks, which were kept at laboratory temperature, and the unused barium hydroxide was titrated with N/10 hydrochloric acid at intervals. A blank with no phosphate was included.

The results of this experiment, expressed as ml. N/10 barium hydroxide used per 1 g triple superphosphate, are given in Table 1 and indicate that the initial reaction leading to the formation of dicalcium phosphate terminated within 3–4 days.

The finding of the first experiment supports the assumption of Lehr *et al.*[2] that the monocalcium phosphate in fertilizer granules can absorb sufficient water from the vapour phase for complete dissolution. The formation of dicalcium phosphate dihydrate by reaction between calcium carbonate and the acidic solution from monocalcium phosphate is also in agreement with investigations at Tennessee Valley Authority[2,3]. The length of the period required to complete the reaction (Table 1) corresponds well to the time needed by tablets of monocalcium phosphate to absorb enough water from saturated air for complete hydrolysis[2].

Soil Nitrogen Accretion under Different Covers in a Tropical Rain-Forest Environment

IN the course of an investigation[1] of soil fertility-levels in plots on the Faculty of Agriculture farm at University College, Ibadan, total (Kjeldahl) nitrogen accumulation in the upper 16 in. of soil under five different covers over a three-year period was measured.

The plots (not replicated) were laid down at the end of 1953 on a site cleared from secondary bush, as a pilot experiment to examine changes in soil microflora and physical and chemical properties. Most of the surface soil layer, high in organic matter, was removed in the process of clearing and levelling. The cover treatments were: (1) stargrass (*Cynodon plectostachyus*); (2) no vegetation; (3) a mulch of speargrass (*Imperata cylindrica*) renewed about once a month in the wet season; (4) tropical kudzu (*Pueraria phaseoloides*); (5) regenerated bush. With the exception of the mulched plot no plant material was removed from, or added to, the plots at any time. Annual rainfall at the site was as follows: 59·6 in. (1957); 39·2 in. (1958); 45·1 in. (1959). Losses as a result of leaching and gains in rainwater are not known, but published figures indicate that the net gains or losses due to these factors are likely to be small compared with the differences reported in this communication. Under tropical conditions losses by leaching may be 15–35 lb.[2] and additions in rainwater and dust 4–50 lb.[3] nitrogen per acre per annum.

Soil samples were taken to a depth of 16 in. in January 1957 and December 1959; the two sampling sites on each plot were 4–5 ft. apart.

Table 1 shows the total nitrogen contents of these samples. In converting nitrogen percentages to lb./acre it has been assumed that an acre-6 in. of soil weighs two million lb. Differences between the values for the 1957 and 1959 samples give a measure of accumulation or loss of nitrogen over a period of about three years.

Striking differences are apparent in the legume and bush plots, increases of 770 lb. and 640 lb. nitrogen per acre per annum respectively having occurred in the 0–16 in. layer. In the case of the legume, which was well-nodulated, most of this increase may be attributed to symbiotic nitrogen fixation. This average annual increase in soil nitrogen was two or three times that usually anticipated under either tropical or temperate legumes, although in New Zealand

symbiotic fixation of 600 lb. nitrogen per acre per annum has been reported[4]. It is perhaps significant also that the annual nitrogen fixation by certified New Zealand white clover ranges from 400–500 lb. per acre in the warmer northern areas to 200–250 lb. per acre in the colder south[5], suggesting that temperature is an important factor in the rate at which fixation occurs.

The increase in soil nitrogen in the bush plot was somewhat lower than that in the legume plot. If, however, nitrogen stored in the vegetation is taken into account, the annual increase in nitrogen in the soil–bush system is probably greater than that in the soil–legume system since an equilibrium amount of green vegetative matter would have been reached by the legume before 1957 while the bush would not reach this stage until at least five years[6] had elapsed. The large gains of nitrogen under bush are something of an enigma, particularly as there appeared to be no legume species present in this vegetation. The possibility of non-legumes being symbionts in nitrogen fixation or of free-living nitrogen-fixing micro-organisms in the phyllosphere[7] making an appreciable contribution cannot be dismissed. It is more probable, however, that the greatest nitrogen-fixing activity, presumably by free-living micro-organisms, was in the litter and surface soil layers where very rapid turnover of organic matter occurs.

In the absence of a statistical estimate of error too much emphasis should not be placed on the smaller gains of nitrogen reported for the remaining three treatments. On the mulched plot, of course, nitrogen has been added in the mulch and this is reflected in higher values for the 1959 samples. The apparent accumulation of nitrogen in the 0–16 in. layer of the bare plot, amounting to 110 lb. per acre per annum, may or may not be real. Most of the increase occurred in the surface layer and the possibility of non-symbiotic fixation by blue-green algae cannot be excluded. These are commonly observed in the tropical rain-forest region on bare soil surfaces when the latter are moistened (cf. Lawson[8]). Fuller *et al.*[9] have reported that soil crusts containing blue-green algae showed increases in nitrogen of up to 0·04 per cent in four weeks. Fixation of this magnitude could account for increases of the order mentioned here.

The grass plot showed an increase in nitrogen in the 0–16 in. layer amounting to 80 lb. per acre per annum more than that in the bare plot. Non-symbiotic fixation has very likely made a contribution in this instance as it has been shown in a greenhouse experiment with a similar soil that the presence of grass stimulated nitrogen fixation[10]. It should be noted, however, that the upper 0–8 in. layer showed an increase of 980 lb. nitrogen per acre over the three-year period while the 8–16 in. layer showed a decrease of 410 lb. per acre. This suggests that some, at least, of the nitrogen accumulation in the surface soil layers under the grass was due to the redistribution of nitrogen in the profile. Obviously care must be taken in the interpretation of nitrogen increases in soils under grass if only the upper horizons have been sampled.

It is probable that the same redistribution mechanism was operating in the other plots carrying living vegetation as no nitrogen accumulated in the 12–16 in. layer of the bush plot. In the legume plot this appears to have been masked by symbiotic nitrogen fixation, nitrogen being added down to the 16 in. depth by excretion or death of roots.

A factor which may be involved in the vegetated plots is the release of fixed ammonia in the lower parts of the profile and its transfer to the surface via vegetation. This suggestion is purely speculative as little is known of the quantities of fixed ammonia present in tropical soils, or its significance as far as plant growth is concerned. An appreciable proportion (14–78 per cent) of the total nitrogen in some British Caribbean soils has been reported to consist of fixed ammonium nitrogen[11], and it is known that enormous quantities of nitrogen are present in igneous rocks[12]. Under tropical conditions, in particular, where weathering frequently extends to a considerable depth, the release of this nitrogen may be important in plant nutrition.

Over the 0–16 in. depth little change in the carbon : nitrogen ratios occurred during the three-year period between samplings, with the possible exception of the tropical kudzu plot where the ratio declined from 9·8 to 8·1 (cf. the experiments of Chapman *et al.*[13] with temperate legumes in lysimeters). The other plots showed differences of 0·5 or less. In general, therefore, it appears that net carbon fixation and net nitrogen fixation occurred at approximately the same rate. This has been observed previously by other workers[12–16].

The experiment described here was of a preliminary nature only and any conclusions are of necessity tentative, but the data do suggest that the following processes were involved to a significant degree in the nitrogen economy of the latosol under consideration: symbiotic and non-symbiotic fixation; redistribution by vegetation of nitrogen within the profile; and, perhaps, the release of fixed ammonia by weathering.

It is intended that this experiment be followed by similar experiments, involving larger plots, adequate replication, periodic sampling over a long time, and repetition at a number of locations in different ecological zones within Nigeria.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk are open to the public*)

Monday, January 21

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at p.m.—Mr. Peter Salway: "Exploring the Roman Fenland".

Institution of Electrical Engineers, Electronics Division (at voy Place, London, W.C.2), at 5.30 p.m.—Dr. P. C. Clemmow: "Magtohydrodynamic Waves in the Ionosphere".

Institute of Metal Finishing (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. B. E. Bunce: rying of Electroplated Parts".

Royal Institute of Chemistry, London Section (at Enfield Technical llege, Queensway, Ponders End), at 7 p.m.—Dr. A. G. Maddock: "Actinide emistry".

Tuesday, January 22

University of London (in the Anatomy Theatre, University College, wer Street, London, W.C.1), at 1.15 p.m.—Dr. A. D. Blest: "Moths d Predators".*

University of London (at the Imperial College of Science and Techlogy, London, S.W.7), at 5.30 p.m.—Prof. A. G. Gaydon: "Application Spectroscopy to the Study of High-Temperature Gases" (Inaugural cture).

University of London (at the London School of Hygiene and Tropical edicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—of. K. R. Hill: "Hepatic Veno-Occlusive Disease".* (Fourth of twelve ctures on "The Scientific Basis of Medicine" organized by the British stgraduate Medical Federation.)

Society of Chemical Industry, Plastics and Polymer Group (at Belgrave Square, London, S.W.1) at 6.30 p.m.—Prof. H. Batzer (Basle): ycloaliphatic Epoxides, Synthesis and Properties".

Institute of Biology (at the Royal Entomological Society, 41 Queen's ate, London, S.W.7), at 7.15 p.m.—Mr. W. H. Dowdeswell: "Research in hools".

Wednesday, January 23

University of London (at the Postgraduate Medical School of London, oane Road, London, W.12), at 2 p.m.—Dr. K. L. Goldsmith: "Antidies to Platelets and Leucocytes".*

Institution of Electrical Engineers, Power Division (at Savoy ace, London, W.C.2), at 5.30 p.m.—Mr. T. B. Burnett and Mr. G. W. aham: "Transductor-Assisted Tap Changing on a 50 c/s Locomotive with miconductor Rectifier".

British Institution of Radio Engineers, Computer Group (at the ondon School of Hygiene and Tropical Medicine, Keppel Street, Gower reet, London, W.C.1), at 6 p.m.—Symposium on "Tunnel Diodes as orage Elements".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westinster, London, S.W.1), at 6 p.m.—Prof. M. Yoshiki: "The Construction d Fabrication of Large Tankers in Japan" (Thomas Lowe Gray Lecture).

Society of Chemical Industry, Food Group (joint meeting with the emical Engineering Group, at 14 Belgrave Square, London, S.W.1), at 15 p.m.—Meeting on "Heat Transfer in Food Processing".

Royal Institute of Chemistry, London Section (joint meeting with e Slough College Scientific Society, at Slough College of Further ducation, William Street, Slough), at 7.30 p.m.—Prof. Wilson Baker, R.S.: "Non-benzenoid Aromatic Hydrocarbons".

Thursday, January 24

University of London (in the Anatomy Theatre, University College, ower Street, London, W.C.1), at 1.15 p.m.—Mr. A. P. Cavendish: "Philophy as Ritual".*

Linnean Society of London (at Burlington House, Piccadilly, London, .1), at 5 p.m.—Dr. C. G. Johnson: "Insect Migration, Dispersal, and the rial Plankton"; Mrs. Maureen E. Lacey: "The Discovery of *Pithomyces artarum* in Britain"; Dr. R. R. Davies: "Studies on the Microbiology City Atmospheres".

University of London (at Westfield College, Kidderpore Avenue, ndon, N.W.3), at 5.15 p.m.—Prof. E. H. Bellamy: "Elementary Partles" (Inaugural Lecture).*

University of London (at the London School of Hygiene and Tropical edicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—r. J. C. F. Poole: "Structural Aspects of Thrombosis".* (Fifth of twelve ctures on "The Scientific Basis of Medicine" organized by the British stgraduate Medical Federation.)

Institution of Mechanical Engineers, Hydraulic Plant and achinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), 6 p.m.—Discussion on "Hydraulic Engineering and the Common Market".

Friday, January 25

Royal Astronomical Society (at Burlington House, Piccadilly, London, .1), at 4.15 p.m.—Geophysical Discussion on "Long Sea Waves". Chairan: Prof. J. Proudman, F.R.S.

University of London (at the Royal Holloway College, Englefield reen, Surrey), at 8.15 p.m.—Sir Richard van der Riet Woolley, F.R.S.: The Size of the Galaxy".

Royal Institute of Chemistry, London Section (joint meeting with e Cambridge University Chemical Society, at the University Chemical aboratory, Lensfield Road, Cambridge), at 8.30 p.m.—Mr. D. G. Ohlman: The Developing Activities of the Royal Institute of Chemistry".

Saturday, January 26

Systematics Association (in the Department of Botany, The Univerty, Edgbaston, Birmingham), at 2.15 p.m.—Meeting on "The Place of axonomy in the Teaching of Biology".

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. G. de G. Sieveking: "Upper Palaeolithic Cave Painting in Europe".*

Monday, January 28

Plastics Institute, Reinforced Plastics Group (at the Wellcome Building, Euston Road, London, N.W.1), at 4 p.m.—Symposium on "Costing".

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Ju Chin Chu (Polytechnic Institute, Brooklyn): "The Role of the Chemical Engineer in the Space Age".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Electricity as a Measure of the Rising Standard of Material Prosperity" opened by the President.

Institution of Mechanical Engineers, Education and Training Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on the Government White Paper "Industrial Training: Government Proposals".

University of London (in the Chemistry Lecture Theatre, Birkbeck College, Malet Street, London, W.C.1), at 6 p.m.—Prof. D. J. G. Ives: "Some Reflections on Water".* (Inaugural Lecture.)

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Chief Inspector (with a first- or second-class honours degree in physics or engineering, and corporate member of an appropriate professional institution) in the Inspectorate of Nuclear Installations of the Ministry of Power, to take charge of sections of the Inspectorate concerned with the safety assessment of nuclear installations, and with special problems in nuclear physics, chemistry, metallurgy, and health physics—The Civil Service Commission, 17 North Audley Street, London, W.1, quoting Ref. S/5612/63 (January 31).

Lecturer in Physics—The Registrar, King's College (University of London), Strand, London, W.C.2 (January 31).

Senior Lecturer, Lecturer, or Assistant Lecturer in Mathematics—The Registrar, University of Sussex, Stanmer House, Stanmer, Brighton (January 31).

Assistant Lecturers (2) in the Department of Physics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 2).

Lecturer or Assistant Lecturer (one or two posts) in Chemistry—The Registrar (Room 22, O.R.B.), The University, Reading (February 2).

Research Demonstrator in the Department of Physics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 2).

Lecturer or Assistant Lecturer (with special interests in vertebrates) in Zoology at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 4).

Assistant Lecturer (with a good degree and preferably teaching experience) in Physics and Mathematics at Bendigo Technical College, Bendigo, Victoria, Australia—Council for Technical Education and Training for Overseas Countries, 12 Lincoln's Inn Fields, London, W.C.2 (February 5).

Lecturer in Biochemistry—The Secretary of University Court, The University, Glasgow (February 7).

Reader (preferably with a higher degree and appropriate professional qualifications) in Fluids and Hydrology in the Department of Civil Engineering—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (February 8).

Lecturer and an Assistant Lecturer in Physics—The Registrar, The University, Sheffield (February 9).

Assistant Lecturer or Lecturer in the Department of Applied Mathematics and Mathematical Physics—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (February 11).

Lecturer (graduate with some research experience, with special interests in soil or rock mechanics) in Civil Engineering—The Secretary, University College, Gower Street, London, W.C.1 (February 14).

Reader in Organic Chemistry at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 14).

Lecturer in the Department of Biological Chemistry—The Secretary, The University, Aberdeen (February 15).

Lecturer or Assistant Lecturer (preferably with morphological and taxonomic interests) in Botany at the University College of Rhodesia and Nyasaland—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 15).

Lecturer or Assistant Lecturer (preferably with the ability to teach either logic or the philosophy of science) in Philosophy—The Registrar, The University, Hull (February 15).

Lecturer/Senior Lecturer in Pure Mathematics at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 15).

Senior Tutor–Demonstrator in Applied Mathematics at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 15).

Official Fellow and Tutor in Pure Mathematics—The Master, St. Catherine's College, Oxford (February 15).

Chair of Animal Science—The Registrar, The University, Nottingham (February 18).

Chair of Zoology in the School of Biological Sciences at King's College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 19).

Chair of Botany in the School of Biological Sciences at King's College—The Academic Registrar, University of London, Senate House, London W.C.1 (February 20).

Chair of Electronic Engineering—The Registrar, The University, Nottingham (February 22).

Lecturer (chiefly concerned with mycology and cytogenetics) in the Department of Botany—The Registrar (Room 22, O.R.B.), The University, Reading (February 23).

Lecturer/Senior Lecturer in Physics at the University of Tasmania—The Secretary, Association of Universities of the British Commonwealth

(Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, February 25).

Reader in Science of Materials at Queen Mary College—The Academic Registrar, The University of London, Senate House, London, W.C.1 (February 25).

Chair of Civil Engineering—The Secretary, The Queen's University, Belfast, N. Ireland (February 28).

College Lecturer in Pure Mathematics—The Master, Emmanuel College, Cambridge (March 1).

Lecturer in Agricultural Chemistry with special reference to Animal Biochemistry and Nutrition—The Secretary, Wye College (University of London, near Ashford, Kent (March 1).

Chair of Veterinary Clinical Studies—The Registrar, The University, Liverpool, quoting Ref. No. CV/233/N (March 2).

Research Fellow for Independent Research—The Assistant Registrar (Room 28, O.R.B.), The University, Reading (March 4).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Civil Engineering or **Physics**—The Registrar, Trinity College, Dublin 2, Republic of Ireland (March 5).

Imperial Chemical Industries Research Fellows in Chemistry or **Physics**—The Registrar, The University, Keele, Staffs (March 5).

Chair of Biology (in the field of genetics) in the School of Biological Sciences, University of Sydney, Australia—The Secretary, Association of the Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 15).

Lecturer (with qualifications and experience in the general field of inorganic, structural and physical chemistry) **in Chemistry** at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, March 31).

Second Chair of Biochemistry in the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, March 31).

Graduate Research Assistant for the tissue-culture assay of drugs—Dr. O'Sullivan, Courtauld Institute, Middlesex Hospital Medical School, London, W.1.

Graduate Research Assistant, to work on the chemistry of medicinal natural products—Dr. G. B. Francis, Department of Biochemistry, The Medical College of St. Bartholomew's Hospital, Charterhouse Square, London, E.C.1.

Lecturer (man or woman) **in Geography and Education**—The Principal, Hockerill College, Bishop's Stortford, Herts.

Lecturer or **Assistant Professor** (Ph.D. physicist) **in the Department of Physics**—The Chairman, Department of Physics, Sir George Williams University, Montreal, Quebec, Canada.

Librarian (female, with a science degree and preferably a working knowledge of German and French), for a small scientific library—The Director of Research, Cereals Research Station, Research Association of British Flour-Millers, Old London Road, St. Albans, Herts.

Marine Botanist in the Department of Biology—Head of the Department of Biology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Physicist (honours graduate) for basic research of considerable human interest concerning the physics of respirable dust production, its measurement and control—The Personnel Officer (X1650), Mining Research Establishment, National Coal Board, Worton Hall, Worton Road, Isleworth, Middlesex.

Plant Breeder (22–45, with a degree in natural science and two years postgraduate training with plant breeding as a major discipline) in the Ministry of Agriculture, Kenya, to work as a member of the Plant Breeding Team in particular on wheat breeding—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. C.1/RC.213/80/04.

Principal Lecturer (well qualified and with sound teaching and research experience) **in Chemistry**—The Academic Registrar, Hatfield College of Technology, Hatfield, Herts.

Technician in the Department of Zoology—The Assistant Secretary, Westfield College (University of London), Hampstead, London, N.W.3.

Vice-Principal—The Secretary and Registrar, Bristol College of Science and Technology, Ashley Down, Bristol 7, quoting Ref. CST.63/2.

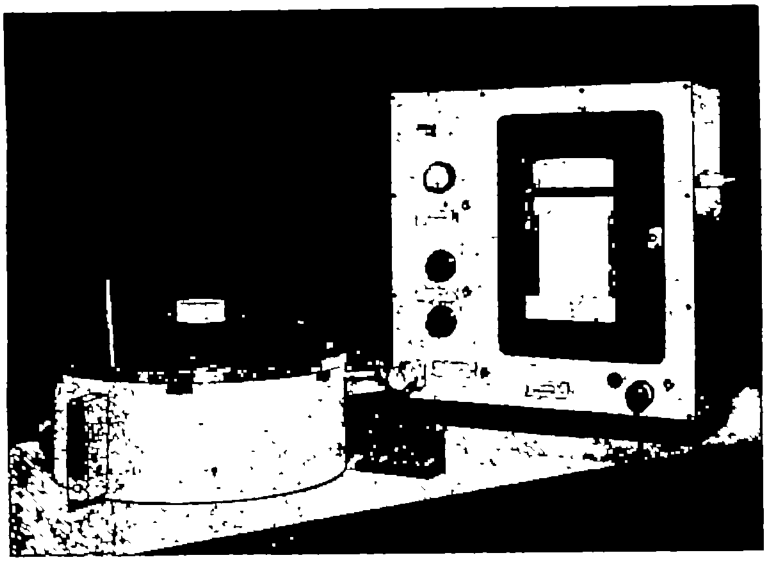
ANNOUNCEMENT

A new British Company presents the wide range of laboratory equipment by Jouan of Paris.



No. 1 THE BONET-MAURY

BIOPHOTOMETER

For continuous recording of optical density changes in culture media—up to six samples at a time.

A recent evaluation is given in :

'Metabolism of Resistant Mutants of Streptococcus faecalis—IV. Use of a Biophotometer in Growth-Curve Studies' by M. Katharine Coultas and Dorris J. Hutchison, Journal of Bacteriology (U.S.A.), Vol. 84, No. 3, pp. 393–401, Sept. 1962.

Write for details to :

S T **SCIENTIFIC TECHNIQUES LTD.**

9, RELIANT WORKS, BETCHWORTH, SURREY.

In association with Metallurgical Services (Planned Products (Metallurgy)) Ltd.

TELEPHONE: BETCHWORTH 2686

£500 A YEAR TAX FREE FOR YOUR FAMILY

The Equitable offers you a special plan to protect your family's future at the lowest possible cost. Should you die within a period of 20 years your dependants will receive £500 a year tax free for the balance of the period.

You only pay premiums for 15 years and if you are 29 now the cost is as little as £18.5.0. a year—about 7/- a week. The premiums for larger benefits are in proportion.

The Equitable offers attractive terms because it has no shareholders to take any part of the profits and pays no commission for the introduction of business.

THE EQUITABLE

FOR A BETTER DEAL

The Equitable Life Assurance Society,
19, Coleman Street, London, E.C.2.
Please send me full details of the 'Income for Dependants' Policy.

CYGNET meets the demands of science

Murex Ltd., Rainham. Architects: P. Edwin & Partners, A.R.I.B.A., London

We equip many of this country's most important laboratories. Progressive design, superb craftsmanship and versatility of arrangement contribute to the maximum efficiency of our installations. Specially selected timbers are used for our furniture and we can supply single units or complete installations at highly competitive prices. Our design experts work in close collaboration with the architect in the submission of plans. And Cygnet's complete consultative service is always available.

APPOINTMENTS VACANT

KWAME NKRUMAH UNIVERSITY OF SCIENCE AND TECHNOLOGY

KUMASI, GHANA

DEPARTMENT OF PHARMACY

Applications are invited for the following posts
(a) Senior Lecturer in Pharmacognosy.
(b) Lecturer in Pharmacognosy.

Qualifications: Applicants for either post should hold a degree in either pharmacy or botany. In the latter case, a recognized pharmaceutical qualification would also be desirable. In the case of the senior appointment, applicants should have previous experience in either teaching or industrial research.

Duties: Successful candidates will be expected to teach up to the level of the General Degree in Pharmacy of the University. In addition to teaching duties, candidates will be expected to participate in a research programme of investigation of the medicinal and toxic plants of Ghana. This programme is being carried out in conjunction with the Chelsea College of Science and Technology, London.

Appointments are normally for five years and may be renewed: one term's notice of resignation of an appointment is required on either side.

SALARY SCALES:
Ghanaian Lecturer: £G.1,050 by £G.50 to £G.1,400 by £G 75 to £G 1,850, £G.1,900
Ghanaian Senior Lecturer: £G 1,750 by £G 75 to £G 2,200
Expatriate Lecturer: (Contract) £G.1,386 by £G 66 to £G 1,848 by £G 99 to £G.2,442, £G.2,508.
Expatriate Senior Lecturer: (Contract) £G 2,310 by £G.99 to £G.2,904.

Children's allowances are paid in respect of expatriates up to a maximum of five at the rate of £G.50 per annum per child resident in Ghana and £G.100 per annum per each dependent child in full-time education overseas up to a maximum of 21 years of age

Annual leave with three free return passages in four years is granted to expatriate members of staff and their families.

Application forms and any additional information may be obtained from Assistant Registrar, Kwame Nkrumah University of Science and Technology, 15 Gordon Square, London, W C 1.

Completed application forms in triplicate, should reach the above-mentioned address not later than February 15, 1963.

TEXAS TECHNOLOGICAL COLLEGE

LUBBOCK, TEXAS, U.S A

The Physics Department of Texas Technological College invites applications for appointment at the rank of Assistant Professor and above These positions include a combination of teaching and research Applicants should hold the Ph D degree and be prepared to participate in research at the M.S and Ph.D level Salaries for the academic year for the inexperienced Ph D. will begin at $7,500 with appropriate adjustments in rank and salary for experienced persons

Applications, including the names of three references, should be sent directly to Professor H. C. Thomas, Physics Department, Texas Technological College, Lubbock, Texas.

UNIVERSITY COLLEGE OF NORTH WALES

BANGOR

Applications are invited for the post of Professor and Head of the Department of Physics. The appointment will date from October 1, 1963, and the salary will be not less than £2,600 per annum, with superannuation and family allowances.

Ten copies of the application should reach the undersigned, from whom further particulars may be obtained, not later than February 8, 1963.

KENNETH LAWRENCE,
Secretary and Registrar.

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF LAND RESEARCH AND REGIONAL SURVEY

SOIL SCIENTIST

Applications are invited for appointment to a position of Soil Scientist with the Organization's Division of Land Research and Regional Survey, located at Canberra, A.C.T.

The appointee will be a member of the Division's scientific unit which for the past fourteen years has been conducting land resources surveys on the Australian mainland and in Papua and New Guinea In these studies the geology, geomorphology, pedology, botany and climatology of regions are integrated. The officer will be expected to contribute to composite reports and to publish individual specialist papers. The appointee will make field studies initially with the unit working in Papua-New Guinea for three to four months in at least alternate years. The remainder of the time will be spent at the Headquarters of the Division in Canberra, A.C.T., where the compilation of maps, reports and papers dealing with the field surveys and subjects arising from them will be prepared. The work will involve the extensive use of aerial photographs and their interpretation.

Applicants should possess at least a university honours degree in science, rural science, or agricultural science or equivalent qualifications and at least two years' research and field experience in soil survey. Training in allied subjects such as plant ecology, geomorphology and land use classification is desirable

SALARY: Dependent upon qualifications and experience within the ranges:

£A1,541 to £A2,296 per annum or £A2,426 to £A2,751 perannum.

Promotion within C.S.I.R.O. is by merit and may ultimately go beyond the upper limit of the scale within which the original appointment is made.

Fares for the appointee and his dependent family. Further particulars supplied on application to:

Mr. P. F. Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2,

to whom applications (quoting Appointment No: 618/112) should be addressed by February 23, 1963.

Research Engineers
Research Chemists

GROUP LEADERS

A re-organization and expansion of Research and Development activities at Columbia Cellulose have created a number of interesting and challenging opportunities for Research Engineers, Research Chemists and Research Administrators in the following areas.

- **DEVELOPMENT WORK**
  The development programme is directed towards improvement of present products and processes involving evaluation of wood species properties, pulping and bleaching studies and the development of new pulp products.
- **APPLIED RESEARCH**
  This area of work is concerned with new products and processes outside our present operations. It involves studies of new methods of delignification and purification, chemical modification of cellulose and new uses for wood.
- **BASIC RESEARCH**
  Studies of a long-term nature are concerned with providing data for ultimate use by the Applied and Development groups. These studies are conducted on the chemical and physical properties of wood, the purification of cellulose, cellulose derivatives and pulp purification processes.
- **QUALIFICATIONS AND EXPERIENCE**
  Applicants should hold a Bachelor or higher degree in chemistry or chemical engineering with experience in Physical Chemistry, Cellulose Chemistry and Chemical Engineering preferred.

Dr. John C. Clunie, Technical Adviser to the President, will conduct interviews in the United Kingdom during February, 1963. Please write him c/o British Columbia House, 1-3 Regent Street, London, S.W.1, England, or reply in confidence to.

COLUMBIA CELLULOSE
COMPANY, LIMITED
1030 West Georgia Street, Vancouver 5, B.C.
Attention: Director of Research and Development.

CONTROL OF WATER SUPPLY AND CONSERVATION IN GREAT BRITAIN

THE widespread interest aroused by the debate in the House of Lords last February, when the Manchester Corporation Bill proposing to take water for Manchester and south-east Lancashire was rejected, was not entirely due to the amenity aspect and the defeat of an attempt to intrude on a national park. It was also due to the wider issues of water supply generally and the possibilities of alternative sources of supply. The Manchester submission as to the need for extra water supply had been carefully prepared and was fully supported by the evidence of the Committee on the Growing Demand for Water in its first, second and final reports. Since then a technical committee of water engineers has been studying the present and future water demand in the Manchester region and the possible sources of supply, and another group, including representatives of the Lake District and of water users in south-east Lancashire, has been examining the amenity aspect of various projects.

In the meantime, however, the national aspect of the whole problem of water supply and conservation has come to the front, and the particular issues of Manchester and south-east Lancashire, and Ullswater or Windermere seem more likely to be considered, as they should be, in the national context. The Proudman Committee had already presented its final report, in December 1961, when the debate was held, and shortly afterwards, in April 1962, the Government published its proposals in a White Paper, *Water Conservation in England and Wales* (H.M.S.O. Cmnd. 1693). This was debated in the House of Lords on May 23, and later the Government produced its *Water Resources Bill**, which received a first reading in the House of Lords on November 22.

The White Paper sets forth very fairly the background against which the Government had decided that the rising demand for water for domestic, industrial and agricultural use would require action over a wide front and had been led to extend the terms of reference of the Sub-Committee inquiring into the situation. The Sub-Committee's final report convinced the Government that comprehensive action to conserve water resources was urgently required, and, in particular, that a new approach was needed to the whole problem. The Government accepted the recommendation for the establishment of river authorities throughout England and Wales, to be responsible for water conservation and also for the functions now performed by river boards. Moreover, it accepted the need for a central authority distinct from the Ministry of Housing and Local Government, but responsible to the Minister, to collate information about water resources on a national basis and to secure and co-ordinate the promotion by river authorities of major conservation schemes, particularly schemes to transfer water from one river basin to another.

As to the size of the river authorities, the Government agreed with much that the Sub-Committee had to say regarding the advantage of a small and compact body. However, because much of the income of the river authorities, particularly for land drainage functions, will be raised by precept on local authorities, the Government considered that local authorities should be represented and that the proposed membership of 10–15 was too small for this purpose—the White Paper suggests instead 21–31 members. At Ministerial level, however, the Government contemplated a division of responsibility, the Minister of Agriculture, Fisheries and Food being responsible for land drainage and fisheries aspects and the Minister of Housing and Local Government for water conservation and prevention of pollution aspects.

It is to be regretted that the amenity aspect was completely ignored in the White Paper, for inasmuch as the Minister of Housing is responsible for national parks it should be carried out by him. However, the same Minister is to be specifically charged with appointing a small central authority to build up a national picture of water resources and requirements, determine where alternative supplies are best available, advise on capital investment and initiate research. This central authority is to be concerned with water conservation only but, although primarily an advisory body, it will have powers to control the fact-finding activities of the river authorities. Land drainage, prevention of pollution and the administration of fisheries are regarded as local in character and it is considered that the resulting problems can be solved within the individual river basin. The Government accordingly contemplate an authority of not more than six members, mainly, if not wholly, part-time, but comprising a wide range of professional and technical experience and provided with its own expert staff.

When these proposals were discussed in the House of Lords on May 23, Lord Silkin, who had begun by stressing the need for full information as to Britain's natural resources and the prospects of increased consumption, questioned the adequacy of the proposed advisory authority, and, as regards the central authority itself, suggested that the representation of consumers rather than of the local authorities should dominate. This view found wide support in the debate and the advisory character of the proposed authority was also criticized, the preference on balance being for a body with executive powers. The question of amenities was raised by Viscount Colville, Lord Chorley and Lord Walston, who urged that this aspect should be considered from the start and required decisions at a national and not a local level. It was also urged that statutory water suppliers should be more ready to provide non-potable water to industry.

In replying to this debate, the Parliamentary Secretary to the Ministry of Housing and Local Government, Earl Jellicoe, claimed that a consistent national water policy had been pursued since the publication in 1944 of the White Paper, *A National Water Policy*. He pointed out that the present paper showed that the Government fully accepted the view of the Proudman Committee that it should no longer be left to individual initiatives to develop Britain's water resources according to their separate needs. Comprehensive action was urgently required as well as a new approach, and this for the first time was proposed in the White Paper. He also added that it was proposed that conservation should be self-supporting, the large expenditure involved being met from fees and charges from all extractors and users. He suggested that the Government still had an open mind as to the number of authorities, but he strongly defended the view that the new central authority must in the main be advisory.

---

* Water Resources Bill. (H.L.) Pp. x+vi+122. (London: H.M.S.O., 1962.) 8s. net.

Earl Jellicoe confirmed that the new central authority would have power of initiation and that its proposed responsibilities were those detailed in the White Paper, but on the question of research, which had been mentioned by several speakers in the debate, he laid particular stress on the part which the central authority might have to play. It would be difficult, he thought, to overstress the importance of research into all aspects of water. As visualized at present, basic research would remain the responsibility of the Hydraulics Research Station, the Water Pollution Research Laboratory at Stevenage, the Meteorological Office, the Geological Survey, the Water Research Association and other existing bodies. However, he pointed out that a special Hydrological Research Unit had recently been established under the wing of the Hydraulics Research Station and suggested that the new authority would be represented on the Co-ordinating Committee on Hydrological Research, and besides commissioning basic research the new authority would stimulate and supervise applied research falling within the province of the new authorities. For these reasons the new central authority would require its own permanent staff and the services of men with a wide range of technical and professional competence.

There is obviously room for some discussion as to the effectiveness of the proposed organization for research. Apart from possible overlapping, the division of responsibility does not appear to be by any means clear, and although two at least of the bodies concerned—the Council for Scientific and Industrial Research and the Nature Conservancy—are responsible to the Minister for Science, the position of the latter was never mentioned. Earl Jellicoe was clearly hoping for a good deal of voluntary agreement, but on the amenity issue he himself said very little—the record of his Ministry as a co-ordinating authority is not at all encouraging in this context.

These points were not discussed further in the debate on May 23, nor was the question of such alternative sources of supply as the use of sea-water mentioned. However, when the Water Resources Bill received its second reading in the House of Lords on November 22, this aspect and the question of research were repeatedly stressed. In introducing the Bill, Lord Hastings directed attention to the research function of the proposed Water Resources Board. Besides making known to the several research agents the questions to which answers would be needed, the Board would organize the necessary field work through the river authorities, and would also be empowered to carry out research if it seemed to be the most appropriate agency for a particular project. He also submitted that the Board had a key role in planning the development of water resources, and without promising the disappearance of such controversial issues as the water schemes discussed under the Manchester Corporation Bill, he maintained that once the Bill was operative the Board would be able to review alternative ways of meeting a particular need. Moreover, it would be able to reach an informed judgment on the practical merits of any particular proposal, in which due account would be taken of the amenity aspect.

In the earlier debate Lord Jessel had put the cost of distilled sea-water as 10*s*. per 1,000 gal. as against an average of 3*s*. for treated or potable water. In the meantime, a good deal of further attention has been directed to the use of sea-water as well as to the re-use of industrial effluent, and it was not surprising that this aspect should be particularly prominent in the debate on November 22. A symposium on the re-use of water in industry had already been arranged in April by the Industrial Water and Effluent Group of the Society of Chemical Industry, although the papers presented were not published in *Chemistry and Industry* until December. The symposium brought out the way the high cost of town water already induced industry to keep its consumption to a minimum. With the need for water of low hardness for some processes, obtainable only by de-ionizing, and, on the other hand, the increasing emphasis on the treatment of effluent to ensure that the water discharged from industrial processes was substantially free from toxic constituents, the electroplating industry, for example, had found that very considerable economies could be obtained by re-using water in plating processes. Probably the greater part of the water used by industry is for cooling purposes and this water can commonly be used again without difficulty.

Obviously, any national water policy should give the maximum encouragement to the re-use of water in such ways; but it is no less important that every encouragement should be given to the possibility of obtaining fresh water from the sea. It was, in fact, stated at the first European symposium on "Fresh Water from the Sea", held at Athens during May 31–June 4, that, with the rapid growth of industry and populations, every country will before long face a water shortage and will require to supplement its supplies by producing fresh-water from sea-water. At present, evaporation is the only commercially feasible method of de-salination and is likely to remain so for the next decade, though ultra-filtration or reverse osmosis is regarded as offering the most promising of the more-distant prospects. Dr. R. S. Silver claimed, however, that distillation was now only a fifth of the cost of what it was in the early 1950's and that distillation was a completely proved and practical process at costs competitive in many areas with those of normal water catchment methods.

Production of drinking-water from sea-water in Britain, using cheap sources of waste steam, for example, is estimated as costing at present rather more than 3*s*. per 1,000 gal., but it is predicted that within five or ten years this could be reduced to 2*s*. per 1,000 gal. Lord Balfour of Inchrye in the House of Lords debate said that in the United States four or five demonstration plants were already producing water at 6*s*.–7*s*. per 1,000 gal., a quarter of the cost in 1952, and that plant to supply 50 million gal. a day now under investigation was expected to give a cost of 2*s*. 6*d*. per 1,000 gal. Lord Balfour urged that the closest possible touch should be maintained on this subject with the United States.

Lord Balfour, who had also cited three examples of such distillation plants in actual use, had stressed the research responsibilities of the Water Resources Board in this connexion. Those responsibilities were equally emphasized by Lord Silkin, who was concerned with the possibility of some confusion of responsibility between the Water Resources Board and those to the Central Advisory Water Committee, and by Lord Fleck. The latter thought that it was important that industrial water should have an adequate place in the organization established, and that Britain should have regard also to the International Hydrological Programme of Unesco, the World Health Organization, the Food and Agriculture Organization and the World Meteorological Organization. Lord Burden also strongly urged the need for directing adequate attention to the distillation of sea-water, and the Earl of Malmesbury again pointed to the risk of duplication of research if the Water Resources Board was not adequately represented on the Hydrological Research Committee.

In replying on the debate, Earl Jellicoe welcomed the references to research and agreed as to the need of directing attention to the possibilities of distilling salt water. The need for the complementary use of surface- and ground-water was also recognized, and the stimulation and co-ordination of research in that field would come within the orbit of the Water Resources Board as well as of the Committee on Hydrological Research, on which the Board would be represented. On the question of amenity, which had been raised again very firmly by Lord Silkin, Lord Fleck (who referred particularly to the Nature Conservancy), Lord Henley, and Lord Chorley, Earl Jellicoe was scarcely more forthcoming than in the earlier debate. Without denying that the defence of amenity might perhaps be strengthened in the Bill, he reiterated that the Bill necessarily represented a balance of interests. Meanwhile, it seems very clear that the Bill demands very close scrutiny from the point of view of research as well as of amenity—including in this context the position of inland waterways generally, though they may also have a supply function. Particularly, it needs close scrutiny in order to ensure that the allocation of responsibility is sufficiently clear to enable effective action as well as efficient diffusion of information to take place. In its present form there is some room for doubt whether it is likely to ensure the co-operation which the Government itself desiderates to command adequate resources and avoid duplication or overlapping of effort, quite apart from providing adequate defence or hearing for what may be minority, but no less vital, national interests.

WATER-RESOURCE PLANNING

Design of Water-Resource Systems

New Techniques for Relating Economic Objectives, Engineering Analysis, and Governmental Planning. By Arthur Maass, Maynard M. Hufschmidt, Robert Dorfman, Harold A. Thomas, Jr., Stephen A. Marglin and Gordon Maskew Fair. Pp. xviii + 620. (London: Macmillan and Co., Ltd., 1962.) 90*s*. net.

THE appearance of an American manual on the design of water-resource systems during the passage of the English Water Resources Bill through Parliament is indeed fortunate, for the Bill proposes the setting up of research groups for which such a manual would be invaluable.

Any organized community needs water for a great variety of uses. Domestic purposes and the disposal of waste products immediately spring to mind, but water is also needed for industrial and agricultural purposes, for transportation and power production, and for recreational facilities. These uses often overlap, sometimes supplementing, but more often conflicting with each other in any tightly packed community. So it is necessary to turn to multi-purpose projects in the use of water. These multi-purpose schemes will cost different amounts according to their composition, while subsequent financial returns will also differ according to the basic design. This brings us to an operational field where economists, engineers and politicians all overlap.

The engineer can indicate what can be done and how much it will cost. The economist can perhaps more readily indicate what is worth doing and how essential it is to the community, while it is more often than not the politician who eventually decides because of the large sums of public money involved. Arriving at the right answer to provide a reliable guide for the politician involves the close co-operation of the engineer and the economist, and this manual on the *Design of Water-Resource Systems* is an attempt to effect this kind of co-operation.

Under the direction of Prof. Arthur Maas, all the interests involved were brought together at Harvard University in a water-research programme and this book of 620 pages, 93 tables and 98 diagrams is the final report of the group inquiry. The methodology of system design, as defined in the book, involves four related steps: identifying the objectives of design, translating these objectives into design criteria, using the criteria to devise plans for the development of specific water-resource systems, and evaluating the consequences of the plans that have been developed.

The book presents the first attempt to work out methods of choosing the right and most economic design method of multi-unit, multi-purpose, water-resource development in any given river basin. New methods of river-system design and a comparison with those now in use are featured. The two chief new techniques considered are the construction of mathematical models that produce optimal decisions and the simulation of systems on high-speed digital computers. The treatment is necessarily detailed and in places somewhat complex; but for those who need only the main principles, there are four generalized chapters which, taken together, give a comprehensive account of the investigation and its results.

W. G. V. Balchin

POPULARIZATION OF SCIENCE

Atoms and the Universe

An Account of Modern Views on the Structure of Matter and the Universe. By Prof. G. O. Jones, Prof. J. Rotblat and G. J. Whitrow. Second, revised edition. Pp. 275 + 37 plates. (London: Eyre and Spottiswoode, 1962.) 30*s*. net.

IT is nowadays generally thought desirable that the intelligent layman should have a knowledge of the work of the scientist. Just what form this popularization should take is less clear. One approach is to emphasize the wonder and excitement of modern scientific achievement so that it can be read as romance. Another approach is to try to explain the scientific method and the way scientists think. Still another approach is strictly practical—how to build your own radio telescope, for example. The best examples of popularization combine some aspects of all these approaches, and if, with all this, real scientific accuracy can be retained, the result is exciting for the layman and respected by the scientist.

The present volume is an excellent example of the best of such books. It is the second edition of a review of nuclear and atomic physics which has already established an enviable reputation. The authors lead the reader from the discovery of the electron and the nature of the elements to the age and size of the universe. They emphasize the unity of the scientific view of Nature and show that the division into physics, chemistry and the biological sciences is largely one of convention and convenience. To discuss the whole of modern physics in 250 pages is clearly impossible; but the authors have made a careful selection of those phenomena to be included. Invariably these are clearly and simply described. After all, most of the concepts of modern physics can be extremely simply described in words. It is only when a quantitative mathematical formulation is required that complexity is revealed.

This second edition is satisfyingly up to date, including the most recently discovered hyperon and the latest in high-energy accelerators. The last third of the book is an excellent sketch of our present knowledge of the solar system, galaxy and universe. This is the oldest of the branches of physics with a 5,000-year history at least. Yet it still abounds with open questions, and now that man is becoming able to make faltering forays into space the whole subject is one of the highest excitement for both scientist and layman.

The authors have wisely chosen to abandon almost completely the historical approach which is so often used in popular scientific books. Instead, they describe the physical world, starting with its smallest constituents, continuing with the binding of atoms into solid matter and finishing with the universe. This emphasizes the unity and beauty of the physicists' picture of our environment which is the concept which gives most thrill and satisfaction to the scientist himself. He is normally less moved by the romanticized history of his subject. However, there is one interesting feature of the scientific scene which is obscured by the non-historical approach, though the authors occasionally refer to it. These are the conditions historical, philosophical, social, psychological, technical and economic which make a scientific break-through possible. The flash of insight may occur, but it is the result of a very large number of pre-conditions. The scientist must be looking with sufficient flexibility of mind at the right class of phenomena with the right class of instrument. The last requirement, which depends on engineering and industrial developments often far removed from physics in their motivation, may be the limiting factor in many cases. Developments in vacuum engineering, electrical engineering, and precision mechanical engineering underlie much of what is described in this book. History suggests that as soon as a new equipment becomes possible to build, the physicist will appear to use it to further our knowledge and sometimes to give a really fresh insight.

The authors do not overlook what might be called the philosophical aspects of physics, and in the introduction and an appendix, and in a chapter on the transition from classical to modern physics, touch on many of the interesting aspects of how scientists operate and think.

There are few errors or mistakes in such a book. However, the statement on p. 50 that the apparatus for identifying the antiproton was 'ingenuous' is surely an understatement!

It is hoped that this excellent little book reaches an even wider public, and enhances people's interest and understanding of the physical world in which, for better or worse, they find themselves.

E. B. PAUL

TERTIARY FLORA OF SPITSBERGEN

Studies in the Tertiary Flora of Spitsbergen

With Notes on Tertiary Floras of Ellesmere Island, Greenland, and Iceland—a Palynological Investigation. By Svein Manum. (Skrifter Nr. 125.) Pp. 128 + 21 plates. (Oslo: Norsk Polarinstitutt, 1962. Distributed by Oslo University Press.) 26 Kr.

THIS book describes the pollen and spore flora of Palæocene to Eocene beds in West Spitsbergen. Seventy pollen and spore types are described (15 Sporites, 54 Pollenites and 1 uncertain), and many of these are illustrated by line drawings and photographs. Most of the types described could not be referred to species previously described, and a number of new species are made. The palynology is largely qualitative, but a few quantitative analyses were made. In addition to the Spitsbergen material samples from the Lower Tertiary of Ellesmere Island, Greenland and Iceland are described and compared with the Spitsbergen flora. Though the floras from these regions are not identical, they appear to be composed of the same families and genera. The commonest pollen grains in most of the samples are coniferous, and of the inaperturate type.

The Arcto-Tertiary flora has received much attention since Heer's pioneer studies in the late-nineteenth century. The previous records are largely of macroscopic plant remains, and Dr. Manum makes an interesting comparison of these with the microfossil record. There are curious divergences. Among the macrofossils, *Metasequoia occidentalis* is very common, but few *Metasequoia*-type pollen grains are found. Conversely, *Sciadopitys* pollen occurs in all the samples, but its macroscopic remains have not been found. In general, macroscopic remains of Pinaceae are rare, but pollen of Pinaceae-type is fairly abundant. In the Angiosperms *Cercidiphyllum arcticum* is the most abundant macrofossil, but pollen grains of this genus have not been found. On the other hand, *Betula* and *Alnus* have been found—both macrofossil and microfossil.

The new plant records from Spitsbergen make little difference to Heer's original interpretation of the climate as temperate. Dr. Manum shows, however, that the original conception of an Arcto-Tertiary flora of deciduous type is too simple an interpretation of the vegetation, and that, as might be expected, there must have been a diversity of temperate vegetation types, both deciduous and evergreen, the latter containing an important element of evergreen conifers.

CHEMISTRY FOR ENZYMOLOGISTS

Molecular Biochemistry

By Edward M. Kosower. (McGraw-Hill Series in Advanced Chemistry.) Pp. xii + 304. (New York: McGraw-Hill Publishing Company, Ltd., 1962.) 97*s*.

ONE may ask: Is biochemistry to-day other than molecular? However, this book is far from being yet another addition to the accelerating flow of works on general biochemistry. The title stems from the concept of molecular biology, and the author defines his subject as the study of the detailed chemical mechanisms of the chemical transformations in biology. In fact, he presents an analysis of selected enzymological reactions within a sophisticated framework of modern physico-organic chemistry.

The three parts of the book are entitled: "Biochemical Patterns", "Chemical Patterns" and "Physical Patterns". The first part, of 63 pages, surveys some of the main integrated enzymological pathways: glycolysis, tricarboxylic acid cycle, terminal oxidation and phosphorylation, etc. Within the space allowed the author can do little more than enumerate the reactions and indicate possible mechanisms. For the chemist-turning-biochemist there are pitfalls to be avoided: clear distinction between hypothetical and experimentally established reactions is not always made clear. Particularly unfortunate is the chapter on photosynthesis. After a résumé of carbon dioxide fixation reactions and discussion of semi-conductors, the author presents a speculative mechanism for oxygen evolution (p. 34). It is not clear why this was put forward, rather than a scheme based on the experimental studies of Hill, Duysens, Kok, Witt and others.

The second and largest section of the book is devoted to mechanisms of the reactions summarized earlier. Armed with an extensive knowledge of chemical theory, the author systematizes a wide range of scattered material which the enzymologist could not hope to encompass unaided. The subjects treated include enolization, hydration and dehydration, hydrolysis, organic phosphates, pyridinium compounds and oxido-reductions. The treatment of the nicotinamide coenzymes in the light of pyridinium chemistry is outstanding, as might be expected from the author's deep interest in the subject. A fitting climax is provided by the final section, which is devoted to the fundamental problem of enzymology: the nature and function of active sites. Compressed within nineteen pages are not only useful evaluations of published work but also the author's original views on approaches to the problem.

The text is unusually free from errors and is carefully indexed. References are numerous and up to the minute. One can criticize the excessive use of inverted commas, which can give the text a disjointed appearance. This book will be useful to all who delve into the mysteries of enzyme action.

E. F. Hartree

ACTIVITY IN ANALYSIS

Analytical Chemistry

Vol. 2. Edited by Carl E. Crouthamel. (Progress in Nuclear Energy, Series 9.) Pp. vii + 400. (London and New York: Pergamon Press, 1961.) 100s. net; 15 dollars.

THE first volume of this series consisted of a collection of papers from among those presented at the second International Conference on the Peaceful Uses of Atomic Energy held in 1958. The papers in this second volume have not previously appeared though references to the 1958 Conference proceedings occur frequently in several of the sections. The eight topics dealt with here, each by an authority in his field, are those considered likely to have a marked influence on the future of analytical methods associated with nuclear energy.

The first chapter on "Recent Advances in Counting Techniques" opens with an excellent account of gas ionization proportional counters and their use in non-dispersive X-ray analysis. The theory and construction of these counters are dealt with in detail. This is followed by sections on p–n junction and surface barrier counters, and on scintillation spectrometry.

The second chapter, on the "Applications of Electron Spin Resonance Spectroscopy", gives a full account of the theory of electron spin and of the many types of interaction affecting the energy-levels of the 'spinning' electron. This is followed by a description of many applications, including investigations on transition elements, donor concentrations in semi-conductors, organic free radicals and radiation-induced free radicals. Some notes on microwave and radiofrequency electron spin resonance equipment conclude this section, but the experimental approach is not covered as completely as the theoretical.

The next chapter, on "Recent Advances in the Separation and Analysis of the Transuranium Elements", covers the analytical chemistry of ten elements and closes with a footnote on the discovery of element 103. This is followed by one on "Applications of Liquid–Liquid Extraction in Inorganic Separations". The general concepts of the process are lucidly described and there is a good account of positive and negative synergistic effects. Many examples of fundamental research on separations of potential use in analysis are given.

A review on "Flame Photometry and Atomic Absorption Spectroscopy" describes the principles of the methods and in the case of flame photometry emphasis is placed on high-temperature oxycyanogen flame photometry and on Dean's technique of using as carrier an organic solvent which has previously extracted and concentrated the elements of interest. The limits of detection of a large number of metals, under different experimental conditions, are given in tabular form.

A chapter on "Recent Advances in Ultra-violet, Visible and Infra-red Spectrometry" covers the period of the past decade. The determination of a number of metals including technetium, of interest as a corrosion inhibitor, is described followed by practical details of the pressed pellet technique in infra-red analysis and of absorption spectrometry in molten salts.

The penultimate chapter considers two aspects of the interaction of beta particles with matter. The first deals with backscattering and describes the effect of atomic number of the backscatterer, and the energy degradation and angular distribution of the backscattered beta particles. The second details the excitation of characteristic X-rays by beta particles and the design and uses of X-ray sources based on this phenomenon.

The volume ends with a general account of ion exchange chromatography, including the use of hydrous oxide and heteropolyacid salt inorganic exchangers and cellulosic exchangers. Organic applications are included.

A good feature of this volume is the comprehensive bibliography at the end of each chapter. The editor's aim of including the basic principles of new techniques in addition to covering recent advances is amply fulfilled in this book. The subject index is scanty, and it might have been better to omit the lengthy author index, which includes all the names in the references, and devote more space to the former.

D. I. Coomber

ADVANCES IN INORGANIC CHEMISTRY

Advances in Inorganic Chemistry and Radiochemistry

Vol. 4. Edited by Prof. H. J. Emeléus and Dr. A. G. Sharpe. Pp. viii + 344. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962. 88s.

THE previous volumes in this series have each strongly emphasized the chemistry of a particular group of elements, but in the present volume it is the subject of organometallic compounds which recurs throughout the book. They are the subject of the very complete and up-to-date review on "Olefin, Acetylene, and π-Allylic Complexes of Transition Elements", by R. G. Guy and B. L. Shaw, and figure extensively in the review on the stereochemistry of nickel, palladium and platinum by J. R. Miller, and in "The Use of Nuclear Magnetic Resonance in Inorganic Chemistry", by E. L. Muetterties and W. D. Phillips. There is a certain amount of overlap, particularly between the first two of these chapters, but this is not serious as Miller emphasizes the actual stereochemical structures adopted by the compounds of these elements while Guy and Shaw pay major attention to the compounds themselves. The article on nuclear magnetic resonance, a technique which has played a fundamental part in the elucidation of the structures of organometallic compounds, only deals with the spectra of these compounds as particular examples but also deals very fully with most of those aspects of nuclear magnetic resonance spectroscopy which would be of interest to a physicist or physical chemist interested in the spectra of inorganic compounds.

K. W. Bagnall writes on "The Chemistry of Polonium". Extensive reviews were written on this little-known element as recently as 1957, but in spite of this its reactions are being so actively investigated that a new review is amply justified. On the other hand, I was rather disappointed in "Condensed Phosphates and Arsenates", by E. Thilo, as there is no great extension to the discussion given by Van Wazer in his book of 1958 while the treatment is rather classical with only brief reference to some of the modern physical methods which have been used in the study of these compounds. Finally, J. D. MacKenzie reviews "Oxide Melts". The examination of melts is rapidly becoming of major importance as they provide opportunities for carrying out reactions in a non-aqueous medium at an elevated temperature. Oxide melts are little understood at the moment but this review summarizes the known properties of these systems. There are no articles on radiochemistry in the present volume.

D. W. A. Sharp

PHYSICAL AND CHEMICAL TABLES FOR X-RAY CRYSTALLOGRAPHY

International Tables for X-ray Crystallography

General Editor: Dame Kathleen Lonsdale. Vol. 3: Physical and Chemical Tables. Edited by Caroline H. Macgillavry and Gerard D. Rieck. Pp. xvi+362. (Birmingham: The Kynoch Press, 1962. Published for the International Union of Crystallography.) 115s.

THE fifty years which have elapsed since the discovery of X-ray diffraction by crystals have witnessed the development of X-ray crystallographic techniques as a structure-determining tool of unprecedented power and catholicity of application. By it the complexities of mineral structures have been rationalized, the exotic configurations of natural products elucidated and the elaborate architecture of the giant globular proteins mapped out. Fortunately, it was recognized early that this diversity would make discipline in the presentation of results, and uniformity of nomenclature and convention particularly desirable. The first attempt to provide such an authoritative basis was by the *Internationale Tabellen zur Bestimmung von Kristallstrukturen* of 1935. In 1946 the International Union of Crystallography decided on a complete revision and extension of these tables under the general editorship of Dame Kathleen Lonsdale. Two volumes, one on space groups, one with mathematical tables, have already appeared; Volume 3, dealing with physical and chemical tables, represents the completion of the 1946 project.

Section 1 describes the general physical properties (morphological, mechanical, optical, magnetic, electrical and thermodynamic) which should be determined in a preliminary investigation of any crystal; it provides data on immersion media for measurement of refractive-indices and detailed methods for determining crystal density. The preparation, mounting and setting of crystal specimens is also discussed. Section 2 is concerned with data needed for analysing basic interaction of X-rays and crystals: tables of wave-lengths and absorption edges are followed by lists of filters, monochromators and standard crystals the diffraction spacings of which can be used for calibration. A set of best values of the universal physical constants is provided together with a valuable resolution of the confusing situation about the use and standardization of Å, A and X units. Section 3 is concerned with the next phase of an X-ray crystallographic investigation: the measurement of photographically and counter recorded intensities and their correction for the effects of absorption of the radiation by the specimen. Atomic scattering factors for all the elements are collected together and a critical appraisal of the methods used to derive them is provided. Other sections provide important interatomic distances determined in inorganic, organic and metallic systems; deal with small-angle scattering, texture and line-broadening analysis in polycrystalline material; and catalogue the precautions to be taken against radiation injury.

Unlike the two preceding volumes these tables are concerned with experimental techniques and data from physical measurement. Discussion of the former is necessarily prone to the vagaries of subjective appraisal and the latter will have to be amended as better results become available. This volume does not, therefore, have the air of authoritative finality possessed by its more mathematical predecessors, but its comprehensiveness and the sound judgment in appropriately weighting the various topics is a triumph for its Dutch editors, Prof. Caroline Macgillavry and Dr. Gerard Rieck, and their assistants.

No X-ray crystallographical laboratory worthy of the name will fail to add this magnificently printed and luxuriously bound volume to the two they already should possess.

STRUTHER ARNOTT

NITROGEN RELATIONS OF PLANTS

Nitrogen Metabolism in Plants

By H. S. McKee. Pp. 728. (Oxford and London: Clarendon Press: Oxford University Press, 1962.) £5 5s.

PRIOR to the publication of this large and important new book, Dr. McKee, now of the Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra, had already a reputation as the writer of valuable review articles on nitrogen metabolism in plants which have appeared at intervals over the past twenty-five years and have been indispensable to workers in that field. This book represents a synthesis of these earlier reviews, now brought up to date and extended by a widening of the field covered and by the incorporation of historical matter.

As might be anticipated, the main sequence of treatment is to proceed from the uptake of nitrogen compounds from the soil and their transformation within the plant to the occurrence, biosynthesis and breakdown of amino-acids and amides, leading to the composition and synthesis of proteins and of alkaloids. Valuable chapters on the storage and transport of nitrogenous substances in the plant and on the nitrogen-cycle are included, as well as a substantial treatment of the biological fixation of nitrogen, extending to sixty-three pages.

Dr. McKee writes interestingly, with a historical approach, one effect of the citation of so many old writings being that the bibliography and author index together account for some two hundred and fifty pages. Some of the material that he has gleaned from these older sources is of considerable interest, as, for example, is a report (of which I myself anyway was unaware) of the occurrence of root nodules on a species of *Rhamnus*. In other cases the reader is left in doubt whether an old paper is worth hunting for: thus he is not told whether any attempt to maintain aseptic conditions was made in nineteenth-century work alleged to show uptake of amino-acids by higher plants. In a few instances there is a lack of balance between the old and the new. Thus quotations from a highly conjectural paper dated 1829 are prominent in a short account of carnivorous plants, while there is no reference to the invaluable monograph by Lloyd published in 1942. It could also be considered an omission that, though the preparation of food protein from leaves is mentioned, no references are cited in this connexion. As examples of a tendency to repetition may be noted similar statements concerning the form of nitrogen in snow on pp. 437 and 440, the constitution of insulin on pp. 301 and 351, the origin of combined nitrogen in sedimentary rocks on p. 434 (the same information is given twice on that page), and fixation in *Cycas* nodules on pp. 45 and 71.

For the most part Dr. McKee is very well informed, but on p. 78 it is wrongly stated that Pommer classed as a fungus the organism which he recently isolated from alder nodules and held to be the true endophyte. Though he felt unable to decide its precise systematic position, Pommer thought that the isolate was probably an actinomycete or related organism. The description on p. 114 of the content of an article by Cheniae and Evans on nitrate reductase is inaccurate; moreover, if this enzyme does form part of the fixation mechanism it seems more likely to me that oxidized forms of nitrogen will precede rather than follow ammonia formation. Very few misprints have been noted. The text would have been brightened by a few illustrations.

Despite these minor strictures, with which not all readers may agree, there is no doubt that this volume will make a very valuable addition to the libraries of the many institutions and individuals interested in the nitrogen relations of plants. It would indeed be a tribute to the industry of one man that he should even attempt to review so large a sector of plant physiology and chemistry, let alone bring the venture to a highly satisfactory conclusion, as Dr. McKee has done. He has every reason to take pride in the publication of this book—a signal event in the history of Australian and Commonwealth botany.

G. Bond

MICROFAUNAS OF EUROPE

Leitfossilien der Mikropaläontologie

Ein Abriss herausgegeben von einem Arbeitskreis deutscher Mikropaläontologen. Pp. viii + 432; Tafeln und Tabellen (in separate volume) mit 61 Tafeln und 22 Tabellen. (Berlin-Nikolassee: Gebrüder Borntraeger, 1962.) D.M. 182.80.

These volumes—text and plates—are the work of fifteen German micropalæontologists closely connected with the oil industry. The treatment is severely practical; micropalæontology may be a branch of biological science, but its aim is to enable exact stratigraphical correlations to be made. The fossils described and figured are those which are most useful from this point of view. Even twenty tiny siderite nodules, characteristic of the zone of siderite (base of Wealden 3), make an unexpected appearance on Plate 30. On the other hand, no consideration is given to fossil pollen, and fossil spores are only cursorily discussed. This omission can be easily defended since the two sides of micropalæontology appeal to quite distinct groups of people. In the present work an admirable uniformity of treatment has been attained; the authors appear to have the same views on the species problem and on stratigraphical subdivision. Presumably this is the result of many conferences and considerable editorial care.

The first part of the text consists of a discussion of taxonomic problems and palæontological and stratigraphic nomenclature worthy to rank with the famous chapters in Arkell's *Jurassic System*. Later sections are stratigraphically arranged, commencing with a discussion of some Palæozoic microfaunas which includes short accounts of the ostracods of the Upper Devonian, of zoning in the productive Coal-measures of the Ruhr, of foraminifera from the Middle Devonian, Upper Devonian, Lower Carboniferous and Zechstein. A fine well-illustrated section deals with zonal division based on conodonts in the Devonian and Lower Carboniferous. The discussion of the succeeding Mesozoic begins with a short account of micropalæontological divisions in the German Keuper and continues with chapters on the Lias, Dogger and Malm. In these, after short but valuable discussions on stratigraphy and faunal assemblages, descriptions of zonal fossils, chiefly ostracods, occupy many pages. The two succeeding chapters on the Lower Cretaceous are devoted to the German Wealden and the marine rocks of north-west Europe and Tethys. Both are of considerable interest to British readers, since they contain detailed discussions of stratigraphy and facies and the succession of ostracods and foraminifera which are directly relevant to British stratigraphy. Equally important in this regard is the chapter describing the Upper Cretaceous rocks of north Central Europe in which the emphasis is on biostratigraphy and foraminiferal succession, 67 species of foraminifera being described and figured.

The text ends with two chapters on the Tertiary of Germany, one a valuable general account of the stratigraphy, facies and microfauna (chiefly foraminifera) of north-west Germany, the other a very detailed study of the Rhine Graben, with a description of characteristic foraminifera and ostracods.

The volumes are well produced, with wide margins and excellent plates. Many species are illustrated three times, once as an isolated object in half-tone, a second time as a component of a typical assemblage of microfossils, and a third time as a line drawing in the margin of a stratigraphic table. The good practical sense of the authors can even be seen in the colour of the binding, which can be easily picked out on the bookshelf, and the bold lettering of the title on the spine. The price may seem high, but the sheer bulk of information presented is quite remarkable. Anyone interested in the zonal stratigraphy and microfaunas of Europe will find this work indispensable.

A. Wood

MACROMOLECULES: BIOSYNTHESIS, STRUCTURE AND FUNCTIONS

The Structure and Biosynthesis of Macromolecules

Edited by D. J. Bell and J. K. Grant. (Biochemical Society Symposium No. 21, held at Senate House, University of London, 27 and 28 March, 1961.) Pp. v + 132 + 4 plates. (Cambridge: At the University Press, 1962.) Cloth 30s.; Paper 20s. net.

This volume has to be judged both as a collection of essays and reviews published for the dissemination of information and as a record of the proceedings during part of the fiftieth anniversary meeting of the Biochemical Society.

As a contribution to the scientific literature, the volume presents a mixture of interesting history and exciting news. When the lectures were delivered, in the spring of 1961, two of them were particularly timely: M. F. Perutz gave a lucid account of the work of J. C. Kendrew and himself on the success in the determination of amino-acid sequences in proteins by X-ray crystallographic techniques. This was a fine progress report of a subject which will produce a more definitive statement soon. J. Monod's lecture was noteworthy for its scientific content, the description of the controlling steps in enzyme formation, and for the fine presentation. Both these lectures made very personal impressions of the authors' recent interests and achievements. Prof. Monod's account of the prediction of the existence of messenger RNA from his work and its subsequent experimental demonstration by British and American workers has a very special intellectual appeal.

P. Doty gave a stimulating account of the consequences of the established structures of nucleic acids in terms of physicochemical behaviour in solution, and J. N. Davidson described polynucleotide biosynthesis with more examples from mammalian systems than one usually gets in such accounts.

E. L. Smith's account of protein structure in relation to enzymatic activity, with special reference to papain, was an interesting if somewhat circumscribed survey of progress in that field. His judgment and contributions in the field of protein chemistry of enzymes is undisputed. His interpretations of kinetics and mechanisms are, however, not quite so unambiguous, and the reader would be advised to consult them side by side with other views.

W. Z. Hassid and E. L. Hirst discussed, respectively, the biosynthesis and structure of polysaccharides. Both these articles will serve for some time as authentic accounts of important chapters in biochemistry.

Prof. F. G. Young, who introduced the symposium, presents us with a very stimulating account of various problems and ideas in modern biochemistry. The meeting, as a whole, was a good reflexion of those aspects of biochemistry to which British biochemists have made their greatest contributions in recent years. The resulting volume should make exciting reading for those who were unable to enjoy the lectures and useful reference for all of us.

H. Gutfreund

Marine Molluscs of Victoria

By J. Hope Macpherson and C. J. Gabriel. (Handbook No. 2.) Pp. xv+475. (Victoria, Australia: Melbourne University Press; London and New York: Cambridge University Press, 1962.) 63s.

THERE is no doubt that students of the marine biology of south-eastern Australian shores will find this book of considerable help in their investigations. For amateurs taking their first steps into conchology, it will also be of great value. There are comprehensive, and yet not over-powering, introductions to each of the five classes of the phylum Mollusca and sensible notes on methods of collecting. The descriptions are basically sound, and provide adequate comparisons between different genera and species; these compensate for the lack of keys which would have made the book much more useful to everyone. There is a very good glossary.

This work, however, is not intended as an introductory text-book, and it is beyond the elementary stage that some features could have been improved. It is regrettable that measurements have been presented only in inches and too frequently as, 'size 1¼"'. This is not sufficient. Size ranges must be available for collectors and students. Although executed with a high degree of technical skill some of the black-and-white figures could have been more accurate—in *Xenogalea thomsoni*, for example, the columella callus plate is ridged, not smooth as illustrated in Fig. 177. This shell is also much more handsome than this figure shows—indeed, it is doubtful if there is a place to-day for a shell-book which does not at least have some of the illustrations (certainly the cowries and murex shells) in colour. The value of a good coloured photograph of a shell to a working systematist cannot be over-estimated.

Greater detail of distribution outside Victorian and Australian waters would have been a useful addition and a map showing the principal localities in Victoria itself a great help. There can be no virtue in making up common names for all shells, some of which are far from common, as has been done in this book. This does not present a good example to students and amateurs, who must become familiar with the binominal system of nomenclature from their earliest days if their collecting is intended to be at first purposeful and then scientific. NORMAN TEBBLE

Destructive and Useful Insects

Their Habits and Control. By C. L. Metcalf and W. P. Flint. Fourth edition. Revised by Prof. R. L. Metcalf. (McGraw-Hill Publications in the Agricultural Sciences.) Pp. xii+1087. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Company, Ltd., 1962.) 135s. 6d.

METCALF and Flint has been a standard reference book since its original appearance in the 'twenties. Dr. R. L. Metcalf, professor of entomology at Riverside, California, has carefully revised the whole book and entirely re-written the chapters on "Insect Control" and "The Applications of Insecticides", as well as greatly increasing the size of the sections on classification and on the morphology, physiology and biochemistry of insects. Most of the illustrations of the earlier editions are retained but all have been printed from new blocks which, with the improved paper, give the new edition a refreshingly clean and tidy appearance. Only a very few of the figures (for example, the fly in Fig. 2.16) are less pleasing than the old. All have been re-lettered and labelled in full. A small error has been introduced into Fig. 4.15, where two different structures are called the hypopharynx.

The thinking in the book remains rather old-fashioned—you name your pest and spray it according to the recipe. Perhaps in future editions more attention could be given to the long-term ecological effects of continued insecticide treatment. Where insecticides have caused pest outbreaks it is not enough to term them 'side-effects' and explain them away as the result of 'improper' application of insecticides. At present one cannot tell what long-term effects treatment may have on other species, beneficial or otherwise. Obviously there is still much to learn in this rapidly advancing field in which the full testing of one new insecticide would take years of careful experiment.

This book should have at least as good a run of useful life as the earlier editions it so worthily replaces.

G. C. VARLEY

Animal Ecology

By Prof. S. Charles Kendeigh. Pp. x+468. (London: Prentice-Hall International, 1961.) 70s.

THIS volume is intended for undergraduates with at least one year's training in zoology and appears to form the basis of a lecture course in animal ecology given by the author at the University of Illinois. It would be easier to assess its full worth if one could also attend the practical course at which one hopes the major defect of the book would be remedied. Here is a large work with approximately 1,500 references and an astronomical number of facts. It could have been of more value to the student had there been fewer facts and more guidance on how to assess their worth. As in all branches of biology, the value of any ecological work relies on a full understanding of the methods and techniques utilized and the rigorous interpretation of the results obtained. It is a pity that this is not communicated to the reader.

Nevertheless, this comprehensive and reasonably well-illustrated account may be read with interest. Following introductory chapters devoted to the scope and history of the subject and the general nature of environmental responses, there are accounts of different habitats (streams, lakes, ponds, forests, etc.), ecological processes, and community dynamics (dispersal, migration, food and energy relationships, speciation). The final part deals with the geographical distribution of communities (temperate deciduous forest, coniferous forest, tundra, grassland, desert, tropical and marine communities).

R. H. HEDLEY

South African Lepidoptera

By L. Vári. Vol. 1: Lithocolletidae. (Transvaal Museum Memoir, No. 12.) Pp. xix+238+112 plates. (Pretoria: The Transvaal Museum, 1961.) n.p.

THIS is the first volume of a proposed series of taxonomic revisions of the world genera and southern African species of the lepidopterous superfamily Tineoidea. The family Lithocolletidae is characterized, and keys are provided to genera and species. Twenty-four new genera and more than a hundred new species are described. Where knowledge of a species permits, an account is given of the type of leaf-mine formed by the larva. Mention is also made of the distribution of each species, but not of some of the genera. Critical examination of the type species and the previously included southern African species of each genus has resulted in the lumping or splitting of many genera, the transference of many species from one genus to another, and the discovery of many synonyms, necessitating many changes in nomenclature. The descriptions of new species are unfortunately not accompanied by a differential diagnosis, and there is no clear statement that type material of species other than new has been examined. It is disputable whether there is much advantage to be gained from quoting the sometimes long original descriptions of previously described species. The selection of a male from a Meyrick syntype series of one male and one female and its designation as holotype, instead of lectotype, is incorrect.

The numerous drawings of wing-venation and genitalia and the excellent coloured reproduction of paintings and colour-photographs merit special mention.

From the outset, this work will be indispensable to those engaged in taxonomic work on the group and to collectors of African microlepidoptera. A. WATSON

MARTIAN BIOLOGY: THE EXPERIMENTALIST'S APPROACH

By S. M. SIEGEL, L. A. HALPERN, C. GIUMARRO, G. RENWICK and G. DAVIS
Union Carbide Research Institute, Tarrytown, New York

RECENTLY, Salisbury, in a provocative article[1], has constructed a speculative picture of possible Martian life-forms, and of possible biogeochemical cycles in which such forms might participate.

We are in general agreement with the concepts which Salisbury has presented; as experimentalists, however, we question his reservations about the use of simulated environments. Speculation or even sound theorization notwithstanding, the sole model for life now available to us is life on Earth. Because statistical factors influence evolution, one would expect even identical planets to exhibit appreciable divergences in life-forms. Nevertheless, Earth and Mars might contain local environments in which convergent forms could arise. Thus, Salisbury suggests that the higher terrestrial plant, rather than the lower forms traditionally postulated in astronomical circles, is a good model for explaining some of the phenomena which have been held to indicate the presence of life on Mars. On the other hand, he distinguishes higher plants as plants which "universally require oxygen". This distinction suggests a divergence between the terrestrial model and its Martian counterpart which we believe may not exist.

Higher Plants at Low Oxygen Pressures

Mature air-grown plants, including *Coleus*, marigold and *Alyssum*, can survive many days under near-anaerobic conditions in spite of their aerobic history[2]. Lettuce, tomato, cucumber, bean, marigold, *Zinnia*, rye, corn, *Ageratum*, *Dianthus*, *Celosia*, rice, turnip, broccoli and other common plants germinate well and produce sizable seedlings in an atmosphere containing 5 per cent oxygen or less (ref. 3, Table 1). Several of these plants—notably cucumber, rye, corn, rice and *Celosia*—produce some seeds which are facultative anaerobes.

Table 1. GERMINATION PERCENTAGE AFTER 3-6 DAYS

Kind of seed	Atmosphere Argon (or nitrogen)	2% oxygen + 98% argon	5% oxygen + 95% argon	Air
Lettuce	0	78	78	98
Marigold	0	33	—	57
Zinnia	0	22	—	57
Celosia	22	81	—	89
Alyssum	0	21	—	80
Portulaca	0	50	—	55
Carrot	0	50	—	33
Onion	0	65	—	69
Cucumber	17	88	96	100
Bean	0	—	60	53
Coleus	0	—	54	91
Tomato	0	—	33	91
Dianthus	7	—	50	82
Ageratum	—	—	33	84
Cabbage	0	9	71	95
Turnip	0	16	21	90
Beet	0	—	40	50
Rye	40	50	95	95
Barley	—	—	28	80
Corn	29	—	—	80
Rice	17	24	24	23

If our results with more than 30 higher plant species are at all representative, they indicate that, among terrestrial plants, many (perhaps most) require little oxygen; some (perhaps many) might qualify as microphilic aerobes; and a sizable minority, perhaps 10 per cent, can function anaerobically.

Low Oxygen–Low Temperature Interaction

Many terrestrial plants are hardy enough to survive freezing and to grow during the more moderate phases of the extreme diurnal temperature cycles reported for Mars. The south tropical latitudes of Mars are notably mild[4,5]. Furthermore, we have found that cultivation of seeds in atmospheres containing little oxygen enhances the resistance of the seedlings to freezing and lowers the minimum temperature required for germination. Three-week-old cucumber seedlings grown from seed in air or in an atmosphere of 2 per cent oxygen and 98 per cent argon were cooled to −10° C, kept at that temperature for 1 h, and then allowed to thaw. As the air-grown seedlings thawed, they collapsed, presumably because of mechanical damage by ice crystals (Fig. 1, left). In contrast, the sturdy seedlings grown in an atmosphere of 2 per cent oxygen were not damaged (Fig. 1, right). At temperatures below 10° C, cucumber seeds will germinate in air to an extent no greater than 10 per cent in 10 days. If, however, the seeds are incubated in an argon atmosphere (containing only 0·005 per cent oxygen) 50–90 per cent germinate in 20 days at 6°–7° C, and subsequent shoot extension at a rate of 10 mm a day has been noted. Even under aerobic conditions, germination of cucumber seeds exposed daily to temperatures of −7° C for 8 h and 23° C for 16 h was about 30 per cent in 2–3 days and 50 per cent in 4 days. Cucumber is not noted for its resistance to cold.

Hardier species can germinate when exposed daily to temperatures of −7° C for 16 h and 23° C for 8 h. For the common 'rock garden' species, *Dianthus* and *Ageratum*, germination is 10 per cent in 3–4 days in these temperature conditions. Germination for these species was doubled or tripled when the daily freezing period was shortened to 8 h.

We have already reported[6] the germination of winter rye and the development of green winter rye seedlings under a synthetic atmosphere which simulates in most respects the atmosphere believed to exist on Mars[5], using a temperature-cycle of +20° C (day) and −10° C (night). In one respect our synthetic atmosphere differs considerably from the real Martian atmosphere in that we added 1–2 per cent by weight of water in the soil, which results in a substantial partial pressure of water in the enclosed atmosphere. The best available information indicates a much lower (perhaps 2 orders of magnitude) average water content in the Martian atmosphere than is present under our conditions. However, it must be borne in mind that astronomical observations of the Martian atmosphere as a whole would not, in all probability, reveal the presence of localized bodies of water, or of microclimates at the surface of Mars which are much higher in water content than for the total Martian atmosphere.

Xerophytes

Xerophytes are also markedly conditioned by their gaseous environment. Only a few specimens, of *Euphorbia clandestina* and *Gymnocalycium friedrickii*, were tested, but the results were none the less striking.

In this experiment, specimens were grown in 16·l. jars either in air or in a synthetic atmosphere of volume composition as follows: oxygen, 0·09 per cent; carbon dioxide, 0·24 per cent; argon, 1·39 per cent; and nitrogen, 98·28 per cent.

This gas mixture was used at a total pressure of 0·1 atmosphere (after De Vaucouleurs[5], who provides a good general treatise on aerography). The plants were placed

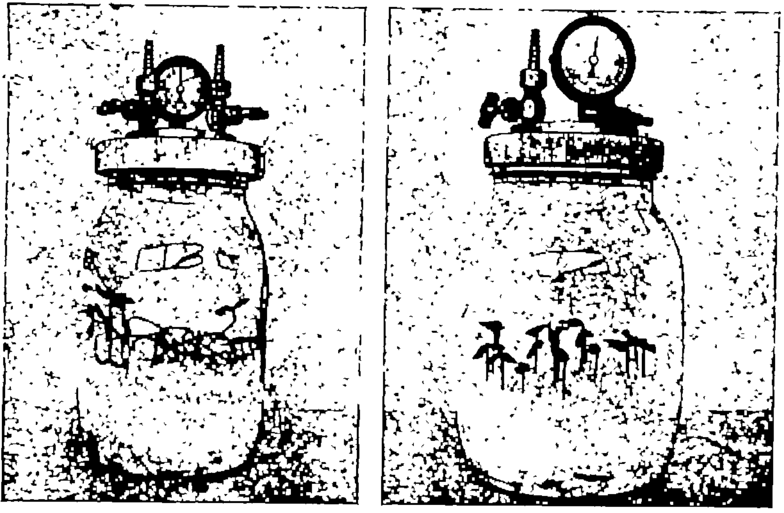

Fig. 1. Left: air-grown 3-week-old cucumber seedlings damaged by freezing (−10° C); right, freeze-resistant cucumber seedlings grown for 3 weeks in an atmosphere of 2 per cent oxygen plus 98 per cent argon

Both groups had been kept at −10° C for 1 h and allowed to thaw for 1 h before being photographed

in a 1:1 mixture of potting soil and 'Perl-lome' ('Perl-lome', a product of Certified Industrial Products, Inc., Hillside, New Jersey, is a derivative of perlite. De Vaucouleurs suggests that a felsitic rhyolite covers the Martian surface, and perlite is such a volcanic mineral). The water content of the soil and 'Perl-lome' mixture was about 1–2 per cent by weight.

After about a month at 25° C, the jars were transferred to an unheated greenhouse. Temperatures were recorded and observations on plant conditions were made during January, February and March 1962. The mean daily maxima for these months were +5° C, −2° C and +8° C, respectively. The mean nightly minima were −9° C, −12° C and 0° C.

By the end of February the four *Euphorbia* specimens grown in air were dead, but the four grown in the synthetic atmosphere were normal in appearance—green and erect by contrast with the yellow, shrivelled group grown in air. At the end of March, only one of the plants in the synthetic atmosphere appeared normal. The remaining three were no longer erect, although they retained green coloration and were not desiccated. Six *Gymnocalycium* plants were grown in each atmosphere. Three of those grown in air survived through February, and all those grown in the synthetic atmosphere still appeared normal at the end of February. During March, the remaining plants grown in air died, while only one of those grown in the synthetic atmosphere died.

After 3 months of cold, the plants were examined and analysed. The *Euphorbia* plants grown in air had lost height, diameter and fresh weight (Table 2). Plants grown in the synthetic atmosphere showed a gain in these measurements, and all had retained some green coloration, even though only one out of four was scored as 'normal'. All the *Gymnocalycium* plants lost weight, regardless of the atmosphere in which they were grown.

Table 2. CHANGES IN WEIGHT AND SIZE OF XEROPHYTES UNDER EXPERIMENTAL ATMOSPHERIC CONDITIONS

Height (cm)			Diameter (cm)			Fresh weight (g)			Dry
Initial	Final	Change	Initial	Final	Change	Initial	Final	Change	wt. (g)
*Euphorbia**, grown in air									
11·4	10·1	−1·3	1·0	0·5	−0·5	12·0	5·4	−6·6	4·7
*Euphorbia**, grown in synthetic atmosphere									
11·6	11·9	+0·3	1·0	1·1	+0·1	12·0	12·5	+0·5	5·5
Gymnocalycium†, grown in air									
						13·9	5·2	−8·7	2·2
Gymnocalycium†, grown in synthetic atmosphere									
						14·5	6·3	−8·2	1·7

* Four specimens in each atmosphere.
† Six specimens in each atmosphere.

Comparative chemical and biochemical tests made on *Euphorbia* plants grown in the two atmospheres revealed an interesting pattern of similarities and differences. Spectrophotometric determination of chlorophylls[7] in acetone extracts of the leaves (which form an apical whorl) showed that none was present in the group of dead plants that had been grown in air. Chlorophylls *a* and *b* were present in the usual 3 : 1 ratio in extracts from plants grown in the synthetic atmosphere. Longitudinal sections (3–5 mm) from the aerial portions of the plants were tested by immersion in several common reagents. Tissues from the two groups were similarly treated. Marked differences were observed in peroxidase activity and in the results of non-carbohydrate aldehyde determinations. (A mixture of 10^{-3} M pyrogallol and 10^{-3} M hydrogen peroxide in phosphate buffer (*p*H 4·5) was used as the peroxidase developer.) Even sharper were the distinctions in the results of tests for reducing sugar, starch, phosphorylase activity (tissues were immersed in 1 per cent glucose-1-phosphate at *p*H 6·6 for 1 h at 25° C, then stained with KI_3 (after S. Siegel, *Bot. Gaz.*, 114, 139; 1952) and indole; all results were negative for the air-grown group and positive for the test group. Determinations of element composition for the two groups reflected no striking differences. (The determinations were made by Micro-Tech Laboratories, Skokie, Ill.)

Germination Without Liquid Water

Xerophytism is a relative condition, and it seems reasonable to suppose that plants other than typical desert forms may be able to adapt to dry conditions. The seed, generally a rich source of hydrophilic colloids, is well known for its imbibitional powers. Accordingly, some experiments were carried out in which dry seeds were supported in closed jars, in air at a pressure of 75–125 mm of mercury, above a source of liquid water. Germination was slow as compared with usual rates, but the results (Table 3) show that a number of species can germinate and produce seedlings without difficulty under such conditions. When winter rye was placed in the synthetic atmosphere at a total pressure of 75 mm of mercury, 150 mm above a source of liquid water, germination was reasonably prompt and considerable root growth was noted after several days (Table 4).

Table 3. GERMINATION OF SEEDS IN WATER VAPOUR IN AIR AT 25° C

Kind of seed	Germination after 13 days (per cent)	Root-length after 13 days (mm)
Phlox	52	7·3
Cucumber	37	7·7
Marigold	18	1·0
Portulaca	63	4·9
Alyssum	26	8·3
Turnip	88	16 5
Carrot	40	18·3
Celosia	100	18·2
Rye	100	20·5

Table 4. GERMINATION OF RYE IN EXPERIMENTAL ATMOSPHERE IN WATER VAPOUR AT 25° C

Incubation time (days)	No. germinated	Germinated (per cent)	Longest roots (mm)
1	6	4·5	1
4	45	33·8	5
5	100	75·8	15

Other Factors

In our laboratory we are also investigating the effects of substratum and of ultra-violet radiation on plant growth under conditions of low temperature and low oxygen supply. We have observed that remarkably high levels of ultra-violet radiation are sometimes needed to suppress the growth of higher plants (energy of 10^{6} ergs/

cm^{3} is only marginally effective as an inhibitor of growth in bean embryos).

Animal Forms

Most of our investigative efforts have been concerned with the flowering plant. Other plants also show promising behaviour at low oxygen-levels. The fungus *Alternaria* and gametophytes of the fern *Pteridium* have been grown in an atmosphere of 5 per cent oxygen and 95 per cent argon.

Among animal forms, the ciliate *Colpoda* grows in hay-infusion cultures prepared and maintained under the synthetic atmosphere. HeLa cells, which can grow for 4 days under strictly anaerobic conditions more rapidly than in air, are being examined for adaptability (including clonal selection) to anaerobic culture of indefinite duration at low temperature in media of high osmotic concentration. *Planaria* have thus far shown rigidly aerobic behaviour, but they have been maintained for as long as 23 days in 5 per cent oxygen and 95 per cent argon and 16 days in 2 per cent oxygen and 98 per cent argon, as compared with 93 days in air.

The most striking results have been obtained with the common brine shrimp, *Artemia salina*. In sea-water (salinity 3 per cent) or diluted sea-water (salinity 1 per cent) in both liquid and agar media, active, viable *Nauplius* larvæ have been hatched in approximately equal percentages in air, in air reduced to 0·03 atmosphere, and in the synthetic gas mixture of 0·1 atmospheres. Typical values for hatching, based on findings with several hundred eggs per trial range from 35 to 45 per cent in 2 days.

It seems likely that marine organisms could adapt to the requirements of existence in a variety of synthetic environments—existence in a medium which is 'dry' in the physiological sense and has a depressed freezing point[8]. If, as in the case of *Artemia*, such organisms were also facultative anaerobes or near anaerobes, their prospects for survival would be good indeed.

Members of other invertebrate phyla also possess unusual ranges of tolerance to low pressure, low oxygen, and low temperature. The small black ant, *Monomorium minutum*, retains general activity and positive phototaxy after more than 15 h in 1 per cent oxygen and 99 per cent argon. The nematode *Cephalobus* remains active indefinitely under anaerobic conditions or at total pressure of 0·03 atmosphere and shows remarkable tolerances to freezing and to salinity well in excess of that of sea-water.

Conclusions

Our results show that complex terrestrial organisms can survive and grow under conditions which constitute an extreme departure in one or more respects from the normal terrestrial environment. Of particular importance was the finding that tolerance of plants to low temperatures could be conditioned in a favourable manner by synthetic atmospheres low in oxygen. It would be reasonable to expect other combinations of stress factors to give rise to unusual and exciting biological responses.

While it is impossible to project these findings on to present-day attempts to anticipate the nature of life elsewhere in the solar system, it is reasonable to conclude that the 'plasticity' of organisms as we recognize them is far greater than the teachings of modern biology indicate. Thus, whatever environments may be encountered during future explorations of the solar system there is every prospect that those which are not too extreme relative to Earth, for example, those expected on Mars may well support forms of life that we could recognize readily.

FUNCTIONS OF THE TWO FORMS OF LACTIC DEHYDROGENASE IN THE BREAST MUSCLE OF BIRDS

By Dr. A. C. WILSON, Dr. R. D. CAHN and Prof. N. O. KAPLAN

Graduate Department of Biochemistry, Brandeis University, Waltham 54, Mass.

TWO basically different molecular forms of lactic dehydrogenase occur in the tissues of most animals[1-3]. They differ in amino-acid composition, immunochemical structure, electrophoretic mobility, relative rates of reaction with analogues of the coenzyme nicotinamide–adenine dinucleotide (NAD) and several other physicochemical and enzymatic properties. One of the enzymes, the more negatively charged at *p*H 7, predominates in the heart musculature of most vertebrates, and is called the *H* enzyme. The other, called the *M* enzyme, predominates in many skeletal muscles.

The *H* enzyme consists of four identical sub-units of molecular weight about 30,000 as does the *M* enzyme. But the *M* sub-units differ from the *H* sub-units in many properties, including amino-acid sequence, as tryptic digests give different fingerprint patterns. When these two different sub-units are produced in the same cell, they combine with each other in groups of four in essentially random fashion to give the two 'pure' enzyme types—H_4 and M_4—and three 'hybrid' enzymes having the composition H_3M_1, H_2M_2, and H_1M_3. This accounts for the five electrophoretically distinguishable forms of lactic dehydrogenase detected in most animals examined.

This article is concerned with the metabolic functions of these two basically different types of lactic dehydrogenase. It was noted previously that the conversion of pyruvate to lactate by the *H* enzyme is strongly inhibited by fairly low concentrations of pyruvate. By contrast, the *M* enzyme functions with increasing efficiency at these same pyruvate concentrations and is inhibited only by very high pyruvate concentrations (Fig. 1)[3,4]. It was therefore suggested that the *H* enzyme could not permit the rapid production of lactate and would favour complete oxidation of glucose via the Krebs cycle; the *M* enzyme, on the other hand, should permit the rapid conversion of pyruvate to lactate and the accumulation of an oxygen debt under anaerobic conditions. In support of this suggestion the *H* enzyme predominates in the heart, a highly aerobically oriented and well-oxygenated tissue; and the *M* enzyme predominates in skeletal muscles many of which function only on sudden occasions and then relatively anaerobically with the consequent production of lactic acid and oxygen debt.

Table 1. LACTIC DEHYDROGENASES OF BREAST MUSCLE

	Common name	Scientific name	Substrate inhibition $\frac{\text{NADH}_L}{\text{NADH}_H}$	Electrophoretic forms				
				M_4	M_3H	M_2H_2	MH_3	H_4

Sources of organisms Nos. 1–5, 7–11, 13, 16–23, 25–29, 31, 32, 37–39 from Dr. W. Drury and Mr. J. Baird, Massachusetts Audubon Society; Nos. 33, 36, 40 from Dr. C. Gandal and Mr. W. Conway, Bronx Zoo (New York); No. 14 from Drs. J. King and D. Farner, Washington State University; No. 6 from Dr. C Sibley, Cornell University, No. 24 from Messrs. W. Palas, M. Lundy and J. Appel, U S Bureau of Sport Fisheries and Wildlife North-east Region; and Nos. 12, 15, 30, 34, 35, 37 were collected by us or obtained from commercial sources in the Boston area. We examined several specimens from each of the following species: Nos. 1, 14, 24, 34, 35 and 37; and one specimen from each of the other species. No individual variation outside the limits of analytical error was detected in the substrate inhibition or electrophoretic results.

Tissue homogenates were made in 0·25 M sucrose or, in a few cases, in 0·1 M *tris* at *p*H 7 and centrifuged at 100,000*g* in a Spinco ultracentrifuge. The supernatants were assayed for lactic dehydrogenase activity as described in Fig. 1 and subjected to starch gel electrophoresis as described by Cahn *et al.* (ref. 3). The different electrophoretic forms usually separated at *p*H 7·0 but in the case of the petrel and charadriiform birds, *p*H 8·6 was required. The intensity with which the various electrophoretic forms were stained by nitro blue tetrazolium is indicated by. + +, intense staining, +, weak staining; or −, little or no staining.

Substrate inhibition. Further support for this suggestion concerning the different metabolic roles of *H* and *M* lactic dehydrogenase has now come from examination of the breast (pectoral) muscles of more than thirty species of adult birds. The results are summarized in Table 1. The degree of substrate inhibition is indicated by the ratio $\frac{\text{NADH}_L}{\text{NADH}_H}$, which is the ratio of the lactic dehydrogenase activity at $3·3 \times 10^{-4}$ M pyruvate to the activity at 10^{-2} M pyruvate.

Pyruvate does not inhibit the breast muscle enzyme of the pheasant, grouse, guinea fowl, partridge or domestic fowl. Usually these birds fly only occasionally and then in short bursts. After they have been flushed a few times in rapid succession their breast muscles are greatly fatigued[5], owing in all probability to the accumulation of a severe oxygen debt. The majority of birds, which fly more often or in longer bursts, show even more substrate inhibition. The strongest substrate inhibition, similar to that shown by the heart, is found in the breast muscle of the storm petrel, the humming-bird and the swift, which spend much of their waking lives in active flight, and the dovekie, which flies swiftly with a rapid wing beat for long distances and swims under water by means of its wings. The rough-legged hawk spends much time in the air, but usually glides in such a leisurely way that little breast muscle activity would seem to be involved. It shows only a moderate degree of substrate inhibition. There is therefore a good qualitative correlation between the degree to which the breast muscle of birds can maintain continuous activity and the degree to which the lactic dehydrogenase is inhibited by high pyruvate.

The correlation is also apparent, on a smaller scale, within taxonomic sub-divisions of the birds. Among the passerine birds, for example, the towhee (a ground

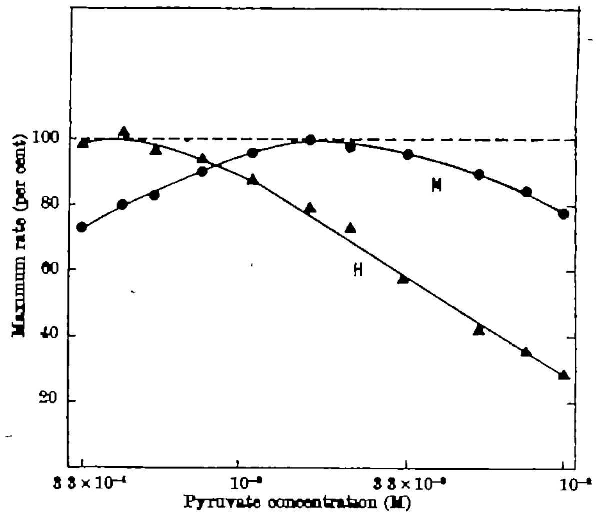

Fig. 1. Effect of pyruvate concentration on the activity of the pure *H* and *M* enzymes of the domestic fowl. The enzyme preparations were described by Cahn *et al.* (ref. 3). Lactic dehydrogenase activity was measured by following the oxidation of NADH spectrophotometrically at 25° C in potassium phosphate buffer (0·1 M, *p*H 7·5)

finch) gives a low value consistent with its reluctance to fly often or in more than short bursts, whereas the jay, sparrow, starling and grackle, which give higher values, fly more frequently and in more sustained bursts. Birds like the warbler, vireo, chickadee and kinglet which hunt insects among the branches and in the undergrowth do not usually fly in such sustained bursts as the starling or grackle, yet they give a high value. This can be associated with the fact that they flick their wings incessantly while hunting; in addition, the kinglet has a habit of fluttering its wings even while perching[6].

The trend is also demonstrable within a single species, for example, *Anas platyrhynchos*, the duck. The mallard (*A. p. platyrhynchos*) and the black duck (*A. p. rubripes*) both exhibit a moderate degree of substrate inhibition and often fly in a sustained manner. The domestic duck (*A. platyrhynchos*) and the Laysan duck (*A. p. laysanensis*)[7] have lost the capacity for sustained active flight and their breast muscle lactic dehydrogenase exhibits virtually no substrate inhibition.

The correlation between the degree of substrate inhibition and flight habits is good, but may not be perfect. The dovekie and the murre seem to have rather similar flight habits; but their degrees of substrate inhibition differ markedly. Their flight habits may differ more than has been generally assumed[8]. What is probably more important, their underwater habits differ. Murres dive more deeply and for longer periods than dovekies[9–11]. Murres must, therefore, have the capacity for developing a pronounced oxygen debt. This would account, at least in part, for the lower degree of substrate inhibition shown by the breast muscle lactic dehydrogenases of murres.

The woodcock has flight habits more like those of the galliform birds than those of its relatives, the charadriiform birds (for example, murre, gull, plover and dovekie), which are all capable of sustained active flight. The substrate inhibition exhibited by the woodcock breast seems more in keeping with its ancestry than its present flight habits.

Another problem is raised by birds like the rail, which show little substrate inhibition although they can migrate long distances. Except in the migratory season they fly very little and in short bursts. The capacity for sustained active flight may be less important than the practice of sustained active flight in determining the degree of substrate inhibition. Possibly the degree of substrate inhibition changes at the time of migration. However, our results with a strongly migratory race of the white-crowned sparrow (*Zonotrichia leucophrys gambeli*) do not support this possibility. Drs. J. R. King and D. S. Farner kindly supplied us with the breast muscles of two groups of captive sparrows.

(1) Three birds in the non-migratory state. These birds had been kept on short photoperiods (8 h/day) from the previous winter, when they were captured, until June 29, 1962, when they were killed.

(2) Three birds in a state of migratory unrest (*Zugunruhe*). These birds were kept on the short photoperiods until June 4, 1962. They were then exposed to long photoperiods (20 h/day) until July 12, 1962, when they were killed. King and Farner have previously shown that a strong urge to migrate develops in such 20-h birds but that the 8-h birds are devoid of the urge[12,13]. The results are presented in Table 2. The two groups had the same degree of substrate inhibition, although the concentration of lactic dehydrogenase in the migratory group was double that of the non-migratory group. Still, this experiment does not rule out the possibility that actually migrating birds, in contrast to caged birds with a strong urge to migrate, would have an enhanced degree of substrate inhibition.

To summarize the results presented so far, the correlation between substrate inhibition and flight habits is remarkably good, although there are some possible discrepancies which need to be examined further.

Table 2. LACTIC DEHYDROGENASE FROM BREAST MUSCLE OF WHITE-CROWNED SPARROWS

Migratory state	Substrate inhibition (NADH*L*/NADH*H*)	Enzyme concentration* (units/g wet wt.)
Non-migratory	1·55 1·62 1·66	163 105 178
Mean	1·61	149
Migratory unrest	1·54 1·63 1·59	361 349 476
Mean	1·59	395

* A unit is that lactic dehydrogenase activity which causes unit decrease in absorbance at 340 mμ/min, when measured in a final volume of $3{\cdot}0$ ml. and a pyruvate concentration of $3{\cdot}3 \times 10^{-4}$ M, as described in Fig. 1.

Relative Proportions of H and M. Electrophoresis of breast muscle extracts in starch-gel reveals that the different degree of substrate inhibition in the breast muscle of different birds is largely due to different proportions of the *M* and *H* sub-units (Table 1). The galliform birds and the domestic duck have the pure *M* enzyme (M_4) and at most a trace of the M_3H hybrid. A small proportion of *H* sub-units occur in the rail and the towhee as shown by the presence of considerable amounts of the M_4 and M_3H_1 forms together with a little of the M_2H_2 form. The species showing intermediate degrees of substrate inhibition contain nearly as many *H* sub-units as *M* sub-units because the M_1H_3 and even the H_4 forms are detectable. Finally, birds which show strong substrate inhibition have mostly *H* sub-units.

Taxonomic differences in the properties of H and M. The results in Table 1 illustrate that the differences in substrate inhibition among the various species is due mainly to differences in the relative proportion of *H* and *M* sub-units and not due to great differences in the catalytic properties of the sub-units themselves. However, it should be pointed out that there are small differences in the properties of the *M* and *H* sub-units in the various taxonomic groups of birds. The results in Table 1 indicate small differences between the *M* enzyme of the various galliform birds. This has been confirmed by a comparison of reaction rates with a number of coenzyme analogues as well as by immunological methods as illustrated by the complement-fixation results in Table 3. Complement-fixation methods[14] also reveal differences between the *H* enzymes of different galliform species (Table 3). Details of these investigations will be presented in a future publication.

Table 3. COMPLEMENT-FIXATION TEST, USING ANTIBODIES DIRECTED AGAINST THE *M* AND *H* ENZYMES OF THE DOMESTIC FOWL

Species	Relative percentage of complement fixed	
	M enzyme versus anti-fowl *M*	*H* enzyme versus anti-fowl *H*
Domestic fowl	100	100
Guinea fowl	98	99
Ring-necked pheasant	59	12
Domestic turkey	54	48
Ruffed grouse	40	48

The pure *M* and *H* enzymes of the domestic fowl and the two antisera were those described earlier (ref. 3). Crude extracts (100,000*g* supernatants) of breast muscle and heart were the source of *M* and *H* from the other species. The antisera were tested by the method of Wasserman and Levine (ref. 14) at a 1/5,000 dilution against eight different concentrations of the corresponding enzyme. Peak fixation occurred at the same enzyme concentration for all species. The results are expressed as percentages of complement fixed at peak fixation relative to the domestic fowl value.

Discussion. Insects have provided results analogous to those presented here on birds. The flight muscle of the locust and other insects is capable of sustained, highly aerobic activity and contains a high level of α-glycerophosphate dehydrogenase but only a trace of lactic dehydrogenase. In contrast, the jumping muscle of the locust, which functions only in occasional brief bursts, has more lactic dehydrogenase than glycerophosphate dehydrogenase[15-18]. We have found that the lactic dehydrogenase of the jumping muscle of the locust (*Schistocerca gregaria*) and the cave weta (*Pachyrhyma fascifer*) resembles the *M* enzyme of birds in having a low degree of substrate inhibition.

A possible histological basis for our breast muscle results is provided by the work of George *et al.*[19], who have demonstrated two types of muscle fibre in breast muscle. One type, called the white fibre, is broad, pale in colour, rich in glycogen and poor in mitochondria; the other, called the red fibre, is narrow, red and rich in fat and mitochondria. Only white fibres are found in the chicken, but the pigeon, which is quite a strong flier, has both fibre types. Since the pigeon was shown in the present work to contain both *H* and *M* sub-units in its breast muscle, one is tempted to guess that the *H* sub-units are produced by the red fibres and the *M* sub-units by the white fibres. However, in the pigeon and all other birds examined, the hybrid forms of lactic dehydrogenase occur in the proportions one would expect if both *H* and *M* sub-units were produced in the same cell. For this reason, it seems unlikely that the two fibre types produce different lactic dehydrogenase sub-units.

We thank the people who supplied many of the birds (Table 1) and the two insects (Dr. P. T. Haskell of the Anti-Locust Research Centre, London; Dr. K. C. Highnam of the University of Sheffield; and Mr. G. B. Kitto of the Victoria University of Wellington, New Zealand). We also thank Drs. C. Thorne of Brandeis University, R. Paynter of Harvard University and R. Orr and W. Hamilton of the California Academy of Sciences for helpful discussions. We thank Mrs. James Lucchese and the Misses Natalie Grimes and Pat Boulton for assistance.

This work was supported in part by grants from the National Science Foundation (*G*–14612), the National Institutes of Health (*CY*–3611) and the American Cancer Society (*P77–E*, Thomas S. Miller Memorial Grant for Cancer Research).

LOCOMOTION IN WHALES

By P. E. PURVES

Department of Zoology, British Museum (Natural History)

THE best authenticated maximum speed of swimming in whales is 15 knots, although bursts of 20–25 knots have been claimed by some observers. Using the equations relating to rigid and streamlined bodies, Gray[1] was able to show that the power available in the locomotory muscles of dolphins was insufficient to overcome the drag of the body at these high speeds. From this he concluded that the flow of water around the whale's body must be almost completely laminar, and suggested that this might be due to the acceleration, by the action of the caudal flukes, of the water particles in the boundary layer. It is proposed to show that the anatomical facts favour Gray's hypothesis.

Parry[2] reviewed Gray's Paradox, as it was called, and gave a quantitative treatment of the dynamics of the tail, based on the equations of v. Holst and Kuchemann[3] relating to the flight of birds. He, too, concluded that the power available was only consistent with the assumption of laminar flow. Kramer[4], in attempting to explain the apparent absence of turbulence, invoked the structure of the skin and subjacent oil sinuses as being responsible.

The task of measuring the water flow around the body of a swimming dolphin is perhaps insurmountable; but there is a great deal of indirect evidence by which it is possible to deduce the average orientation of the slip-stream and the relative velocities of its components. In the first instance, most of the observations of whales and dolphins swimming at high speed have been made while the animals were at, or near to, the surface, and it was considered by me that in such circumstances there must often have been a strong pressure gradient postero-dorsally along the flanks, and consequently an average displacement of water in this direction. Furthermore, since, for reasons which will be explained later, it is considered that there is only one true power stroke in the tail, this being the upstroke, it was presumed that there must be a predominant upwash of water in the direction of the tail. It is noteworthy that in all the fast-swimming odontocetes, the entire dorsal surface of the body, posterior to the dorsal fin, is strongly 'faired'; while on the ventral surface this 'fairing' does not extend beyond the level of the anterior extremity of the caudal peduncle.

Fig. 1 is a photograph by F. C. Fraser showing a common dolphin, *Delphinus delphis*, just breaking surface in still water. The photograph was taken in the North Sea in the morning sunlight and is in itself unique; but it also provides a great deal of information about the average displacement of water around the animal's body. The bow-wave is spread out in two extremely thin sheets of water on either side of the body, like the wings of a butterfly. The thinness and clarity may be judged by the lack of distortion in the reflexion of the body, dorsal fin and those of the sheets themselves, in the undisturbed water in the vicinity. One would imagine that if the animal were just submerged these two sheets of water would be closed over the back, like the wings of a butterfly at rest. Posteriorly, there is a powerful upwash of turbulent water over the dorsal edge of the caudal peduncle, and two trailing vortices in the wake. This would correspond in the submerged condition to a powerful acceleration of water over the dorsal aspect of the flukes.

If it be accepted that the foregoing assumptions are true, it follows that the shearing stresses at the surface of the skin, due to the flow of water, should be at an average maximum in a postero-dorsal direction. It will be seen now that the detailed mechanical structure of the skin is consistent with this hypothesis. According to Johnston and Whillis[5] the main function of the papillary form of the corium is that of preventing the epithelium from

Fig. 1. A common dolphin just breaking surface. (*Photo: F. C. Fraser*)

being stripped off the surface of the skin by shearing stresses, and it is interesting in this respect, that the dermal ridges on the palm of the human hand are orientated in such a way, that when a shaft is grasped by the hand, the ridges lie approximately parallel with the long axis of the shaft.

The dermal ridges are extremely well developed in whales and have been described by a number of authors—Japha[6], Schumacher in Bolk[7], Parry[8], van Utrecht[9] and von Naaktgeboren[10], and it is generally stated that the ridges lie parallel with the long axis of the body. However, the stratum corneum is perfectly smooth and undifferentiated, so that it is quite impossible to determine their total orientation by superficial examination, and the conclusions of most of the above authors have been arrived at largely from the examination of sections of isolated pieces of skin.

In order to investigate this subject more fully, the stratum corneum was removed from the entire body of a preserved, juvenile common dolphin, *Delphinus delphis*, by the laborious, but effective, process of rubbing it down with a very fine grade, waterproof, abrasive cloth. The skin was then examined over the whole surface of the body through a binocular microscope. It was found that the dermal ridges lay parallel with the long axis of the body only in certain clearly defined areas, and that the latter represented an extremely small porportion of the total surface area. The whole system follows a pattern now to be described (Fig. 2).

Over the forehead, and along the entire length of the upper two-thirds of the flanks, the ridges passed obliquely upwards and backwards, making an angle of approximately 30° with the long axis of the body. The ridges on the caudal peduncle were also thus orientated, except near the insertion of the flukes, where they swept posteriorly towards the caudal notch. From the insertion of the rostrum, a long, narrow band of ridges passed backwards, dividing round the eyes, and, undulating along the ventral limit of the flanks, terminated at the anterior ventral extremity of the tail. Another band of ridges, commencing at the rostrum and posterior part of the mandible, passed obliquely downwards over and under the flippers. On the chin, throat and belly, the ridges were poorly developed but there was some orientation of those behind the flippers towards the central axis of the abdomen.

On the flippers, dorsal fin and flukes, the ridges lay almost horizontally, but tended to become orientated towards the normal of the anterior curvature of these appendages, that is, along the lines of minimum width. Anterior to the dorsal fin, the ridges on the upper surface of the head and chest formed a narrow, horizontal band which divided round the base of the fin and then swept upwards in conformity with those on the flanks. Along the faired edge behind the dorsal fin the ridges of the two sides converged in a multiple chevron pattern without the least trace of horizontal ridges.

It is the small band of ridges reaching down to the flippers which probably provides the clue to the mode of locomotion. These lines are strongly reminiscent of the theoretical 'downwash' effect shown by Harris[11] on wind-tunnel models of the dogfish. It will be recalled that the pectoral fins of the side-gilled selachians, unlike those of the bony fishes, provide for lift of the thorax by a hydroplaning effect against the downward and forward thrust of the heterocercal tail. It was then considered that in the living dogfish there might also be an 'upwash' effect, due to the action of the tail, which would not be demonstrable in the wind-tunnel model. Although the dermal denticles are arranged like the scales of bony fishes, in oblique, parallel rows, the spines of these denticles are orientated on the ventral half of the body in the direction of the theoretical downwash, while those on the dorsal half are orientated obliquely upward and backward, in the direction of an apparent upwash (Fig. 3). It will be seen that there is some resemblance in the orientation of these spines to that of the dermal ridges of the dolphin.

It is apparent from the arrangement of the pectoral muscles of the dolphin that the main function of the flippers is also that of maintaining a hydroplaning effect. The muscles of extension are poorly developed and the trapezius is vestigeal, the greater part of the work of extension evidently being performed by the pressure of water on the ventral surface of the thorax and flippers. On the other hand, the muscles of flexion, abduction, adduction and circumduction are all well developed. These are the muscles which act antagonistically to the pressure of the water.

Turning now to the action of the tail, it has been stated, Parry[8], that the tail and flukes oscillate inde-

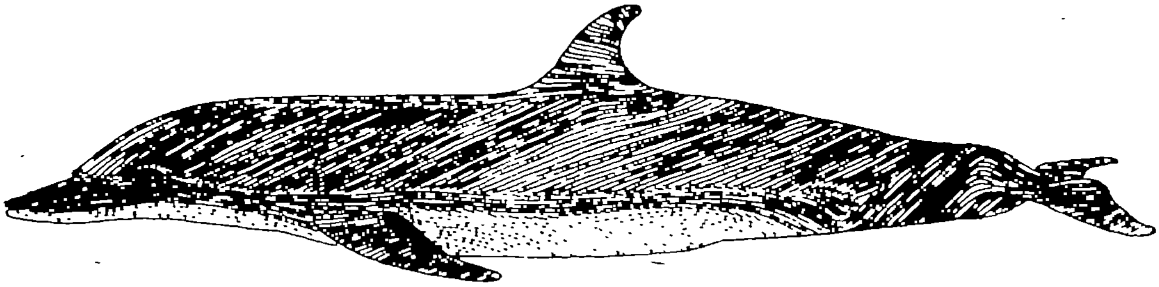

Fig. 2. Diagram of common dolphin, *Delphinus delphis*, showing orientation of the dermal ridges

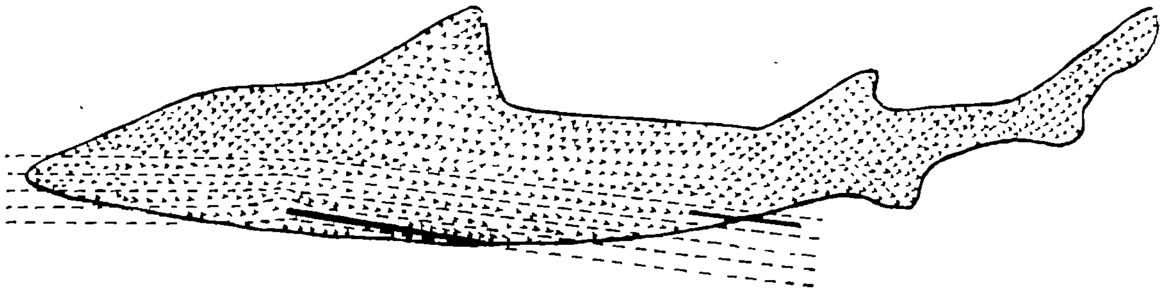

Fig. 3. Diagram of a dogfish (adapted from Harris) showing the theoretical downwash and the orientation of the dermal denticles

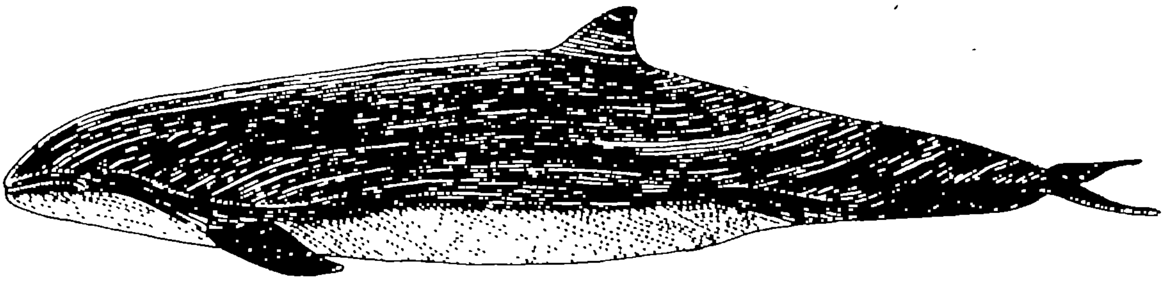

Fig. 4. Diagram of a common porpoise, *Phocaena phocoena*, showing orientation of the dermal ridges

pendently and sinusoidally in a direction at right angles to their course, this movement being compared with similar oscillations in the wings of birds. Closer inspection shows that such movement is true in both these animals only when the time factor is ignored. In cetaceans, the epaxial locomotor musculature, when the spinalis and longissimus dorsi are included, is approximately double that of the hypaxial muscles mass, while in birds, the pectoralis major, which depresses the wing, is many times the weight of the pectoralis minor, which raises the wing. The power and velocity of the upstroke of the tail in the dolphin are apparently greater than those of the downstroke, and provide the greater part of the forward thrust. The forward momentum, thus imparted, together with the buoyancy, assists materially in returning the tail to the horizontal position on the downstroke. Conversely, in the bird, the downstroke provides the main forward thrust and raises the body, while the wind velocity and gravitation on the body provide most of the lift of the wings during the upstroke.

It is clearly important, in assessing the power available, that some agreement should be reached about the identification of muscles which constitute the locomotor organs in whales. Slijper[12] has accurately demonstrated the fusion and interdependence of the whole epaxial muscle mass from occiput to tail, yet he denies any asymmetry in the weight of the epaxial and hypaxial locomotor muscle masses. Kermack[13], in his tabulated lists relating to fin whales, obviously recognizes such an asymmetry. An asymmetry of function, in the case of the bottle-nosed dolphin, is demonstrated in the serial film shown in Parry's[2] paper. It will be seen that 10 frames are required to return the tail from maximum elevation to the horizontal position. From maximum depression to the horizontal position only 5 frames are required. The extra thrust of the upstroke is also seen in the independent movement of the flukes. On the downstroke there is no clearly defined angle of attack between frames 1 and 9, that is, not until the tail is clear of the upwash. On the upstroke, however, the angle of attack changes rapidly between frames 16 and 18.

That Slijper[12] made this observation from Parry's film is apparent from his modified reproduction of the serial which he uses to demonstrate the interdependent movement of the flukes; thus frames 1 and 2 in Slijper's paper represent frames 2 and 9 from Parry's film, while frames 5 and 6 in Slijper represent frames 16 and 18 from Parry's film.

The effect of a more powerful upthrust would be essentially similar to that of the heterocercal tail of the dogfish, that of tending to push the body downwards and forwards. The poor development of the dermal ridges on the throat and belly seems to indicate that the latter are pressure areas. The antero-posterior circulation round the hydrofoil of the flukes induced by a powerful upthrust would produce an acceleration of water particles over their dorsal aspect, and consequently obliquely over the flanks. This excess of velocity over the observed momentum of the animal is that to which Gray referred, and is analogous with that part of the velocity of the slip-stream which produces the 'lift' on an aircraft wing. It is expected that during rapid swimming the amplitude of the tail beat would be much smaller than that shown in Parry's film, the frequency of oscillation being correspondingly greater. It is possible that in these conditions there is never any appreciable angle of attack on the downstroke.

If the orientation of the dermal ridges does indeed indicate the average flow pattern round the dolphin's body, it would clearly be erroneous to use the total length of the animal in the calculation of Reynold's number. The calculation of total resistance would appear to be a rather complex matter involving a great number of different values of *Re.* and a correspondingly large number of 'drag coefficients'. No attempt has been made here to give a quantitative assessment of the drag on the dolphin's body, not only because of the departure from simple boundary layer phenomena expected by the accelerations, described here, but also because very little agreement can be found in the literature about the exact value of *Re.* at which the transition from laminar to turbulent flow occurs. For example, Gray[1] gives the figure as *Re.* 5×10^5, Kramer[4] $2{\cdot}8 \times 10^6$, while Sutton[14] states that the slightest disturbance will cause the flow to become turbulent above *Re.* 2×10^5. It may be stated, however, that if Kramer's value is used, then the oblique flow over the body of a 6-ft. dolphin at 15–20 knots would be 90 per cent laminar, irrespective of any moulding of the skin due to dermal ridges, or subdermal oil sinuses. As previously stated, the dermal ridges are not apparent on the external skin of a healthy dolphin, and the oil ducts, which lie deep to the panniculus carnosus, are only conspicuous in the thoracic region, where they are associated with the pectoral musculature. The panniculus carnosus is very well developed in cetaceans and takes the form of broad, but discrete sheets, covering over the muscles of the shoulder, chest, neck and abdomen. From the general appearance and disposition of its components it would seem that its main function is that of smoothing out the transverse contours of the subjacent muscles.

A paper by van Heel[15] recently received, concerning experimental work with the common porpoise, *Phocaena phocoena*, stated that these animals "never showed their flukes and seldom jumped . . . in smooth water a conspicuous surface wave could be observed if the animals were moving quickly or near the surface". This observation seemed to indicate that *Phocaena* is a rather slower swimmer than *Delphinus*, but that there is an average upward displacement of water in this species also. Van Utrecht's statement that the dermal ridges lay at a slight angle to the long axis of the body was found to be true over the greater part of the flanks and the dorsal surface, but the head, belly and caudal peduncle showed the familiar 'upwash' and 'downwash' orientation (Fig. 4).

Van Utrecht's observation that the typical pattern becomes visible at the surface is most clearly seen by careful examination of the fine 'brush marks' in the marginal zones between broad patches of pigment. If the foregoing hypothesis were correct then it is true to say that the streaming lines of colour which are to be seen on many species of odontocete provide, at least, an approximate guide to the flow of water over the body, and it is interesting in this respect that there is scarcely a species which does not show the 'downwash' effect behind the eyes.

Note. A reference discovered after the present article had been submitted for publication shows that Sokolov[16] had made a similar observation. Without giving details he states: "Oblong epidermal septa in the thoracic skin of quick-swimming whales as well as that of the flukes of all Cetacea are always arranged in a definite direction, namely, along the lines of flow of water over the whale's body when swimming".

OBITUARIES

Prof. D. M. Steinberg

PROF. D. M. STEINBERG, who died in November at the early age of fifty-three, was one of the leading figures in the Russian entomological world and well known abroad as an active participant at international entomological and zoological congresses. He was born at Leningrad in a highly cultured family, his father being professor of the theory of music in the Musical Academy and the maternal grandfather the composer N. A. Rimsky-Korsakov. After graduation from the University of Leningrad in 1930, D. M. Steinberg worked for a short time at the Oceanographic Institute at Vladivostok, but soon joined the All-Union Institute for Plant Protection in Leningrad and also lectured at the Medical Institute. In 1945, he moved to the Zoological Institute of the Academy of Sciences, where he spent the rest of his life.

D. M. Steinberg's scientific interests have been very wide, but his works are characterized by their thoroughness, critical insight and often an original approach to the subject. Most of his eighty papers deal with the comparative morphology of insects and their physiological ecology; more recently he turned his attention to taxonomy and produced a monograph on wasps of the family Scoliidae in the *Fauna of the USSR*. Among his outstanding works may be mentioned his doctor's thesis on the morphogenetic potentialities of the larval hypoderm of insects (1942); comprehensive field and laboratory investigations on the web-worm (*Loxostege sticticalis*), containing a wealth of data on its ecology, behaviour (particularly, flight in relation to the dynamics of the air) and physiology, with special reference to the conditions of sexual maturation (1935); a valuable review of Russian work on insect morphology for the period 1917–57 (1957), etc. His latest interest was in the theoretical aspects of biological control of insect pests, in which connexion he spent three months in 1961 in Canada, studying research methods. He also visited Iran (1955) and Ethiopia and the Sudan Republic (1959) for entomological investigations. He organized and led research expeditions of the Zoological Institute to Kazakhstan (1949–51) for a survey of the insect fauna in the steppe areas where the development of forest shelter-belts was planned; and Turkmenia (1952–53) for investigations of the insect of the deserts scheduled for irrigation; the object in both cases was to discover the natural components of the fauna likely to become important pests under the conditions of new land use. D. M. Steinberg's influence on the development of entomology in his country was very great, and his premature death leaves a wide gap in the senior ranks of Soviet entomologists.

B. P. UVAROV

Dr. Richard E. Trees

DR. RICHARD E. TREES, a theoretical physicist at the National Bureau of Standards, U.S. Department of Commerce, died on October 27. Dr. Trees had made distinguished contributions to the quantum theory of complex atomic spectra.

Born in Philadelphia in 1920, Dr. Trees received his B.S. degree in naval architecture and marine engineering at the Webb Institute of Naval Architecture in 1943. He received his M.S. and Ph.D. degrees in physics from the University of Pennsylvania in 1949 and 1951 respectively.

He joined the National Bureau of Standards in 1951 as a physicist. In 1955, Dr. Trees was the recipient of a Rockefeller Public Service Award, which enabled him to spend a year in research at Princeton University. He received a Meritorious Service Award from the U.S. Department of Commerce in 1958.

Prof. T. H. Berlin

PROF. THEODORE H. BERLIN, of the Rockefeller Institute, a leading American theoretical physicist, died on November 16.

Dr. Berlin went to the Rockefeller Institute, New York, in February 1961 to develop a school of physics and mathematics with Prof. George E. Uhlenbeck, a physicist, and Prof. Mark Kac, a mathematician. He was formerly professor of physics in the Johns Hopkins University.

Born in New York City on May 8, 1917, Dr. Berlin received the B.S. degree in chemical engineering from the Cooper Union Institute of Technology, and the M.S. and Ph.D. degrees from the University of Michigan.

His Ph.D. thesis was on the quantization and electric interaction in diatomic molecules. During the Second World War, while a graduate student at the University of Michigan, he worked on the proximity fuse.

He joined the faculty of the Johns Hopkins University in 1946, and was appointed assistant professor in 1947. He was then named associate professor of physics in Northwestern University and, in 1955, returned to Johns Hopkins University as a full professor.

Dr. Berlin in 1952 and 1953 was a member of the Institute for Advanced Study, Princeton University, as a Guggenheim Fellow. At the University of Michigan he studied under Prof. Uhlenbeck, and at the time of his death was engaged in writing a volume on statistical physics with Prof. Uhlenbeck.

A Fellow of the American Physical Society, Dr. Berlin has served as associate editor of the *Journal of Chemical Physics* and the *Physical Review*, publications of the Society. Last year he served for a time as the editor of *Physical Review Letters*.

Mr. C. W. Wood

CYRIL WARCUP WOOD, senior science master at St. Bees School (Cumberland) from 1945 until 1959 and since 1960 executive editor of the new Commonwealth and International Library of text-books, died in an Oxford nursing home on December 20, at the age of sixty-two. He had recently been appointed a director of the Pergamon Press.

Cyril Wood, who was born in Yorkshire, held a first-class honours degree of the University of Manchester and was also a master of science of the same University. He was chief examiner in physics-with-chemistry for the Northern Universities Joint Matriculation Board and assistant examiner in the General Certificate of Education for the Examining Boards of Oxford, Cambridge and Wales. Before joining the staff of St. Bees, Mr. Wood taught chemistry in Leeds Grammar School for twelve years.

During his lifetime Mr. Wood wrote fifteen general science and chemistry text-books.

NEWS and VIEWS

The British Broadcasting Corporation:

Sir Harold Bishop, C.B.E.

SIR HAROLD BISHOP, director of engineering since 1952, will retire on May 10, the fortieth anniversary of the date on which he joined the B.B.C. He is the first man to complete forty years' service with the B.B.C. Sir Harold received his technical education at the City and Guilds College, being awarded the associateship of the College in 1920. He was later awarded the fellowship of the City and Guilds Institute and the fellowship of the Imperial College of Science and Technology. After two years with H.M. Office of Works and a year with Marconi's Wireless Telegraph Co., Ltd., he joined in 1923 the British Broadcasting Company, which in 1927 became the British Broadcasting Corporation. He was senior superintendent engineer from 1923 until 1929, assistant chief engineer from 1929 until 1943, and chief engineer from 1943 until 1952, when he was appointed to his present post. He was awarded the C.B.E. in 1938 and created Knight Bachelor in 1955. Sir Harold was chairman of the Radio Section of the Institution of Electrical Engineers in 1941–42, a member of the Council from 1944 until 1947, vice-president from 1948 until 1953, and president in 1953–54, and was awarded the Institution Premium in 1935. He was president of the Association of Supervising Electrical Engineers from 1956 until 1958 and president of the Television Society in 1961 and 1962.

Mr. F. C. McLean, C.B.E.

SIR HAROLD will be succeeded as director of engineering by Mr. F. C. McLean, who is at present deputy director of engineering. After taking his degree at the University of Birmingham, Mr. McLean joined Standard Telephones and Cables, Ltd., in 1925 as an engineer on radio projects and spent six years in the Paris laboratories of the Company. In 1937 he joined the Station Design and Installation Department of the B.B.C. and became assistant to the chief engineer in 1947. He was promoted to assistant chief engineer in 1951 and deputy chief engineer in 1952, and has been deputy director of engineering since 1960.

Mr. M. J. L. Pulling, C.B.E.

THE new deputy director of engineering will be Mr. M. J. L. Pulling, who is at present assistant director of engineering. Mr. Pulling was educated at Marlborough College and at King's College, Cambridge. After a period in industry he joined the B.B.C. Engineering Information Department in 1934. He became assistant to the assistant chief engineer in 1937 and superintendent engineer (recording) in 1941. From 1949 until 1956 he was senior superintendent engineer (television) and was appointed controller (television service engineering) in 1956. He took up his present post in January 1962.

Mr. D. B. Weigall

MR. PULLING will be succeeded as assistant director of engineering by Mr. D. B. Weigall. On leaving the University of Oxford in 1933, Mr. Weigall joined the B.B.C. as a student apprentice. He was a member of the Research Department from 1935 until 1939 and was seconded as chief engineer to the Malaya Broadcasting Corporation from 1940 until 1942 and afterwards to the Ministry of Information. In 1946 he joined the Department of the

Superintendent Engineer (Sound) and became a senior engineer in the Planning and Installation Department in 1948. From 1961 until 1962 he was in the External Broadcasting Engineering Department and became chief engineer (external broadcasting) in May 1962.

Dr. K. R. Sturley

THE new chief engineer, external broadcasting, will be Dr. K. R. Sturley. On leaving the University of Birmingham, Dr. Sturley joined Marconi's Wireless Telegraph Co., Ltd., in 1936. He remained with them until 1945 when he joined the B.B.C. and was appointed to his present post as head of the Engineering Training Department.

Marconi Director of Engineering :

Dr. E. Eastwood, C.B.E.

DR. E. EASTWOOD has been appointed director of engineering and research of Marconi's Wireless Telegraph Co., Ltd. Born in Rochdale, Lancashire, Dr. Eastwood was educated at Oldham High School and later at the University of Manchester and Christ's College, Cambridge. He joined Marconi's in 1948, from the Nelson Research Laboratories of the English Electric Company, and was appointed deputy chief of research. In 1954 he became chief of research, and in 1962 he was appointed to the new post of director of research. He was awarded the Wakefield Gold Medal of the Royal Aeronautical Society in 1961, in recognition of his contributions towards safety in the air, and he was awarded a C.B.E. in the 1962 New Year Honours List. In 1961 he was elected to the Board of Marconi Instruments, Ltd., and was appointed director of research for the entire English Electric Group in August 1962. He is at present giving the 1962–63 series of Faraday Lectures for the Institution of Electrical Engineers. In this newly created post, Dr. Eastwood will be responsible for all engineering and research work within the Marconi Company.

Mr. R. J. Kemp, formerly deputy engineer-in-chief of the Company, is appointed deputy director of engineering and research.

1962 James Clayton Prize

THE Institution of Mechanical Engineers has awarded the 1962 James Clayton Prize to: Dr. H. E. Merritt, for his contributions to mechanical engineering science by theoretical and practical investigations leading to his solution of many problems involving tooth gearing, in part communicated to the Institution in the form of papers and lectures; Dr. D. G. Christopherson, for his broad contribution to mechanical engineering science by way of his researches into lubrication, elasticity and plasticity, and through his services in the development of engineering education. This Prize is drawn from the Clayton Trust Fund, and represents one-quarter of the annual income of the Fund (nearly £6,500 each year). It is awarded annually to a member or members of the Institution who in the opinion of the Council contribute most in the year to modern Engineering Science by way of research, invention, experimental work or a treatise or paper on a modern engineering subject, or originality in engineering design or by service to engineering.

The Association of Universities of the British Commonwealth

THE report for the year ended July 31, 1962, of the Executive Council of the Association of Universities of the British Commonwealth records a membership of 118 universities, 10 university colleges and 4 other approved institutions of higher education (Pp. 36. London: Association of Universities of the British Commonwealth, 1962). While the final total of 967 vacancies for 1961–62 was not significantly higher than in the previous year (943), the number of applications received for the posts announced fell from 1,634 to 1,398, and the number of announced cases in which the appointment went to a candidate secured by the Association's advertisements rose from 127 to 151; during the year 4,741 specific inquiries about advertised posts were handled. The Association continued to provide the secretariat for the Commonwealth Scholarship Commission in the United Kingdom and to assist in the selection and placing of Scholars and Visiting Fellows, and has also assisted with the competition for the Frank Knox Memorial scholarships, with the Marshall scholarships, the Commonwealth University Interchange, the Drapers' Company scholarships and the admission of candidates to universities in France by virtue of examinations passed in Britain. A note is appended on the work of the Committee of Vice-Chancellors and Principals.

University Support in Canada

THE report on University Support 1961–62 of the National Research Council and the Medical Research Council of Canada records direct expenditure by the former of 8·85 million dollars, of which 82·8 per cent was for some 1,000 research grants to members of university staffs and 17·2 per cent for 675 postgraduate scholarships and fellowships (Pp. vii+138. N.R.C. No. 6862. Ottawa: National Research Council and Medical Research Council, 1962. 50 cents). Of the total expenditure, 8 million dollars was provided by the Council, 700,000 dollars by the Atomic Energy Control Board, 24,460 dollars by the Fisheries Research Board and 120,937 dollars by the North Atlantic Treaty Organization Science Committee. Of expenditure totalling 965,892 dollars for indirect support, 43·6 per cent was to scientific organizations and functions, 36·5 per cent for the publication of six scientific periodicals and the remainder for administration of the programme. The total of 9·81 million dollars compares with 8·17 million dollars in 1960–61 and 3·32 million five years ago. The Medical Research Council's programme of support totalled 3·36 million dollars in 1961–62 compared with 3·31 million dollars in 1960–61 and 894,357 million dollars five years ago. Of the total, 82·7 per cent was for 383 research grants to Canadian institutions and 15 per cent for 60 fellowships, 24 associateships and 24 summer scholarships. Lists of fellowships and scholarships and of research grants are included in each report.

Management Studies in Technical Colleges in Britain

VIGOROUS further development of postgraduate courses of high quality is recommended in the first report of the United Kingdom Advisory Council on Education for Management, 1962, *Management Studies in Technical Colleges* (Pp. viii+19. London: H.M.S.O., 1962. 2s. net). The report points out that the technical colleges provide a wide range of courses in management studies, including the new diploma in management studies, a national award introduced in 1961. It is of great importance that the diploma course should be of a high standard at all centres where it is offered, based on teaching of high quality, with rapid build-up of full-time courses, and concentrated at a relatively limited number of centres, where exploration and development of the field of knowledge are possible. Some full-time staff may be obtainable from industry, and the special needs of management departments should be recognized in settling staff complaints and regard paid to opportunities for research and consultancy. A sustained effort is needed to ensure a continuous flow of information about the purposes of management education and the available facilities. Besides the courses with 2,360 students at forty-three technical colleges (including four colleges of advanced technology) in October 1962, twelve universities are offering courses, in eight of which postgraduate full-time courses of a year's duration are available. The importance of close co-operation between the colleges and the firms providing students is stressed, and the report includes recommendations for the training and development of teachers, such as overseas visits, interchange of staff, and the use of part-time staff.

The Sixteenth Arthur Stanley Eddington Memorial Lecture

IN the sixteenth Arthur Stanley Eddington Memorial Lecture, "On Having a Mind", delivered on November 9, 1962, Prof. W. Kneale concludes that we must retain the Platonic notion of mental events which are distinct from anything in the physical world and manifest a special kind of connectedness (Pp. 56. Cambridge: At the University Press, 1962. 4*s.* 6*d.* net; 95 cents). The occurrence of such events is part of what we ordinarily intend to assert when we speak of the existence of minds and a presupposition of all the more interesting things we want to say about them. He believes that an analysis of perception which does justice to the complications of our ordinary talk about it must be a casual theory of some kind, and that the distinction of primary and secondary qualities, as drawn by Locke at his best, is a very important discovery of philosophy. He does not attempt to consider how it came about that some organisms have minds, nor yet what advantage, if any, an organism can gain from having a mind, but in this part of our search for truth he thinks we are still like children playing with pebbles on the shore of a great ocean. He suggests that the survival of the Platonic theory of mind during the past three centuries in spite of fairly obvious difficulties is not due to the dominance of a religious interest among philosophers but to its leaving the way open for the development of natural science.

U.K. Population Trends in the Late 'Fifties

IN the third part of his statistical review for 1960, the Registrar General remarks on the change in the pattern of population growth which took place in the late 'fifties (*The Registrar General's Statistical Review of England and Wales for the year 1960.* Part III: Commentary. Pp. xiv + 281. London: H.M.S.O., 1962. 21*s.* net). Between 1959 and 1960 the home population increased by 369,000 persons, compared with 277,000 and 202,000 in the previous two years. Natural increase accounted for 255,000, the remainder being due to net migration. As there was a not inappreciable outward movement, total immigration was considerably heavier. Live births at 785,000 were higher than in any year since 1947, and it seems reasonably certain that ultimate family size has been rising. The marriages of 1936–41 achieved about two children apiece, those of 1946 are likely to achieve 2·2, the most recent cohort for which the Registrar General makes an estimate are likely to have between 2·3 and 2·4. A rise of 20 per cent in total family size over a period of 15 years is obviously an important shift and needs explanation, though this is not the task of the Registrar General, who confines himself to the role of chronicler. It is, however, to be noted that the 1962 total of births is likely to exceed that of 1960 by a considerable margin. As regards deaths, the principal comparison made is between 1950 and 1960, two years not very different climatically. Infectious diseases, and particularly tuberculosis, have fallen very considerably, from 47·0 per 100,000 in 1950 to 12·3 in 1960. As regards cancer, an increase of 53 per cent in the standardized mortality ratio is noted for cancer of the lung among males and a 35 per cent increase for females. Expectation of life at birth was 68 years for men and 74 for women, at age 45 the figures were 27 and 32 years, and at age 65, 12 and 15 years, respectively. Marriage rates continued high, the gross nuptiality table for 1960 implying no fewer than 96·4 per cent of females marrying by the age of 50.

Antiquities from Benin, Nigeria

BENIN sculptures are well known and can be seen in most of the major ethnographical museums. Frequently they were made by the *cire perdue* method and the artists showed great skill in their productions. Bronze is commonly the material used, but brass also occurs. As there is no tin available in Nigeria, this latter alloy must have been imported, perhaps from the southern Sudan. These sculptures have been made in Benin for a very long time; indeed, since the sixteenth century. Did the early Portuguese traders have any influence on a native art existing in the country at the time? But it was only really after the punitive expedition of 1897, when the country was opened up, that these splendid sculptures became known in England. Nowadays they are much sought after and command a large price.

Captain A. W. F. Fuller, who was born in 1882, and came of a family long settled in Sussex, started the hobby of collecting at an early age, and his collections from Oceania and Africa became famous. Towards the end of his life he became interested in the Chicago Natural History Museum, and there all his collections are to be found. The Museum already had a good number of specimens from Benin, and these together with the Fuller examples are now on show. A well-illustrated catalogue has been produced, and for those who cannot visit Chicago itself this will be of great interest (*The Art of Benin: a Catalogue of an Exhibition of the A. W. F. Fuller and Chicago Natural History Museum Collections of Antiquities from Benin, Nigeria.* By Philip J. C. Dark. Pp. iii + 74 + 48 plates. Chicago: Chicago Natural History Museum, 1962. 2 dollars).

Russian Geology in Translation

FOR some years the American Geological Institute has been conducting an extensive programme of English translation from Russian, Chinese, and other 'difficult' languages, much of which has been published in its monthly periodical *International Geology Review* (55 dollars per year; 15 dollars to educational institutes and personnel: American Geological Institute Translations Office, 2101 Constitution Avenue N.W., Washington 25, D.C.). A special supplement to the October 1962 issue of this journal, in the form of an 89-page *Catalogue of Translations of Russian Papers in Geology, Solid-Earth Geophysics, and Related Sciences through 1961*, is likely to meet a present need. It records fifteen Russian periodicals in the earth sciences of which cover-to-cover translations are made by American agencies; and it lists a further 1,652 papers from other serials (dating from 1953 to 1961) of which translations are available, with the sources whence copies may be obtained. One noteworthy omission from the list of cover-to-cover translations is the *Bulletin of the Moscow Society for Natural Research* (*Geological Section*), now being produced in English, on behalf of the National Science Foundation, by the Israel Program for Scientific Translations (61, Geological Section, 31, 1st, 2nd, 3rd Editions. Pp. iv + 444. (Jerusalem: Israel Program for Scientific Translations. Available from the Office of Technical Services, U.S. Department of Commerce, Washington, 25, D.C., 1961.) 4.50 dollars.) Beginning in 1963, *International Geology Review* will be expanded to carry selected papers from the *Palaeontological Journal* (*U.S.S.R.*), from the *Izvestiya* (Geological Series) of the U.S.S.R. Academy of Sciences, and from *Soviet Geology*, and it will thus make the results of much Russian geological work more readily accessible to the Western reader.

Bibliography on Soft X-ray Spectroscopy

AN *Annotated Bibliography on Soft X-ray Spectroscopy* has been compiled in connexion with a research programme on the electronic structure of metals and alloys in progress at the U.S. National Bureau of Standards (*Monograph* No. 52: *Annotated Bibliography on Soft X-ray Spectroscopy.* Pp. iv + 108. Washington, D.C.: Government Printing Office, 1962. 1 dollar). The bibliography contains about 550 references and is considered to be a complete coverage of the soft X-ray literature for the period 1950–60. Some references to earlier work are included but the general review references, listed separately, cover fairly adequately previous work. The first group of references in the monograph is of general survey and review papers and books. The main list of references follows, grouped by year and arranged alphabetically by author within each year. The emphasis is on the application of soft X-ray spectroscopy to the study of valence band electronic states in metals and alloys. The spectral region 25–800 Å involving ruled glass grating spectrometers is therefore of principal interest. However, considerable data have been gathered, primarily by the Russians, on valence electronic states by means of high-energy transitions where crystal spectrometers are satisfactory. These references and any X-ray work leading to the distribution of valence electronic states are included regardless of the transitions used. In addition to soft X-ray data, references on all pertinent aspects of the apparatus and experimental problems are included in the bibliography. A number of indexes are given at the beginning of the monograph for ready reference to papers containing the specific data to which the bibliography applies. In the literature the spectra are presented in a variety of energy units, and in compiling the bibliography the units given in the original papers have been retained. A conversion chart of units is appended to the bibliography. It is intended to continue the bibliography and to issue supplements periodically.

Protecting Turtles in Sarawak

A Government Ordinance now protects the greater turtles of Sarawak from disturbance, under penalty of a 1,000 dollar fine. This is the penalty for any unauthorized vessel approaching within half a mile of three islands off the coast of Sarawak, Talang Talang Besar, Talang Talang Kechil and Satang Besar, on which the turtles nest. Carefully conserved by the curator of the Sarawak Museum, Dr. Tom Harrisson, the turtles have provided more than twenty million eggs for local consumption in the past fifteen years (*World Wildlife News*, No. 7; October 1962). Many other eggs have been removed to hatcheries, where the young turtles have been reared safely and released again at sea when they are big enough to fend for themselves.

Incidence and Distribution of Asthma in Australia

An analysis was made of asthma cases in public hospitals in Queensland in the year 1957. Asthma was responsible for 2,673 cases, or 1·62 per cent of the total. It predominated in male children and in adults more than 55 years of age. It predominated in females in the intervening years. A striking fall in the male incidence in the second decennium suggested a favourable prognosis for most asthmatic boys. The apparent incidence of asthma varied considerably from place to place. The variation could not be explained simply in terms of latitude, altitude, temperature, rainfall or distance from the coast. Some of the variation between hospitals was probably due to different criteria for admission. The seasonal distribution changed significantly at about the Tropic of Capricorn. To the south, the main incidence was in autumn; to the north, no seasonal patterns had a wide prevalence. The investigators, Drs. E. H. Derrick and R. H. Thatcher, showed that an aetiological study of asthma must take into account variation in the complex of causes including sex, age, season and locality (Seventeenth Annual Report of the Council of the Queensland Institute of Medical Research for the year ended 30th June, 1962. Pp. 12. Brisbane: Queensland Institute of Medical Research, 1962).

The Society for Visiting Scientists

The report of the secretaries on behalf of the Council of the Society for Visiting Scientists made to the fifteenth general meeting on December 11 refers to the success of the three discussion meetings dealing, respectively, with colour television, the turkey X disease, and matching men and machines. Activities were somewhat restricted by the change of premises from Old Burlington Street to 19 Albemarle Street, and reference is again made to the difficulty of finding new and adequate sources of income.

The Scottish Field Studies Association : Programme of Courses

The Scottish Field Studies Association has arranged the following courses during 1963: *Garth:* geography (April 13–20); spring in the Highlands (May 18–25); geology of Glen Lyon (June 8–15); insect natural history (June 29–July 6); grasses, rushes and sedges (July 6–13); mountain and moorland ecology (August 3–10); mountain flowers (August 10–17); plant ecology (August 17–24); lichens (September 7–14); *Isles of Great Cumbrae:* seashore biology (May 11–18); marine biology (June 1–8, June 8–15, August 24–31); *Black Isle:* geography (June 1–8); *Pitlochry:* archæology (June 1–8); *Isle of Arran:* birds of Arran (April 13–20); geology of Arran (June 1–8, September 7–14); wild flowers (July 6–13); *Strathpeffer:* Highland birds (June 8–15); geographical field studies (July 6–13); *North Ballachulish:* geology of Glencoe (July 6–13); *Alnmouth:* birds of Northumberland (June 1–8); a geographical survey of the Hebridean highlands and islands (April 11–17). Further information can be obtained from the Scottish Field Studies Association, 179 West Regent Street, Glasgow, C.2.

Announcements

Dr. Bernard Kirsch, research physicist with the Phillips Petroleum Company's Atomic Energy Division at Idaho Falls, has been appointed senior scientist at the Nuclear Science and Engineering Corporation, Pittsburgh, Pa.

Changes of name of subsidiary companies of the Derritron Group have been announced as follows: Beme Research and Development Ltd., to Derritron Research and Development Ltd.; Chapman Ultrasonics Ltd., to Derritron Ultrasonics Ltd. (managing director, Mr. C. T. Chapman); Doran Instrument Co. Ltd., to Derritron Instruments Ltd.; Electronic Vibrators Ltd., to Derritron Electronic Vibrators Ltd.; L. S. B. Components Ltd., to Derritron Transformers Ltd.

A programme of twelve courses on the use of isotopes has been arranged by the Atomic Energy Research Establishment Isotope School during the period February 11–December 13. The courses will range between five and twenty-three days in length, with tuition fees between £20 and £60. Further information can be obtained from the Wantage Research Laboratory (A.E.R.E.), Wantage, Berkshire.

A symposium on "Communications in Industrial Relations", organized by the Central London Productivity Association in conjunction with the Department of Management and Social Science, Northampton College, will be held at the Northampton College of Advanced Technology, London, on January 30. Further information can be obtained from Miss C. M. Burnell, Room 101, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Erratum. In the communication by C. Chlouverakis entitled "Adipose Tissue Lipoprotein Lipase Activity in Rats of Two Different Ages", which appeared on p. 1103 of the December 15 issue of *Nature*, the tenth paragraph should read "The average enzyme activity so defined was found to be 19·36 ± 8·25 (mean ± *S.D.*) units in young, and 3·81 ± 2·92 (mean ± *S.D.* as above) units in old rats ($t = 5·3$, $P < 0·0001$)".

FLUORIDE, TEETH AND THE ANALYST

A MEETING on "Fluoride, Teeth and the Analyst", held by the Society for Analytical Chemistry at the Wellcome Building, Euston Road, London, N.W.1, on November 7, under the chairmanship of Dr. A. J. Amos, provided an opportunity for discussion between chemists of widely different interests and specializations.

Dr. H. J. Cluley (General Electric Co., Ltd., Hirst Research Centre, Wembley, Middlesex) spoke on "The Determination of Fluoride in Inorganic Materials by Pyrohydrolysis". Fluorine, he said, interfered with the determination of a number of elements and was itself frequently difficult to determine. One particular difficulty arose from the lack of selectivity of the methods available for the determination of fluoride, so that for fluoride in inorganic materials a preliminary separation of the fluoride from most other elements was almost invariably necessary. The most common method of separation was that of Willard and Winter in which fluoride was distilled as fluosilicic acid; however, this was subject to serious interference from aluminium, boron and gelatinous silica and hence was of little practical value to the silicate analyst.

Against this background, an alternative means of separation was required and 'pyrohydrolysis' offered a method of rapidly separating fluorine from a variety of inorganic materials. This technique involved heating the sample, usually mixed with a suitable 'accelerator', in a current of steam or moist oxygen; the fluorine was evolved as hydrogen fluoride which could be condensed and determined by titration.

The method originated in the atomic energy field where it was observed that the fluorides of uranium and of aluminium, bismuth, magnesium, vanadium, zinc, zirconium and rare earths were rapidly hydrolysed on heating in a current of steam. Other fluorides such as those of calcium, strontium and barium were more reluctant to part with their fluorine but the addition of an accelerator, for example, U_3O_8 or alumina, facilitated their hydrolysis. More recently, tungstic oxide and vanadium pentoxide had been used as accelerators.

Originally, a platinum reactor tube had been used for the pyrohydrolysis. It had now been shown practicable to use a silica reactor tube in conjunction with a glass water-cooled condenser, since the concentration of hydrofluoric acid vapour was always low and the time of contact with the apparatus was short. Typically, pyrohydrolysis was continued for 15–30 min at approximately 1,000° C, with a fast flow of steam to give 3–5 ml. of condensate per min.

Where conventional methods require lengthy separations, for example, the determination of fluorine in silicate materials, the rapidity afforded by the pyrohydrolysis technique is of particular advantage. Dr. Cluley described how the technique had permitted the rapid determination of 5 per cent of fluorine in opal glass, giving results of high precision. He had also used pyrohydrolysis to determine 0·02–0·10 per cent fluorine in very small dentine samples which were supplied by Dr. G. N. Jenkins (who was to speak later) and which originated from 'low' and 'high' fluorine areas.

Dr. J. Longwell (deputy government chemist, Laboratory of the Government Chemist, Clement's Inn Passage, Strand, London, W.C.2) dealt with the fluoridation of water supplies from the analyst's point of view. Not enough was known about the vast amount of work that had been devoted to this subject during recent years in the United States and in Great Britain; it had been the subject of detailed study without parallel in preventive medicine. He recalled how the condition of children's teeth had improved during the Second World War when sugar and sweets were rationed and how their condition had since worsened, and showed colour slides to illustrate the gravity of the problem.

Surveys of children's teeth in the United States had shown how the numbers of decayed, missing and filled teeth were much lower or nil in the areas where naturally occurring fluoride was present and the practice of fluoridation of water supplies at a level of 1 p.p.m. had since been adopted. The improvement in dental health that had been observed after fluoridation for some fifteen years in the United States was described and illustrated.

In 1952, a group from Great Britain went to North America to study the fluoridation of water and, on returning, recommended that fluoride be added to the water supplies of several selected communities before the general adoption of fluoridation. Studies were first carried out on the availability of fluoride in food and drink and on the amounts that would be ingested with and without fluoridation of the water. Fluoridation was started in Kilmarnock, Watford and Anglesey in 1955–56 and a report had just been published by the Ministry of Health *et al.* giving the results obtained after five years of fluoridation (see *Nature*, 195, 760; 1962).

The methods used to add fluoride in a steady and controlled concentration to the water supplies in Britain were outlined and emphasis was laid on the care taken to ensure control—which was two-fold. First, the amount of fluoride actually added was recorded as was the volume of water pumped and from these figures the concentration of fluoride ion in the water was calculated. Chemical determinations at the water plant, using a visual colorimetric zirconium–alizarin lake method were confirmed at the Laboratory of the Government Chemist, using distillation from perchloric acid to remove any interfering ion, followed by colorimetric determination. More than 20,000 samples examined in the five years gave an average of 0·94 p.p.m. fluorine, with a standard deviation of about 0·1 p.p.m. fluorine. The improvement in the deciduous teeth of children in the three study areas, as a result of fluoridation, was illustrated; the reduction of about 60 per cent in the incidence of caries in 3- and 4-year-old children was similar to that observed in the United States, and even more interesting was the increase in the percentage of children with completely sound teeth, from 32 to 60 per cent at 3 years and from 22 to 42 per cent at 4 years.

In time, teeth of older age groups would be improved and teeth of older children and adults in natural fluoride areas were examples of what could and should be achieved by fluoridation. Dr. Longwell ended his talk by showing coloured photographs of teeth of two children, typical of many, living in a natural fluoride area.

Dr. G. N. Jenkins (Reader in Oral Physiology, Medical School, King's College, University of Durham, Newcastle upon Tyne) concerned himself with the role of analysis in investigating the mode of action of fluoride in tooth decay. Fluorine was present in teeth as a result of an ion exchange reaction with the hydroxyapatite of the calcified tissues, and hence in areas with a water of high fluorine content the fluorapatite of the teeth was also high. Topical application of high concentrations of fluoride led to other reactions—double decomposition leading to the deposition or adsorption of calcium and magnesium fluoride, and hence the mechanisms involved by such methods, for example, in toothpastes, were certainly very different and incompletely understood.

Studies of the distribution of fluorine in the tooth showed a very definite pattern, the concentration being much higher in the outer enamel layers than deeper in the tissues of the tooth. Nevertheless, the concentrations even in these deeper enamel layers were higher in teeth from high than from low fluoride areas. The lesser solubility of fluorapatite compared with hydroxyapatite suggested a possible mode of action in reducing the incidence of caries, and detailed investigations of solubility were described in which the outer surfaces of teeth from high and low fluoride areas were compared. The large variation tooth-to-tooth made valid comparison very difficult and the slightly lower solubility found for teeth from a 1 p.p.m. fluorine area, as compared with a zero fluorine area, was not statistically significant. At 2 p.p.m., however, a statistically significant lowering by 21 per cent in the solubility was recorded. The choice of analytical method was of importance in the solubility determinations; in some conditions different results were obtained, according to whether phosphorus or calcium was measured, and workers in the United States had investigated the problem by gravimetric determinations of solubility on powders ground from successive layers of the teeth. By this method, too, the teeth with highest fluoride content were also the most soluble. Experiments with radioactive fluoride revealed that the tooth took up fluoride more readily in the nieghbourhood of a caries blemish, and it had been found that the differences between the fluoride of enamel from areas of high and low intake of fluoride were greater when carious enamel was studied.

Other properties of the fluoride ion were discussed that might be related to its action in reducing dental decay. Since it favoured the precipitation of calcium phosphate from unstable and metastable solutions, such as saliva, it might intermittently reverse the removal of calcium salts in, and thus slow the development of, a dental cavity. The role of fluoride as an enzyme poison might also be related to its decay-inhibiting properties. Attempts were therefore being made to study the fluoride content of the 'dental plaque' (the muco-bacterial film on the tooth surface)—an analytical problem of some magnitude when it is realized that only about 10 mg of plaque can be obtained from one person. It had been shown to be significantly higher in subjects from 'high fluoride' areas. Partial release of the bound fluoride in plaque might occur if the *p*H became sufficiently acid, as it probably did after eating carbohydrate. It had been found with saliva that the addition of fluoride at a concentration similar to that of plaque was effective not merely in preventing the production of acid from carbohydrate by salivary bacteria but could actually bring about an increase in *p*H.

That fluoridation of public water supplies was a subject of great topical interest was evident from the lively discussion that followed each paper. The analyst, it was clear, had an important part to play by developing and applying sensitive methods that were essential not only to ensure its proper regulation and control but also to provide the basic tools for the study of the fundamental mechanism by which fluoride exerted its beneficial effect.

S. A. Price

GROWTH AND NUTRITION OF A WHOLE PLANT

ANYONE interested in the growth of the whole plant should find a recently published memoir interesting, for they will find it a refreshing revision course dealing with some theories of contemporary botany in a more stimulating way than is usually found in text-books*. Prepared by Prof. F. C. Steward and three colleagues it contains, in Parts 2–5, information about the anatomy, growth and development of mint grown with a wide range of nutrient-levels (some of which led to deficiency symptoms) and different light and temperature conditions. Parts 4–6 have details of many chemical analyses, involving chromatographical techniques, carried out on roots, stems and leaves of plants grown under a wide range of environmental conditions. The final section is a synthesis of the earlier parts.

Although the morphology of the plant does make it readily acceptable to sampling procedures, the decline in popularity of mint as an experimental plant (discussed in Part 1) must largely be due to the fact that large numbers of plants are usually needed for experiments associated with analysis of growth. Raising plants from seeds is more satisfactory from many points of view than from cuttings. There are no troubles in keeping stock plants alive, no labour-demanding jobs such as preparing cuttings, and less variation in initial size of plant. The rapid growth rate of mint is obviously valuable; but the fact that it produces much lateral growth and a large number of small leaves is a disadvantage when compared with plants producing a few large leaves from a main axis. The unbranched plant, particularly one the form of which is similar under a wide range of environmental conditions, will, unlike mint, have similar efficiencies of light utilization in, for example, long- and short-day conditions. Would the results of the many chemical analyses that are presented in Parts 4–6 of the memoir have been similar if a plant with a single main axis had been used?

These first seven parts contain a great deal of information about effects of length of day, night temperature and mineral nutrition on some cell constituents; some information in future parts on effects of amount of incident radiation, spectral composition of light and perhaps other environmental variables would obviously give a more complete picture. Finally, most botanists would agree that the chemical analyses which were done on mature tissues should be extended to the growing regions, not only to apical meristems, but also to all organs throughout periods of cell division, expansion and differentiation if a better understanding of organization of growth is to be obtained.

P. Newton

* Growth, Nutrition and Metabolism of *Mentha piperita* L. Parts 1–7. Memoir 379, Cornell University Agricultural Experimental Station, Ithaca, New York. August 1962, 144 pages.

THE CENTRAL FOOD TECHNOLOGICAL RESEARCH INSTITUTE, MYSORE

IT is not uncommon to find that scholarly academic work is undertaken in underdeveloped countries while practical problems of vital interest to the economy of the State are neglected. Sometimes technological laboratories equipped with foreign capital do not function satisfactorily because of lack of suitable personnel. Some of these problems are no doubt due to the type of training given to students sent to Europe and elsewhere, but others to lack of proper incentives presented by the Governments concerned. None of these criticisms can, however, be applied to the Central Food Technological Research Institute at Mysore, which, under its director, Dr. V. Subrahmanyan, is rapidly building a reputation in South-East Asia. The report of its work during 1960–61 covers many aspects of the food industry and includes biochemistry, nutrition and dietetics*.

Emphasis is properly placed on the solution of problems which have a direct application in Asia, but some of the results are of interest to the European technologist. The frying of banana chips, the preparation of buttermilk soup powders, the canning of drinking-water, the utilization of passion fruit waste or the colorization of vanaspati with tumeric would be unusual subjects for study by the Western scientist. But the preparation of foods for infants and children from largely plant sources is well known to be of vital importance not only in India and Asia but also in many other parts of the world. In this respect, the experience of the Indian workers with isolated proteins from groundnut and soya warrants careful attention, especially with regard to the method of presentation to the consumer. Greatest success has been achieved with a high-protein blend of materials designated 'multi-purpose food' which is made on a large scale and has been used in school-meal programmes as a supplement "to overcome the deficiency of the lunch". The manufacture of this product has now been handed over to private industry.

Similarly, the sections of the report dealing with meat and fish technology, packaging, storage and pesticide research have applications in any tropical country. Of particular value is the work on fish, as this source of protein has been somewhat neglected in the past; work is being done to extend the use of traditional methods as well as the development of new products. Sun-drying, salting and curing are likely to be extensively used for many years, and an understanding of these processes is essential to encourage and standardize the production of fish and other foods of high acceptability and nutritive value.

It is a pity that the report of the Institute for 1960–61 was not published more promptly, as for more recent information it is necessary to consult Indian journals some of which have only a limited circulation. Clearly, however, the workers at Mysore are aware of the importance of increasing food supplies to meet the needs of the growing population and are making a real contribution to the problem from the technological side. One hopes that the limitation of human fertility is receiving the same attention elsewhere.

POTASSIUM–ARGON AGES FROM WESTERN OAHU, HAWAII

By IAN McDOUGALL

Department of Geophysics, Australian National University, Canberra

THE large shield volcanoes which comprise the Hawaiian Islands have been the subject of intensive study for many years. Little is known concerning the absolute age of the lavas or the time involved in building these shield volcanoes. Previous workers have based their estimates of age on superposition and geomorphological arguments. A study of the age of the Hawaiian Islands by using the potassium–argon method, mainly on whole-rock samples, is in progress. In this preliminary communication results are given of ages from Western Oahu.

The Waianae Volcano comprises the western half of Oahu, and the volcanic sequence has been divided into the Lower, Middle and Upper Waianae Series[1,2]. The volcano has been profoundly eroded into wide, flat-floored valleys up to 3,000 ft. deep, separated by steep, rugged ridges.

Specimens were collected from the Mauna Kuwale hornblende–biotite–trachyte[1,2], and basaltic rocks of the Middle and Upper Waianae Series. Biotite was separated from the trachyte and used for dating this rock. The age of each of the basaltic rocks was determined on whole-rock samples; about 10 g of sample was used for each argon extraction. The extractions were made in a high vacuum line by fusing the sample, adding a tracer of argon-38, followed by purification of the argon over hot copper oxide and calcium. The isotopic composition of the argon was determined on a Reynolds-type mass spectrometer by the static method[3]. Potassium was measured on a Perkin Elmer flame photometer using lithium as an internal standard; sodium was added as a buffer to both the sample solutions and the standards. Results are given in Table 1, and details of the samples are listed in the appendix. Replicate potassium analyses agree to better than 1 per cent. Duplicate argon extractions agree to better than 2·5 per cent in those cases where the air argon correction is less than 60 per cent; where this correction is greater the precision decreases owing to marked error magnification. The absolute accuracy is probably ± 3 per cent, increasing to ± 6 per cent in those samples with a high air correction, excluding uncertainties in the decay constants. The marked disagreement between replicate argon extractions for *GA*560 is partly because of the high air correction, and partly because of sampling difficulties, as this basalt is amygdaloidal. The fact that the rocks show no evidence of alteration, and that they have never been deeply buried, renders it unlikely that appreciable loss of argon has occurred.

Biotite from the Mauna Kuwale trachyte gives an age of 8·4 ± 0·2 million years, corresponding to the Lower to Middle Pliocene, based on the time scale of Kulp[4]. The basalts of the Middle and Upper Waianae Series yield Upper Pliocene ages ranging from 3·5 ± 0·3 to 2·75 ± 0·1 m.y.

Stearns and Vaksvik[1] included the Mauna Kuwale trachyte in the Lower Waianae Series, regarded as the oldest exposed rocks of Oahu. The trachyte is overlain conformably to the south-west by basalts mapped as Lower and/or Middle Waianae Series[2]. Because silicic lavas are generally associated with the declining stages of activity in the Hawaiian volcanoes and the Lower Waianae Series is composed predominantly of tholeiitic basalts, it was suggested[1] that, alternatively, the trachyte may be associated with an older volcano buried by the later Waianae lavas. The potassium–argon age of the trachyte may lend support for this hypothesis, as the Middle and Upper Waianae Series volcanics are much younger; the results clearly show that there was a prolonged hiatus between the extrusion of the trachyte and the outpouring of the lavas of the Middle and Upper Waianae Series.

The Middle Waianae Series lavas are only slightly older than those of the Upper Waianae Series. Hence, extrusion of the lavas of these two series apparently occurred rapidly, and the change in composition from dominantly tholeiitic to dominantly alkali–olivine basalts, on which the division between the two series is made, occurred over a relatively short period of time.

These results provide some hitherto non-existent control as to the absolute age of the volcanics of Western Oahu, and show that the estimates of age based on geomorphological arguments are qualitatively correct. Thus, Stearns and Vaksvik[1] suggested that the deep valleys of Oahu probably were eroded during early Pleistocene time, by correlating the emerged coral reefs with shifts of sea-level induced by glaciation. They concluded that the building of Koolau Volcano (Eastern Oahu) ceased in the late

Table 1. POTASSIUM–ARGON AGE MEASUREMENTS ON ROCKS FROM WESTERN OAHU, HAWAII

$^{40}Ar^{*}$—radiogenic component $\lambda_{\beta}=4{\cdot}80\times10^{-10}$ yr.$^{-1}$ $\lambda_{e}=0{\cdot}584\times10^{-10}$ yr.$^{-1}$

Tertiary or early Pleistocene, and that as the Waianae lavas are overlapped by the Koolau Volcanics, then eruption from the Waianae centre probably extended farther back into the Tertiary. The potassium–argon measurements indicate that the profound erosion of the Waianae Volcano occurred during the past 2·7 million years, and probably mainly during the Pleistocene.

Normal and reversed polarities recently have been reported from the Hawaiian lavas[5]; by using the potassium–argon method it should be possible to date these reversals.

The potassium analyses were made by J. A. Cooper and the separation of biotite from the Mauna Kuwale trachyte was carried out by R. Rudowski. I thank D. A. Davis and O. Johnson of the U.S. Geological Survey for their co-operation during my stay in Oahu.

APPENDIX

GA 553: Alkali-olivine basalt of the Upper Waianae Series, 2·3 miles south-east of Kaena Point. 21° 33′ N., 158° 15′ W., altitude about 1,120 ft. Massive, slightly vesicular, intergranular basalt with average grain size about 0·1 mm, and composed of plagioclase, iddingsitized olivine, titanaugite, iron ore and about 15 per cent intersertal, poorly crystallized feldspar, probably a potassium-rich oligoclase.

GA 556: Basaltic andesite (hawaiite) of the Upper Waianae Series, 1·4 miles west-north-west of Puu Palailai. 21° 21·4′, 158° 6·6′, altitude about 550 ft. Massive, light grey rock consisting of olivine, augite and iron ore embedded in a felted mass of laths of andesine. Some interstitial oligoclase and also sporadic biotite.

GA 554: Tholeiitic basalt of the Middle Waianae Series, western cliff of Keaau Ridge. 21° 29·1′, 158° 13·6′, altitude about 400 ft. Dark grey, massive rock with plagioclase and olivine phenocrysts up to 10 mm set in a fine-grained (0·1 mm) intergranular groundmass of plagioclase, augite, iron ore, minor olivine and intersertal oligoclase.

GA 560: Tholeiitic basalt of Middle Waianae Series, Kolekole Pass Road. 21° 28·1′, 158° 7·3′, altitude about 950 ft. Massive, dense, slightly amygdaloidal rock composed of sporadic plagioclase and serpentinized olivine phenocrysts set in a groundmass of clinopyroxene, plagioclase, iron ore and minor intersertal green glass.

GA 397: Hornblende–biotite–trachyte from flow 400 ft. thick at Mauna Kuwale. 21° 27·8′, 158° 9·6′, altitude about 300 ft. Dark grey, massive rock composed of phenocrysts of andesine, hornblende and biotite set in a feldspathic microcryptocrystalline groundmass which has a fluidal texture. Phenocrysts average 0·2 mm in length.

CLASTIC QUARTZ, PROVENANCE AND SEDIMENTATION

By DR. J. T. GREENSMITH

Department of Geology, Queen Mary College, University of London

QUARTZ grains in sandstones commonly attract attention by the provenance inferences which can be derived from the nature of their inclusions[1,2]. Krynine[3], Bokman[4], Keller and Littlefield[5] and Doty and Hubert[6] are recent workers who have deduced significant information about the nature of source rocks from a study of the differing varieties of quartz grains, their shape and inclusions.

These investigations, however, do not exhaust the inferences which can be made from quartz grains. This has become apparent during an examination of Carboniferous sandstones in Derbyshire[7] and Scotland[8,9]. All these sandstones were laid down on shallow shelves of varying degrees of stability and are characterized by a dominance of orthoquartzitic textures and shallow-water structures such as ripple marks and cross-bedding[7,8,9]. The preliminary results proved so interesting that additional shelf sandstones of Cretaceous age were examined together with a variety of older Palæozoic sandstones of more mixed tectonic setting. Within them all it is possible to detect a three-fold grouping of the clastic quartz grains. The information deduced from this grouping gives a new insight into provenance make-up and abrasion during the time of deposition of the sandstones.

The basis of this new work is thin-section microscope analysis involving a determination of whether the clastic quartzes are unstrained, strained or compound in nature. The diagnosis requires the use of crossed polars and various magnifications depending on the grain size. Three-fold grouping is adopted for ease of graphical representation; further subdivision would lead to graphical complications.

The definitions of unstrained, strained and compound grains naturally need to be rigid to ensure reproducibility of results by the same or different operators. Unstrained grains are those which do not show undulatory extinction no matter how feeble. They are single crystals. Strained grains are single crystals also in which all degrees of undulatory extinction occur from weak to intense. There must not be any precisely defined internal boundaries between the zones of variable extinction; gradation is the rule. Compound grains show multiple effects composed of the qualities of both strained and unstrained types, but the fundamental distinction rests in the fact that they consist of an aggregate of quartz crystals. Each of the component crystals is separated from the others by a sharp boundary. For all the grain types marginal authigenic outgrowths are ignored.

This method of grain analysis, it will be noted, does not necessarily give a direct indication of the petrographic nature of the specific rock types at source. Strained quartz, for example, could have been derived from acid igneous and metamorphic rocks or older sandstones;

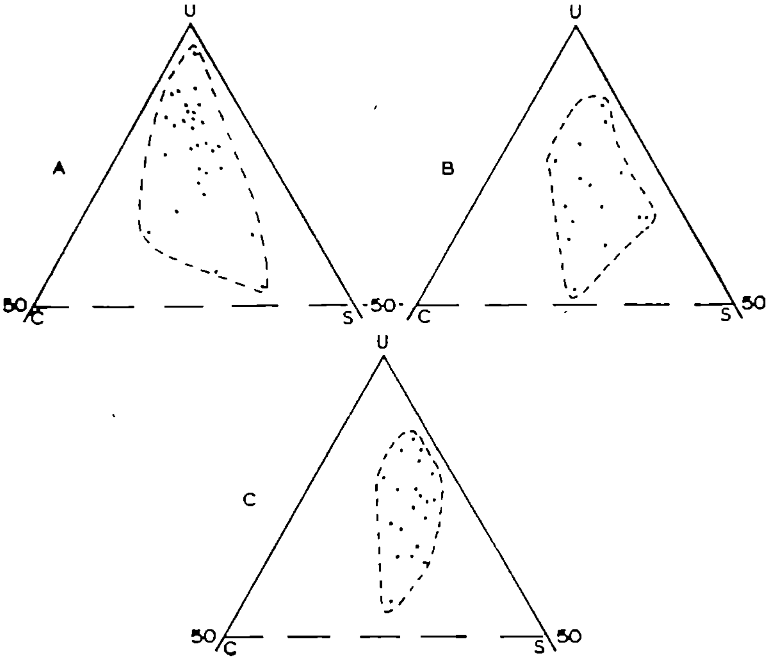

Fig. 1. Comparative UCS (Unstrained, Compound, Strained) diagrams for: *A*, Oil-Shale Group of the Lothians; *B*, Calciferous Sandstone Series of East Fife; *C*, Upper Carboniferous of north Derbyshire. 50 per cent base line for unstrained quartz indicated

similarly with unstrained quartz. The compound grains could have a metamorphic source (metaquartzite, schistose quartzite), sedimentary source (chert, orthoquartzite, re-cycled) or be vein quartz.

The selected sandstones were analysed using a mechanical stage and for each a hundred grains were classified by means of non-duplicatory traverses.

Fig. 1*A* shows the distribution pattern of 29 samples taken at random though fairly evenly spaced intervals through the Carboniferous Oil-Shale Group of the Edinburgh (or Lothians) area. The group has an approximate maximum thickness of 5,000 ft. The pattern is interesting because the field of point distribution appears to be restricted. The proportion of unstrained clastic quartz is clearly dominant over the compound and strained varieties, and a possible conclusion is that more unstrained quartz was being supplied by the source area to the basin of deposition. It seems reasonable to suggest, furthermore, that during the whole of Oil-Shale Group times the clastic quartz sources in the land area to the north-east[8] remained relatively constant both in proportion and nature. If provenance erosion had progressively uncovered older rocks with very markedly different proportions of the three quartz types then this, in all probability, would have been reflected into the resultant shelf (fluvial) sandstones.

The Calciferous Sandstone Series of East Fife are facies equivalents of the Oil-Shale Group and outcrop 20 miles or so to the north-east of Edinburgh. The continuity of sedimentation of the two areas during Carboniferous times can be demonstrated by features such as cross-bedding[8] within the sandstones. Fig. 1*B* suggests that the continuity is also expressed by the quartz grain distribution. The sandstones analysed are taken through the full thickness of the succession, about 4,000 ft.

The Upper Millstone Grit and Lower Coal Measures are at a higher stratigraphical level than the above Scottish rocks and Fig. 1*C* illustrates the field for 20 samples from northern Derbyshire. They are taken through a thickness of 3,000 ft. of strata and, once more, the limited point scatter suggests small variations in supply from the provenance. At the same time there is a noticeable broad similarity of distribution with that of the older Scottish rocks. This is probably significant because it is known from other considerations[2,8,9] that the land source of all these sandstones lay to the north and north-east of the Midland Valley of Scotland.

To extend the knowledge and assess the prospective value of this new technique random samples of Cretaceous shelf sandstones from Surrey were examined. Eleven of the specimens were from Hythe Beds and the rest from the overlying Sandgate Beds. In Fig. 2 the two sets of data are plotted separately, and it appears that there might have been slight differences in the provenance of the clastic quartz for each group of beds. The Sandgate Beds sandstones seem generally to have more strained quartz and less unstrained than the Hythe Beds. Possibly the change could be linked up with an alteration in the palæogeography of the London Platform massif immediately to the north[10]. The other feature of the distribution is the pattern which resembles those of the Carboniferous sandstones. The post-Carboniferous palæogeography is such that derivation from a land mass to the north of the British Isles is unlikely. Therefore the similarity may be fortuitous or express the re-cycling of Carboniferous sandstones originally deposited on the site of the St. Georges Land–London Platform. It is probable, however, that the Hythe and Sandgate grains have passed through at least one post-Carboniferous cycle of sedimentation.

Fig. 3 illustrates a random series of Lower Palæozoic (and one Pre-Cambrian) sandstones of shelf and geosynclinal facies. Considerable contrast in quartz grain distribution is evident between this and those of Figs. 1

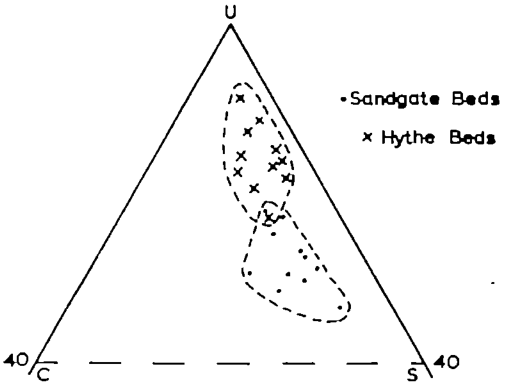

Fig. 2. UCS (Unstrained, Compound, Strained) diagram for Cretaceous sandstones of Surrey. 40 per cent base line for unstrained quartz indicated

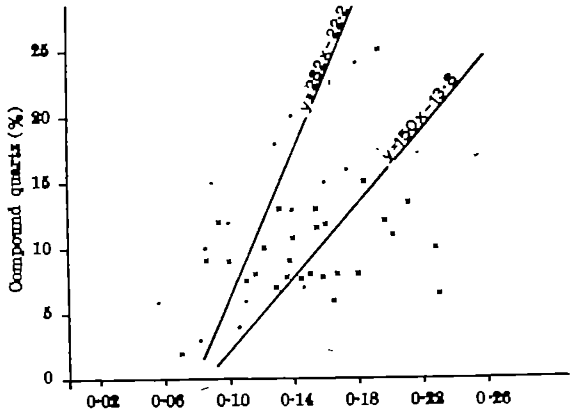

Fig. 4. Variation of compound quartz percentage and median diameter. Regression lines indicated for Calciferous Sandstone Series (•), ($y = 282x - 22{\cdot}2$) and Oil-Shale Groups; (×), ($y = 150x - 13{\cdot}8$)

and 2. It is clear that for most of the individual sandstones the provenance of the quartz grains was entirely different from that of either the Carboniferous or Cretaceous sandstones. What it does not show because of lack of systematic data through any specific sandstone group is the variation, if any, in provenance during the deposition of that group. Further work is needed.

Sandstones, however, are products not only of heredity as broadly indicated here but also of environment. On shallow water shelves the constant agitation of the waters must affect the clastic grains either in terms of sorting or abrasion. To confirm the presence of these processes the Oil-Shale Group and facies equivalent Calciferous Sandstone Series sandstones were examined in greater detail. Cumulative curve data provided the median diameters of the sandstones and these were plotted against the percentage of compound quartz grains. Fig. 4 shows the distribution of points and corresponding regression lines. In both instances it is clear that the percentage of compound grains decreases as the median grain size decreases. This relationship could be explained by fluctuations in the provenance supply of debris, sorting in the depositional areas or physical disintegration of the grains into their smaller component parts. Other evidence[9] suggests that the provenance for both areas was similar and the detritus derived from it varied negligibly. There also seems to be no reason why compound grains should be differentially separated from other quartzes of approximately equal size and specific gravity. Hence it is probable that the regression lines reflect the abrasion and comminution of the compound grains. A lower compound quartz proportion means a greater degree of abrasion and vice versa.

A further point concerning inferred abrasive effects can be deduced from the regression lines by considering any given median diameter. If, for example, in Fig. 4, a median diameter of 0·14 mm is selected then the corresponding quartz percentages are 17·5 per cent for the Calciferous Sandstone Series and 7·5 per cent for the Oil-Shale Group. As provenance and sedimentation of sandstones were similar for both areas it is possible that the differences in percentages reflect the greater distance of transport, and thus abrasion, involved for the Oil-Shale Group debris. The Calciferous Sandstone Series clastic quartz derived from the common source area to the north-east[9] travelled at least 20 miles less than that of the Oil-Shale Group. Sorting does not appear to have played any part in the proportional distribution of the quartz grain varieties.

These conclusions relating the percentage of compound quartz to abrasion history in no way detract from the broad conclusions regarding similarity in provenance which can be drawn from the less refined detail of the ternary diagrams. These diagrams relate the three types of quartz. With the Scottish Carboniferous sandstones it is only because the ternary provenance patterns are similar that possible abrasion inferences can be made about one of those varieties of quartz.

SENSITIVITY IN LEDA CLAY

By EDWARD PENNER

Soil Mechanics Section, Division of Building Research, National Research Council, Canada

THE sensitivity (ratio of the natural strength to the remoulded strength) of Norwegian marine sediments reported in the literature[1] shows an inverse relationship to the existing salt concentration of the pore water. These findings are explained by the 'leaching theory' of sensitivity[2] which is based on the premise that sedimentation took place in sea-water or brackish water. The decrease in the salt concentration of pore water by subsequent leaching and/or diffusion causes the salt-flocculated structure to become 'metastable'. This reduces the remoulded strength much more than the natural strength.

The marine sediments of the St. Lawrence Lowlands (commonly referred to as Leda clay) are similar to the Norwegian sediments in clay mineral composition[3,4]. In both soils unaltered particles of similar minerals make up a considerable proportion of all size fractions. There are also similarities in many of the geotechnical properties the soil[5,6] and in the phenomenon of frequent and sudden earth flow slides in such deposits. The most characteristic property of both soils is the large loss of strength when remoulded. To date, however, it has not been possible to establish for Leda clay how much of the sensitivity can be attributed to the leaching of salts or to what extent other factors are involved.

Certain previous observations may be recounted since they support this aspect of dissimilarity between the Norwegian and Leda clays regarding sensitivity[6]. In the Ottawa area the pore water salt concentration of Leda clay is generally a fraction of a gram per litre and rarely exceeds 1–2 g/l. (In contrast, a wide range of pore water salt concentrations has been reported for Norwegian marine clays.) At the same time the sensitivity may vary from a low value of 10 to values of 200 and higher depending on how it is measured[7]. Usually, high sensitivities are accompanied by low plasticity indices and low liquid limits, and low sensitivities with higher plasticity indices and liquid limits, quite independent of salt concentration. There is also a tendency for the most sensitive portions of the profile to be more silty in nature although the differences are sometimes small or negligible.

In other studies being carried out on Leda clay from a deep excavation, radical changes were observed in

Table 1. SUMMARY OF COMPARISON TESTS FOR TWO SAMPLES OF LEDA CLAY

Sample No.	94–30	94–13
Undisturbed strength (falling cone)	1,930 lb./ft.^{2}	2,080 lb./ft.^{2}
Remoulded strength (falling cone)	1·3 lb./ft.^{2}	68 lb./ft.^{2}
Sensitivity	1,500	30
Geodetic elev.	124 ft.	140 ft.
Depth below surface	47 ft.	22 ft.
Mechanical analysis		
< 2μ (clay size)	71 per cent	83 per cent
2–20μ (silt size)	29 per cent	18 per cent
> 20μ	0	0
Liquid limit	39	69
Plastic limit	24	31
Plasticity index	15	38
Salt concentration (pressure extraction of pore water)	1·1 g/l.	0·6 g/l.
Dry density (field)	68·4 lb./ft.^{3}	61·7 lb./ft.^{3}
Surface area (glycol method)	58·7 m^2/g	72·0 m^2/g
Cation exchange capacity	16·0 m.equiv./100 g	15·9 m.equiv./100 g
*p*H	8·1	8·1
Natural moisture content	55·6 per cent	65·2 per cent
Water content at equivalent strengths	55·6 per cent	136 per cent
Cation content (leached 5 g soil with 200 c.c. of ammonium acetate)		
Ca	0·35 g/100 g soil	0·40 g/100 g soil
Mg	0·09 g/100 g soil	0·12 g/100 g soil
K	0·09 g/100 g soil	0·07 g/100 g soil
Na	0·17 g/100 g soil	0·04 g/100 g soil
Ratio, surface area/per cent clay	1·21	1·15

sensitivity in the absence of any large changes in the pore water salt concentration. With samples from strata of high and low sensitivity exploratory determinations were carried out in an attempt to establish other reasons for this apparently anomalous situation as compared with Norwegian clays.

The results given in Table 1 show that there are only small differences between the two samples with respect to percentage clay- and silt-size particles, surface areas, cation exchange capacity, low salt concentration, natural water content and *p*H. The large differences are in the behaviour of the materials as measured by the Atterberg limits and, of course, in sensitivity. The water content of sample 94–13 had to be increased to 136 per cent before it reached the low remoulded strength that sample 94–30 had at its natural moisture content of 55·6 per cent.

When electrolyte was added, each sample showed the same trend in strength behaviour although there were large differences in the magnitude of the response. Fig. 1 shows the drop in strength resulting from additions of sodium metaphosphate (this compound has a 1·1 mole ratio of Na_2O/P_2O_5) after remoulding the samples mechanically. These strengths were measured with a lightweight drop cone 1 min after mixing was stopped. It is the large change in strength of sample 94–13 that is of significance when compared with sample 94–30. By adding 1 g of sodium metaphosphate per 100 g of soil the strength dropped from 70 lb./ft.^{2} to about 1 lb./ft.^{2}, while the strength of the more sensitive soil changed by only a fraction of this. At higher concentrations flocculation occurred as indicated by the increase in remoulded strength. It is not unreasonable to assume that the stability of the structure of these two samples was quite different as evidenced by the response to the dispersant. In the highly sensitive soil, mechanical mixing was sufficient to cause a high degree of dispersion which could only be achieved in the clay of lower sensitivity by increasing the electrokinetic potential[8] and hence the amount of repulsion between adjacent particles.

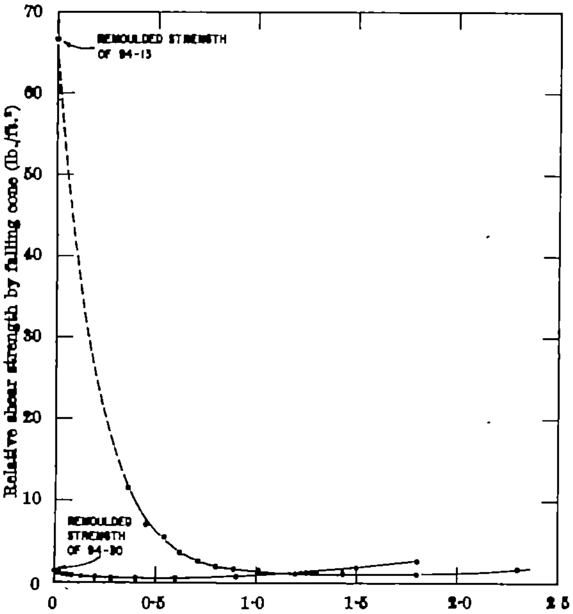

Fig. 1. Comparison of strength reduction of remoulded Leda clay of different sensitivity by adding sodium metaphosphate at the field moisture content

Addition of sodium metaphosphate also reduced the liquid limit and plasticity index. Sample 94–13, originally with a liquid limit of 68·9 per cent, was reduced to 67 per cent at 0·022 g of sodium metaphosphate per litre of pore water to 63 per cent at 0·09 g/l. and to 53·7 per cent at 0·26 g/l.

Fig. 2 shows changes, measured in shear strength, of sample 94–30 by increasing the electrolyte concentration with various salts at natural moisture content. With calcium chloride, sodium carbonate and sodium chloride the strength increased but with sodium metaphosphate the strength decreased. This behaviour can be explained in terms of the effect that changing the interparticle force has on structural arrangement[9] and this is consistent with the behaviour of Norwegian marine clays[1].

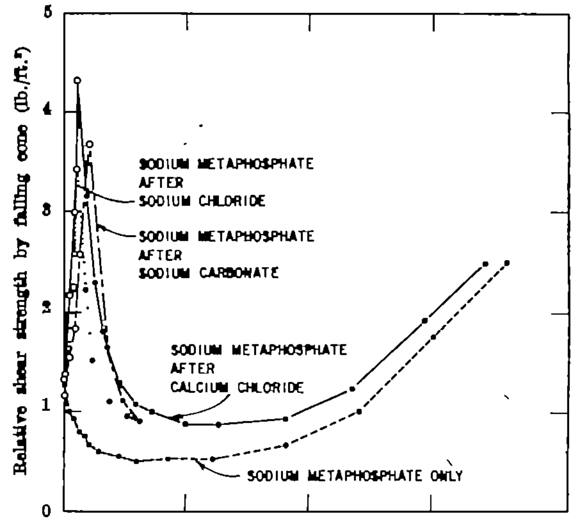

Fig. 2. Remoulded strength of 94–30 as a function of electrolyte content at the field moisture content

The higher sodium content of the leachate from 94–30 (Table 1) may be of significance in assisting more complete dispersion while remoulding and in this case may explain the difference in sensitivity between these two samples. There are apparently factors, therefore, other than reduction of the pore water salt concentration of sediments that have led to the present variation in sensitivity in Leda clay.

ELECTRIC CHARGES AND THIXOTROPY OF CLAYS

By G. H. CASHEN

Physics Department, Rothamsted Experimental Station, Harpenden, Herts

HYDROGEN clays prepared by washing in acid are unstable[1]; on washing in distilled water Al^{3+} is released as the lattice edges crumble[2] and this is followed by a slower release of Al^{3+} involving diffusion of exchangeable hydrogen ions to the edges[3]. In the time required to dialyse a hydrogen clay electrolyte free, the clay has become an aluminium clay, and the permanent charge is balanced by Al^{3+} ions in a Stern layer.

In a standard method (conductometric) for measuring cation exchange capacity by titration with alkali, the aluminium ion is converted to the hydroxide ($Al(OH)_3$), and the negative charge is balanced by alkali metal cations, which form a diffuse layer. Throughout a titration, almost up to the equivalent point, the viscosity is high, but within the last 20 per cent of added alkali the viscosity decreases by a factor of 10^3 (ref. 4), a discontinuity which suggests there might be some unevenness in the charge distribution, greatest in the later stages of neutralization.

Recent work on the hydrolysis of aluminium ion[5] suggests either the formation of a series of complexes $Al[(OH)_5Al_2]_n^{n+3}$, with a limiting OH/Al ratio of 2·5, or of single complexes such as $[Al_6(OH)_{15}]^{3+}$ or $[Al_8(OH)_{20}]^{4+}$, the value of the charge not being known. Conductivity measurements with aluminium salts (Cashen, G. H., in preparation) show that there is a discontinuity at five-sixths of the neutralization, and a probable interpretation of the charge balance for a clay, at the same stage of neutralization, is that five-sixths (83 per cent) is then balanced by alkali metal cations in a diffuse layer, and the remaining one-sixth by complex aluminium ions in a Stern layer. Because there must be some mobility to account for Al^{3+} ions coming together to produce, say $[Al_6(OH)_{15}]^{3+}$, it seems reasonable to suggest that the distribution of the complex ions is in a state of minimum energy, that is, as far apart as possible under their mutual repulsions; and the hypothesis now advanced is that this is so; as a result, the clay particles are positively charged near the periphery by an excess of complex ions in the Stern layer.

The hypothesis, advanced to explain the particular results of work on kaolin, aluminium ion and alkali hydroxides, could be general, and a polar nature might arise for any non-spherical particle, whenever diffuse and Stern layers co-exist.

A mathematical treatment of the interaction between clay particles would be formidable if, in addition to the Gouy repulsive and London attractive forces, forces of a circular dipole nature were taken into account. It is obvious, however, that there could be preferred mutual orientations, for example, to produce the "house of cards" structure in clays, and the decrease in viscosity towards complete neutralization needs no further comment.

Qualitatively, and even semi-quantitatively, the hypothesis explains some puzzling phenomena in colloid chemistry, and provides an alternative explanation for others. For brevity, the following reasoning deals only with clays and clay problems.

Thixotropy. Freundlich[6] demonstrated the effects of added (and adsorbed) divalent and trivalent anions on the coagulation and thixotropy of positively charged ferric oxide sols (prepared from ferric chloride), and was surprised when the same valency rules did not apply to cations and negatively charged 'hydrogen' bentonite. No thixotropic sols were produced by $AlCl_3$ or $Th(NO_3)_4$, the hydroxides and chlorides of divalent metals had little effect, and it needed alkali hydroxides (the most efficient) or chlorides to form strongly thixotropic pastes. He discussed this behaviour in terms of bound water, but his results are much more intelligible if it is recognized that the 'hydrogen' clay was an aluminium clay. Buzágh and Szántó[7] found that the optimum thixotropic behaviour of a 'hydrogen' bentonite occurs between 80 and 90 per cent neutralization—in good agreement with the 83 per cent the hypothesis would predict.

Thixotropic behaviour of clays finds practical application in the preparation of drilling muds. The 'red lime muds' are made highly alkaline by adding both lime and caustic soda, and quebracho extract is used as a liquefier[8]. This again is a two cation system but the conditions are such that large negative edge charge should develop, a state which, according to the usual conceptions, should lead to enhanced deflocculation. If the high alkalinity is essential in these muds, the most probable conclusions are: (1) the negative edge charges increase the kind of polarization suggested in this communication; (2) it must be the calcium ions that are preferentially adsorbed at the edges, a deduction that follows naturally from the argument already advanced. Van Olphen experimented with the trihydric phenols, as typical of components of the quebracho extract, and found that only those with an adjacent pair of hydroxyl groups, and thus able to complex calcium ions, were efficient liquefiers. He discussed the adsorption of anions containing calcium in this state at the crystal edges, but it is much more probable that the action of the quebracho extract is to change the Na^+–Ca^{++} ratio by removing calcium ions from the particle surfaces.

Another example of the effect of a Na^+–Ca^{++} system is the almost perfect petrifaction of soft-bodied sea animals in the Solnhofen slate[9]. The slate contains more than enough calcium carbonate to ensure that the initial clay must have been calcium-saturated and sea-water provided the sodium ion; it is reasonable to suppose that a rapid gelling of the clay around the animal cut off access of oxygen, and if this was not the immediate cause of death it could certainly be the preventive of decomposition. It is, of course, possible that the phenomenon is of a co-operative nature. Peselnick[9] compared the elastic constants of Solnhofen slate and of single crystals of calcite and concluded that the slate behaved as an aggregate of randomly oriented single crystals of calcite. Boswell[10] states that calgon (sodium hexametaphosphate) makes chalk suspensions (whitening) more mobile, a deflocculating effect indicating that sodium ions have replaced calcium ions complexed by the calgon, and that the chalk is negatively charged.

A similar argument might well explain why clay is necessary to produce the thixotropic behaviour of the marine quicksands examined by Freundlich and Juliusburger[11], but here there is no internal evidence of the presence of calcium ion, or of any other polyvalent ion that could act in the same way.

Oriented Flocculation. After treating kaolins with normal sodium chloride at *p*H 3, Schofield and Samson[4] noticed a change in the nature of the flocculation when the kaolins were washed with distilled water. They explained this by a change from face-to-face (salt) flocculation to a more bulky edge-to-face state when removal of the salt allowed interaction between positively charged edges and the negatively charged planar faces. It has

SICS DEPARTMENTAL LIB

been shown that, after washing with distilled water, the edges are uncharged; positive edge charges are lost as aluminium ion, released from the lattice at the crystal edges, appears in the exchangeable form (Cashen[2] and unpublished data); consequently, it is concluded that the edge-to-face flocculation is that for an Na^+–Al^{3+} system.

Effects of Shear. (i) Assuming that the state of least energy for two particles is when they are symmetrically placed at right angles to one another, Gouy forces will not exert a moment tending to disturb the orientation. For small rates of shear, attractive forces between the circular dipoles will predominate and will oppose change in orientation. At some critical rate of shear (and orientation) the Gouy forces will take over and exert a moment assisting the shear, because the repulsive pressures will be greatest where the particles are closest together; the viscosity of the suspension then exhibits the drop characteristic of thixotropic systems as the rate of shear is gradually increased.

(ii) Low[12] prepared a sodium clay by a two-stage process described by Low and Anderson[13]. A clay suspension was passed through exchange resins in the hydrogen and hydroxyl forms and analysis gave the cation status as 60 per cent H^+ and 40 per cent Al^{3+}. The sodium clay, obtained by adding the requisite amount of sodium hydroxide, thus contained $Al(OH)_3$ as the only impurity. While standing undisturbed for six days the water tension of the suspension gradually increased, that is, the vapour pressure gradually decreased. (Experimental conditions are not given fully, and the system may have been adsorbing carbon dioxide from the atmosphere, with formation of the complex aluminium ion.) On the sixth day the suspension was stirred and the water tension decreased almost to zero. Low recognized that the mutual particle orientations were changing with time, but considered that the osmotic activity of the cations should not be affected by stirring. He ascribed the slow gelation to a gradual extension of a water structure, of lower free energy, to rather large distances from the particles. Quite apart from the effect of ionic charges on the structure of water, possible changes in ionic concentration cannot be ignored in a complete interpretation. If, initially, two particles are situated in the same plane, the diffuse layers extend, theoretically, in parallel to infinity (apart from edge effects); on rotation of both particles through 90° to the face-to-face position, the cations tend to pack between the particles (which gives rise to the repulsion) and the 'outer' liquid is depleted of ions. A rotation of one particle only would lead to some intermediate distribution; stirring, which tends to produce the face-to-face orientation, consequently leads to lower ionic concentrations in the 'outer' solution, and the vapour pressure rises. In so far as the free energy of the water is concerned, work done on thixotropic systems by application of shear is analogous to that on salt solutions by application of pressure.

(iii) Similar reasoning would suggest that the freezing-point for the "house of cards" structure in a clay should be lower than the freezing-point of a mechanically sustained ungelled state. It is lower, but the anomalous freezing-point depression is usually explained by the rigidity of the gel structure which so limits the size of the ice crystals that the surface area–size ratio is large when compared with that for macroscopic ice crystals (Weiss and Frank[14]). In a pressure–temperature diagram the sublimation curve would be above that for macroscopic ice, and for equilibrium at some given vapour pressure, the microscopic crystals must be colder than the macroscopic to prevent sublimation between the two types of ice crystal.

The concept that gel rigidity should prevent growth of ice crystals is completely counter to agricultural experience. When soil clods are frozen slowly, the growth of ice crystals compresses the soil which is being dried and produces a favourable, stable crumb structure; when the freezing is fast, the clods are shattered to such an extent that the tilth produced is much too fine[15].

REACTION OF LIME WITH FERRIC OXIDE

By A. K. CHATTERJI and T. C. PHATAK
Central Building Research Institute, Roorkee, U.P., India

It has recently been suggested that the adsorption of lime by fired kaolin and kaolinitic clay, in presence of water, may be considered to be a semiconductor surface reaction[1]. It was also found that the adsorption of lime decreased with the increase in the electrical conductivity of these materials[1,2]. In this article the reaction between lime and αFe_2O_3 (obtained from fired laterite) in the presence of water is considered. The problem arose during a study of the puzzolanic activity of laterite.

At low electrical conductivity of Fe_2O_3 it reacted very little with lime. At high conductivity, reactivity increased but remained constant over a wide range of conductivity, that is, saturation in reaction was obtained. On firing laterite with admixture of small quantities of Cr_2O_3, TiO_2, ZnO, NiO and CoO the nature of the reaction between Fe_2O_3 thus obtained and lime remained generally unaltered. On firing with Cu_2O, at low values of conductivity, the reactivity increased with the decrease in conductivity and at high conductivity, saturation was obtained.

The parallel change in reactivity with conductivity, when considered with the fact that Fe_2O_3 is a '*p*' type semiconductor in an oxidizing atmosphere, indicates that the reaction between lime and Fe_2O_3 in presence of water is a '*p*' type reaction on a '*p*' type semiconductor. The opposite behaviour in Fe_2O_3 obtained when laterite is fired with Cu_2O indicates that Fe_2O_3 may have changed into an '*n*' type semiconductor and the reaction is a '*p*' type reaction on a '*n*' type semiconductor.

A quantity of laterite was powdered, sieved through B.S. 200 mesh and fraction passing through was thoroughly mixed and the samples from it were analysed chemically and by X-ray and differential thermal anaysis.

About 200 g of the sample was drawn from this lot for each experiment and was fired in ordinary atmosphere,

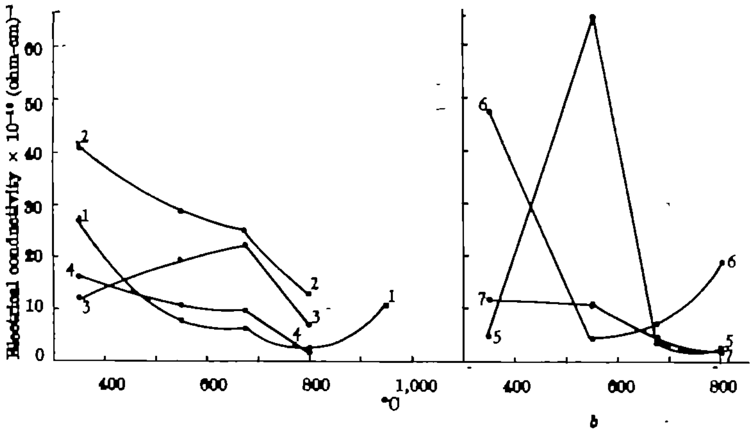

Fig. 1. Variation of room temperature electric conductivity of ferric oxide with firing temperature. *a*, Curve 1, Fe_2O_3 from fired laterite; curves 2, 3, 4 from laterite fired with admixture of Cr_2O_3, TiO_2 and ZnO. *b*, Curves 5, 6, 7, Fe_2O_3 from laterite fired with NiO, Cu_2O and CoO

as such or with admixture of 1 per cent by weight of Cr_2O_3, TiO_2, ZnO, NiO, Cu_2O and CoO. Firing temperatures for natural laterite were 350°, 550°, 675°, 800° and 950° C and those with oxides were 350°, 550°, 675° and 800° C. The firing period was 4 h in each case. The mass obtained on firing was examined visually and under a microscope. No sintering could be detected which meant that the specific surface area remained unchanged. The fired mass was washed clean of colloidal suspensions, dried at 110° C for 24 h and sieved through B.S. 300 mesh. A large portion of the sieved mass had the linear size below the 'screening length' (10^{-4} cm).

The amount of lime removed by the material from a saturated lime solution, at constant temperature 35 ± 0·5° C and in an atmosphere free of carbon dioxide, at intervals of 1 min was measured by the method described earlier[3]. Adsorption was rapid initially and the process continued at a slow rate for a long time and equilibrium conditions was not obtained even after 48 h but a near equilibrium condition was obtained after 5 min. Lime removed by 1 g of the material during the first 5 min was taken as a measure of its reactivity.

For electrical conductivity measurements the samples were made into tablets using a 20-mm cylindrical mould and plunger. 3 g of samples was placed in the mould and compressed in a hand-operated hydraulic-press at a total pressure of 1,000 lb. (Electrical conductivity was found to vary slightly with pressure.) The tablets, taken out of the mould, were coated on the flat ends with a dilute suspension of aquadag in alcohol. These were then dried at 110° C for 24 h and cooled to room temperature over fused calcium chloride and soda lime.

Resistance of the tablets was measured at ordinary temperatures and in ordinary atmosphere with a General Radio megohm bridge by placing the tablets between two flat platinum electrodes under a slight pressure. In some of the specimens resistance was found to increase slowly during measurements; and in such cases resistance at the establishment of contact was taken. There was also a slight change in conductivity with temperature but this was neglected in the present experiments.

Chemical analysis of the laterite sample is (per cent): loss on ignition 14·09, silica and insolubles 30·87, iron (Fe_2O_3) 35·04, aluminium (Al_2O_3) 18·12, calcium (CaO) 0·56, magnesium (MgO) 0·91 and alkalis nil.

X-ray diffraction pattern of the powdered laterite samples shows the presence of goethite, kaolinite and quartz. The differential thermal analysis curve shows endothermic peaks at 125°, 330° and 565° C and an exothermic peak at 940° C. These are identified as due to goethite, kaolinite and gibbsite.

Specific electrical conductivity of the samples of the natural laterite powder passing B.S. 300 mesh, washed, dried and tableted, was found to be in the order of 9×10^{-8} $(\text{ohm-cm})^{-1}$ at ordinary temperature. Its lime reactivity at 35 ± 0·5° C. was 8·18 mg/g.

X-ray powder patterns of the fired samples used for lime and resistance measurements show mainly the pattern of αFe_2O_3. Variation of (room temperature) electrical conductivity of Fe_2O_3 with firing temperature is shown in Fig. 1*a*. Up to 800° C conductivity generally decreases with the firing temperature with a slight hump at 675° C. A rise in conductivity is observed in the samples fired at 950° C.

Curves 2, 4, 5 and 7 (Fig. 1*a* and *b*) show variation in the electrical conductivity with firing temperature of the laterite samples with admixture of Cr_2O_3, ZnO, NiO and CoO. When fired with Cr_2O_3, the room temperature conductivity of Fe_2O_3 is higher (at the corresponding temperature) than the product obtained by firing laterite alone. Decrease of conductivity is, however, maintained. With ZnO, conductivity at 350° C is lower, at 550° and 675° higher and at 800° C of the same order as that of the ordinary laterite fired at the corresponding temperatures. With NiO, when fired at 350°, 675° and 800° C, the conductivities are much lower and show a gradual decrease but when fired at 550° C conductivity has a high value ($6 \cdot 5 \times 10^{-8}$ $(\text{ohm-cm})^{-1}$). With CoO (curve 7) the conductivities are low but these also decrease with firing temperature. Curve 3 (Fig. 1*a*) shows the effect of TiO_2. Conductivity increases up to 675° C and falls to a low value at 800° C. Curve 6 (Fig. 1*b*) shows effect of Cu_2O. There is a large increase in conductivity when fired at 350° C; at 550° C it decreases but again increases at 675° C and 800° C. There are humps at 675° C in the conductivity-firing temperature curves for natural laterite as well as for laterite fired with '*n*' type oxides (Fig. 1*a*). When fired with '*p*' type oxides the hump has shifted to a lower temperature (550° C).

Curve 1 (Fig. 2*a*) shows the variation of lime reactivity with (room temp.) electrical conductivity of Fe_2O_3 obtained from laterite fired without admixture. At low values of conductivity, reactivity increases with conductivity but at high values the reactivity tends to a saturation value. There is a reversal in the specimen fired at 950° C. Here conductivity in increased but reactivity decreases.

Curves 2, 3 and 4 (Fig. 2*a*) show the variation of reactivity with conductivity of the samples obtained after firing with Cr_2O_3, TiO_2 and ZnO. These are similar to curve 1 except for a slight decrease in reactivity at high conductivity which might indicate desorption. The nature of the curves from samples fired with NiO and CoO

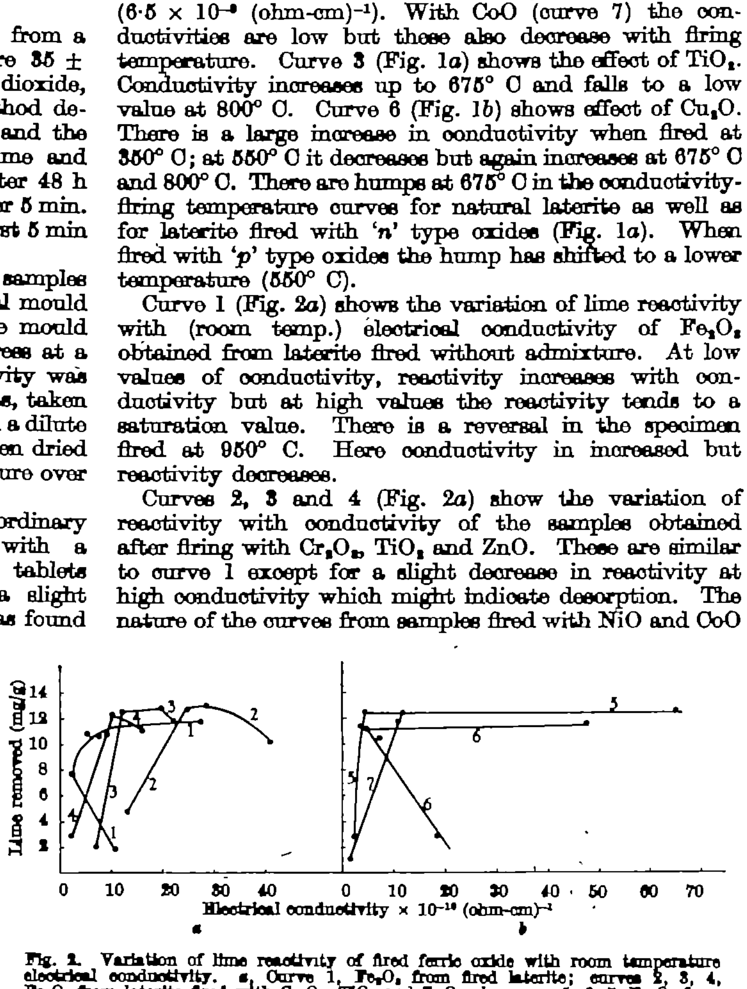

Fig. 2. Variation of lime reactivity of fired ferric oxide with room temperature electrical conductivity. *a*, Curve 1, Fe_2O_3 from fired laterite; curves 2, 3, 4, Fe_2O_3 from laterite fired with Cr_2O_3, TiO_2 and ZnO. *b*, curves 5, 6, 7, Fe_2O_3 from laterite fired with NiO, Cu_2O, CoO

(Fig. 2*b*, curves 5 and 7) is similar to curve 1. Curve 6 is for samples heated with Cu_2O. At high conductivity saturation is obtained but at low values the reactivity decreases with conductivity.

Specific electrical conductivity of pure Fe_2O_3 is of the order of 10^{-12} (ohm-cm)$^{-1}$. Higher conductivity obtained in these experiments may be the result of impurities present.

Fe_2O_3 can be either a '*n*' type or a '*p*' type semiconductor depending on the valence state of the cation. Oxidation changes pure Fe_2O_3 into a '*p*' type semiconductor. In these experiments Fe_2O_3 has been produced by heating laterite in an oxidizing atmosphere. A possibility is that the Fe_2O_3 used is a '*p*' type oxide. Further, on heating with Cr_2O_3, TiO_2, ZnO and Cu_2O (lower valency cations) an increase in conductivity is observed at corresponding firing temperatures in almost all cases. With higher valency cations there is a decrease in conductivity. These facts confirm that Fe_2O_3 used here is a '*p*' type semiconductor.

The decrease in conductivity of Fe_2O_3 with temperature may be due to annihilation of 'holes' by combination with electrons provided by Al_2O_3 (from the decomposition of gibbsite and entering into a solid solution in Fe_2O_3). The fall in conductivity (as well as of reactivity) at 800° C may be due to combination of 'holes' with electrons from enhanced quantity of Al_2O_3 entering into a solid solution with Fe_2O_3. This is possible because of the breakdown of kaolin structure into Al_2O_3 and SiO_2. (There is also a large change in the electrical resistivity of kaolin between temperatures 700°–800° C) (ref. 3). Increase in conductivity when fired at 950° C may be due to more Al_2O_3 entering into solid solution.

Introduction of donor impurities into a semiconductor crystal raises the Fermi level of the crystal towards its conduction band. Under equilibrium conditions, for a '*p*' type reaction, a shift of the Fermi level towards the conduction band adversely affects the number of particles involved in a chemisorption process. Thus the observed fall in reactivity with decrease in electrical conductivity for Fe_2O_3 obtained from fired laterite (Fe_2O_3 was being fired in presence of Al_2O_3) may be explained, if it is assumed that the reaction is a '*p*' type reaction on a '*p*' type semiconductor. Effect of admixture of '*n*' type oxides as Cr_2O_3, TiO_2 and ZnO can be explained in a similar way.

In the sample heated at 950° C the reaction is probably '*p*' type on a '*n*' type semiconductor.

On heating with Cu_2O in the range 550°–800° C reactivity varies with conductivity in opposite direction. This may happen if the reaction is assumed to be a '*p*' type reaction on a '*n*' type semiconductor. Fe_2O_3 may be changed into a '*n*' type semiconductor through Fe^{3+} changing to Fe^{2+} through reduction by Cu.

NiO and CoO have scarcely affected the reactivity of Fe_2O_3 in the way they are expected to do.

The humps at 675° C in the conductivity–firing temperature curves (Fig. 1*a*) may be due to change of Fe_2O_3 from its antiferromagnetic state to a paramagnetic one when fired at that temperature. (~ 675° C is the Néel temperature for Fe_2O_3.) If this is so, then the chemical reactivity of Fe_2O_3 becomes connected with its magnetic property through its semiconducting property and one expects that such a connexion should exist. The explanation of some of the observed results would then need some modification.

The reaction between Fe_2O_3 (obtained from fired laterite) and lime in the presence of water is a semiconductor surface reaction. The reaction type is a '*p*' type reaction on a '*p*' type semiconductor. Fe_2O_3 may be changed into a '*n*' type semiconductor by heating with Cu_2O above 550° C or with active Al_2O_3 above 800° C.

These conclusions need verification with pure Fe_2O_3 and experiments with this in view are in hand.

FIXATION OF RADIOACTIVITY IN SOLID MEDIA: STABILITY OF GLASSES AND GLAZES

By DR. GALEN R. FRYSINGER

Arthur D. Little, Inc., Acorn Park, Cambridge, 40, Mass.

AND

DR. HENRY C. THOMAS

Institute of Natural Science, Chapel Hill, North Carolina

AT the Working Meeting on Fixation of Radioactivity in Stable, Solid Media[1] a standard leaching test was proposed as a basis for the evaluation of the stability of glasses and glazes. The objective was to set up a test which would be easy to carry out and which could be performed on a wide variety of substances in any laboratory. The test was primarily devised to produce a numerical basis on which the relative merits of various materials could be argued, and not necessarily to have any close relation to actual leaching conditions.

The proposed test was very simple, the apparatus being merely a slightly modified Soxhlet extractor. Pure distilled water boiling in the flask of the extractor supplied a continuous stream of condensate from a glass finger which passed over the sample in a thimble arranged with an intermittent siphon. In the initial applications of this test the extraction thimbles were made of 'Pyrex'. These glass thimbles had the advantage of making easily visible the specimen undergoing test. 'Vycor' flasks were first used, but 'Pyrex' flasks proved to be satisfactory and far less expensive.

Leaching conditions. The 1-litre 'Pyrex' boiling flasks containing 200 ml. of water were heated with 'Glass-Col' mantles operated from 'Variacs'. The optimum voltage settings were found to be 70 V to the lower half of the mantle and 60 V to the upper half. This gave a steady reflux rate and maintained a temperature of 92°–98° C in the water of the extractor thimble (according as the thimble was only partly or was completely filled). Temperatures were measured with a copper-constantan thermocouple placed beside the sample in the thimble. The siphon emptied every 5 min under the foregoing conditions.

The principal advantage of this form of the test lies in the reproducibility of the conditions. It is easily possible to support a relatively bulky specimen in the thimble so that its entire surface comes into contact with the hot water. Further, the material tested is not subjected to any abrasive action—as might be the case if it were placed directly in a flask of boiling water. Any abrasion of the sample would certainly give fictitiously high results as to material leached, with abraded particles exposing too much area.

Preliminary test of leaching apparatus. Since the dithizone colorimetric method for determining lead is very sensitive and accurate, the first leaches were made on crushed samples of lead glass. Crushed fragments of 30 per cent lead monoxide lead glass passing a 6-mesh screen and retained on a 30-mesh screen were used. Two weighed samples were taken by 'quartering', every care being taken to keep the particle-size distribution nearly the same in each. The extractions were done over successive 12-h periods with 400 ml. of water in the boiler. The distilled water showed the equivalent of 0·01 mg lead/l., and thus contributed only 1 per cent of the total lead found after a 12-h leach. A blank run, with no lead glass in the extractor, showed a concentration of only 0·02 mg lead/l. after a 5-day leaching period. Thus all blanks are quite negligible.

The rates dropped over the first two or three 12-h periods then reached nearly constant values for a total of seventeen leaching periods. Omitting the abnormally high initial period, we found average leach rates for the two samples of 0·50 ± 0·06 mg and 0·52 ± 0·04 mg lead/12 h/g glass.

Since the amount of lead removed was quite accurately a linear function of time, rather than linear with the square root of time, diffusion of lead to the surface of the glass was certainly not the limiting factor. In all probability the lead was released in proportion to the amount of glass actually decomposed by the hot water.

Similar experiments made with a cobalt glass, in which the ion was present in only very small quantities, gave similar results. A leach rate of about 1γ per day of cobalt was found.

Radioactive glazes. Mr. M. I. Goldman, of the Department of Civil and Sanitary Engineering of the Massachusetts Institute of Technology, supplied us with samples of a glass prepared with small added amounts of cæsium-137 tracer. They contained about 10 per cent alumina, 60 per cent silica, 10 per cent boric oxide and 20 per cent calcium oxide. The leaching period of thirty days was used, with 200 ml. of water in the boiler. After each leaching period the entire contents of the boiler was removed and the flask washed with nitric acid to remove any adsorbed material. Solution and washings were made up to a convenient volume and an aliquot taken for radioactive analysis. In all the experiments silica collected in the boiler as a tenacious encrustation of siliceous matter on the walls of the flasks. This was removed by rinsing with dilute hydrofluoric acid and added to the total sample.

The most consistent results were obtained with a small amount of cæsium salt added to the water in the boiler which probably prevented adsorptive losses.

A γ-count of the whole pellet was taken in the well of a scintillation crystal. Aliquots of the leachate were also analysed. The samples were followed for a period of six months.

If one assumes the pellet to be a sphere (it was actually more nearly hemispherical), we may calculate the equivalent depth to which the glaze was leached. The result of this estimate is:

$$\Delta r = \frac{r}{3}\frac{\Delta V}{V} = \frac{1}{3}r\frac{\text{counts in leachate}}{\text{total count of pellet}} = 0{\cdot}00005 \text{ mm per day}$$

in which r is calculated from the known area of the pellet. This result is very rough and is possibly optimistic by as much as a factor of five.

For accelerated tests it is evident that samples of large surface area will be required. In the equipment we were limited for mechanical reasons to particles at least sufficiently large to be retained on a 30-mesh screen. If it were desirable to test smaller particles the apparatus could be modified, but with smaller particles the uncertainty of exposure of the surface increases.

The release of activity is certainly proportional to the area of the exposed surface and consequently in comparisons between different materials a measure of the surface area will be required. For granular material of irregular shape this is a difficult problem. For non-porous fractured glasses between standard sieve sizes 6 and 30, a procedure based on the work of Gross and Zimmerley[2] is suggested as perhaps the best method of getting an estimate of surface area. The method depends on correlations between measured rates of dissolution of silica specimens of known areas with the results of sieve analyses. The procedure is to determine the sieve distribution in weight per cent of a 100-g sample in the 6–30 range. The approximate area can then be calculated directly from Table 1 for crushed silicas and glasses.

Table 1. COMPUTATION AREAS OF CRUSHED SILICEOUS MATERIALS

Mesh No.	Area (cm)^2 per g of material retained on this mesh size
7	55·6
8	59·6
10	63·8
12	69·4
14	76·1
16	86·4
18	95·3
20	103
25	112
30	127

The amount of radioactive isotope required in a test specimen varies greatly with the nature of the isotope and the type of measuring equipment available to the operator. For highly stable glazes it is essential to incorporate enough radioactive material so that meaningful leaching tests can be made in a reasonable length of time. This means that decisive experiments will often require a high-level laboratory and equipment for remote handling.

SOME BOILING AND TRIPLE POINTS BELOW 0° C

By D. R. LOVEJOY

Division of Applied Physics, National Research Council, Ottawa

As part of the temperature standardization programme of this laboratory we have built an apparatus for realizing the normal boiling point of oxygen, which is a primary fixed point on the International Practical Temperature Scale (IPTS), with a standard deviation accuracy of about 10^{-4} deg. C. In addition, the normal boiling or sublimation points and triple points of other, sufficiently pure, substances in the range 0° C to −196° C could be determined with comparable accuracy.

The apparatus is generally similar to that described by Stimson[1], and consists of a solid copper block, containing four thermometer wells and a cavity in which about 1,000–2,000 cm^3 (at N.T.P.) of the test gas is condensed. The block is contained in an evacuated housing which is surrounded by liquid nitrogen, or, where appropriate, dry ice and acetone. A radiation shield and two thermal guards on the thermometer wells help to maintain an isothermal environment, and for normal boiling or sublimation point determinations, the block temperature is maintained constant with an indicated precision of better than 10^{-4} deg. C, using a vapour pressure sensing servo loop described elsewhere by me[2]. The pressure transducer is backed by a reference pressure of one atmosphere (the normal or standard atmosphere = 1,013,250 dynes/cm^2), given by a precision manostat described by Berry[3]. Either stick type or capsule type platinum resistance thermometers could be used in the apparatus and details of calibration and measurement equipment used with the thermometers may be found in ref. 3.

Purest available materials were used. In the cases of oxygen, nitrogen, argon, krypton, xenon and carbon dioxide purities ranged from 99·99 to 99·999 per cent. The carbon monoxide available was of somewhat lower purity and this resulted in a lowered accuracy for its boiling point determination. Methane of about 99·99 per cent purity was prepared by Dr. J. H. Colwell, of the National Research Council Pure Chemistry Division, and it gave some evidence of forming a constant boiling mixture with about 100 p.p.m. nitrogen.

At the boiling points of the various substances, the vapour was removed from over the liquid in steps of about 100 cm^3, and any resulting changes in the boiling point (which could be detected to better than 10^{-4} deg. C) were observed. By this means the effect of residual impurities could be estimated in most cases to about 10^{-4} deg. C. Triple points were determined from the melting curve, by extrapolating the melting plateau back to the time of intersection with the linear warm-up curve. Triple points determined in this way were reproducible to a few $\times 10^{-4}$ deg. C.

Below 0° C the IPTS is defined by means of platinum resistance thermometers, using for interpolation the Callendar–Van Dusen equation:

$$R_t = R_0 \, [1 + At + Bt^2 + Ct^3(t - 100)]$$

R_t and R_0 are the resistances at temperature $t°$ C and at 0° C respectively, while the coefficients A, B and C are determined by calibrations at the steam, sulphur (or zinc) and oxygen points. It is required, as a rough control of the purity of the platinum, that the coefficient $\alpha (= A - 100B)$ must be greater than 0·003920.

It is likely that different thermometers satisfying the specifications of the IPTS would indicate slightly different temperatures in regions removed from the calibration points. Furthermore the IPTS does not extend below the oxygen point. In order that our measurements should not be limited in accuracy by these considerations we have defined a scale IPTS*, which is the IPTS as realized by a particular group of six thermometers of high purity ($\alpha >$ 0·003925), and is taken to extend by means of the Callendar–Van Dusen equation to temperatures below the oxygen point.

Below the oxygen point the thermometers were also calibrated in terms of the scale N.B.S. 1955, which is maintained by the U.S. National Bureau of Standards. This scale can be related to scales maintained at the Pennsylvania State University, at the National Physical Laboratory, Teddington, and at the Physical-Technical and Radio-Technical Measurements Institute, U.S.S.R., by means of data reported by Barber[4]. The scale N.B.S. 1955 is, at all temperatures, less by 0·010 deg K than the earlier provisional scale of Hoge and Brickwedde[5].

The difference between the scales IPTS* and N.B.S. 1955 is given for the range −183° C to −222° C in Table 1. Interpolation accuracy is better than 10^{-3} deg. C to −210° C reducing to about 5×10^{-3} deg. C near −222° C. Table 1 may be used with any platinum resistance thermometer, which has been calibrated on the IPTS, to extend its useful range to temperatures below the oxygen point. There is evidence that, for thermometers having $\alpha >$ 0·003924, Table 1 is accurate to within 2×10^{-4} deg. C down to about −200° C.

Table 1. DIFFERENCES BETWEEN TEMPERATURE SCALES IPTS* and N.B.S. 1955

IPTS*	IPTS*–N.B.S. 1955	IPTS*	IPTS*–N.B.S. 1955
−183° C	0 $\times 10^{-3}$ deg. C	−204° C	304 $\times 10^{-3}$ deg. C
−186	1·4	−206	390

† Primary fixed points on the IPTS. ‡ Fundamental defining point. § IPTS value of mercury triple point from Dengler (ref. 6).

In Table 2 the measured values of the fixed points are recorded on the scale IPTS* with bracketed values (where appropriate) on the scale N.B.S. 1955. In addition, the primary fixed points used to define the IPTS are listed and also a recent value of the mercury triple point, given by Dengler[6]. The mercury triple point (or the normal freezing point, which is $5 \cdot 2 \times 10^{-3}$ deg. C lower) has frequently been used as a calibration fixed point in this region.

In general, there have been rather few precision measurements of the foregoing boiling and triple points by other workers. The argon triple point has been determined by Michels, Wassenaar, Sluyters and De Graaff[7]. However, they used their own scale in which the coefficients in the Callendar–Van Dusen equation were determined from calibrations at the oxygen boiling point, mercury freezing point and carbon dioxide triple point, estimated thermodynamic values of the latter two points being used. It can be shown that the argon triple point value determined here agrees to within about 2×10^{-3} deg C of Michels's value when allowance is made for the difference between the two scales.

The argon triple point has been determined by Flubacher, Leadbetter and Morrison[8], and the krypton triple point by Beaumont, Chihara and Morrison[9]. In each case the quoted value is 6×10^{-3} deg. C higher than our value. However, it now appears (private communication) that there is a positive systematic error of between 5 and 7×10^{-3} deg. C in Morrison's measurements and the agreement can thus be considered to be quite good.

I thank Mr. N. J. Scardina for help with the experimental measurements, Mr. R. J. Berry for help in the use of the manostat, and Dr. H. Preston-Thomas for useful discussions.

TRANSFER OF ENERGY FROM BACTERIOCHLOROPHYLL TO A REACTION CENTRE DURING BACTERIAL PHOTOSYNTHESIS

By W. J. VREDENBERG and Dr. L. N. M. DUYSENS

Biophysical Laboratory, State University, Nieuwsteeg 18, Leyden

REVERSIBLE changes in absorption occur in purple bacteria when illuminated[1,2]. Part of these changes take place in the near-infra-red region, where the bulk, if not all, of the absorption is due to bacteriochlorophyll. In *Rhodospirillum rubrum* the absorption difference spectrum shows a decrease in absorption of about 2 per cent, with a maximum at about 880 mμ, and an increase around 795 mμ. Since bacteriochlorophyll has a major absorption maximum at 880 mμ and a minor one at 800 mμ, the changes in absorption were attributed to a small fraction of the bacteriochlorophyll[2], which we call *P* 890 or *P*. *P* 890 may be the photochemically active molecule, that is, the 'reaction centre'[1]. The light-induced reversible 'bleaching' at 880 mμ was more rapid and occurred at lower intensities of exciting light in the absence of hydrogen donors under oxidizing conditions[2]. A similar bleaching could be brought about in water extracts on addition of a mixture of potassium ferri- and ferro-cyanide with an oxidation-reduction potential of about 0·5 V (refs. 3 and 4). It has been suggested[2-4] that the light-induced absorption change around 880 mμ reflects the oxidative bleaching of *P* 890. The energy of light absorbed by the bacteriochlorophyll type *B* 890 may be transferred to *P* 890 (ref. 1), which becomes oxidized on receiving energy. Oxidized *P*, (P_{ox}), might oxidize in its turn the hydrogen donor, possibly by way of one or more cytochromes[2,5-8].

If the transfer from *B* 890 to *P* 890 occurs from the fluorescing excited state, the efficiency of the transfer to *P* is lowered on bleaching of *P*, and the fluorescence yield of *B* 890 will increase[1]. In this article it will be shown that the increase in fluorescence is correlated with the bleaching of *P*, and that this correlation can be explained quantitatively by the hypothesis of energy transfer already mentioned. It will also be shown that the bleaching occurs with high quantum efficiency.

Rhodospirillum rubrum, strain 1, was grown in a modified Hutner medium, similar to that used by Cohen-Bazire *et al.*[9]. In most of our experiments 3-day-old cultures were used. After centrifugation, the bacteria were resuspended in fresh medium or water, at a higher concentration than in the growth medium. The bacterial suspension was finally transferred to an absorption cuvette, at a thickness of 1 mm.

All measurements were carried out in a split-beam difference spectrophotometer[10]. Absorption was measured continuously by means of two modulated mutually compensating measuring beams. The intensity of these beams was so low as not to cause measurable changes in absorption. These changes were brought about by an unmodulated actinic monochromatic beam of 589 mμ, which did not cause a deflexion of the detecting apparatus, since this apparatus only responds to modulated light. For measurements of fluorescence the measuring beams were cut off, and the actinic beam modulated; thus the modulated actinic beam also functioned as exciting beam. Since the fluorescence yield changed slowly compared with the modulating time, which was 1/50 sec, the average intensity of the modulated beam was taken as the actinic intensity, which is given in 10^{-9} einstein cm^{-2} sec^{-1}.

Changes in absorption in the infra-red occurred at rather high intensities of actinic light, if the bacteria were suspended in growth medium[2]. We found that the kinetics of the changes on illumination depended on the length of the dark period and on the intensity of the preceding illumination. Figs. 1 and 2 show recordings of the light-induced spectral changes of absorption and fluorescence on illumination. The measurements of change in absorption and fluorescence, represented in each figure, were carried out shortly after each other at the same intensities and with the same light and dark periods. For bacteria suspended in malate, the fluorescence intensity at the beginning of the illumination is *f*. The fluorescence increases, starting from this initial level *f*. At least two phases can be distinguished in both absorption (*a*, *b*) and fluorescence (a_f, b_f); the absorption decreases *a* and *b* are correlated with fluorescence increases a_f and b_f. For bacteria washed and suspended in aerobic distilled water, the changes occur at much lower intensities of actinic light and at a higher initial rate than for bacteria in malate.

In Figs. 3 and 4 the steady-state absorption difference, light minus dark, and the steady-state level of fluorescence are plotted as a function of the actinic intensity, *I*. For bacteria suspended in growth medium (Fig. 3) the change

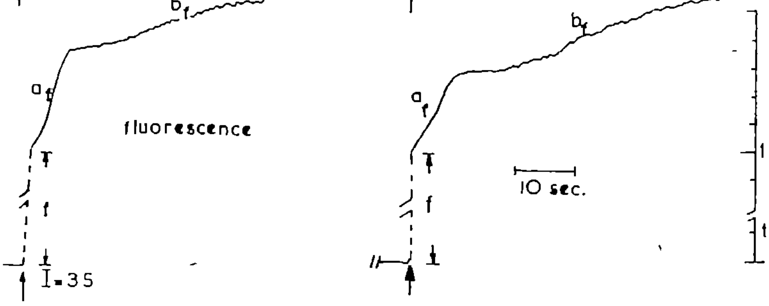

Fig. 1. *Rhodospirillum rubrum*, suspended in malate medium. The top tracings are time recordings of the light-induced absorption change at 880 mμ. The bottom tracings are recordings of the total fluorescence, occurring in the wave-length region above 850 mμ. The switching on and off of the actinic and the fluorescence exciting beams is indicated by upward and downward pointing arrows. The average intensity of these beams (*I*) was 3·5 × 10^{-9} einstein/cm^2 sec, the wave-length 590 mμ. The actinic and fluorescence exciting light was given after 10 sec dark time (left-hand tracing) and after 15 sec dark time (right-hand tracing) for both absorption change and fluorescence

in absorption starts at intensities above $I = 0{\cdot}5$. The increase in fluorescence yield (upwards curvature of fluorescence versus intensity curve) also starts above this intensity. In aerobic water both the decrease in absorption and the increase in fluorescence yield start below this intensity (Fig. 4). In Fig. 3, f is plotted as a function of I. Since f is proportional to I, the fluorescence yield at the start of the illumination is independent of the intensity. This means that under these conditions the change in fluorescence yield (and this is also true for the increase in absorption) is slow compared with the response of the apparatus. For bacteria in aerobic water the change in fluorescence yield is more rapid. The upward bending of the fluorescence-intensity curve starts below $I = 0{\cdot}2$, as we found by plotting a few points, measured at low intensity, on a ten times larger scale than that of Fig. 4. The slope of this intensity curve was estimated at $I = 0$ and is given in Fig. 4 by the dashed straight line. Similarly the absorption change at 880 mμ starts from $I = 0$.

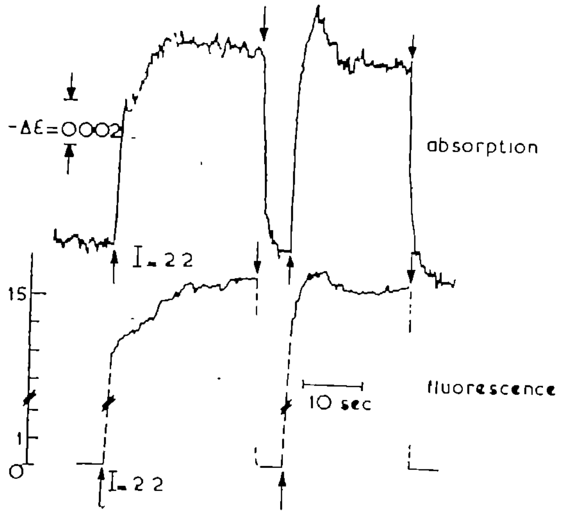

Fig. 2. *Rhodospirillum rubrum*, washed and suspended in distilled water. Time recordings of light-induced absorption change at 880 mμ and of total fluorescence. The first illumination, at the left-hand side of the figure, was given after about 5 min darkness, the second after 5 sec. The intensity of the light was $2{\cdot}2 \times 10^{-9}$ einstein/cm² sec

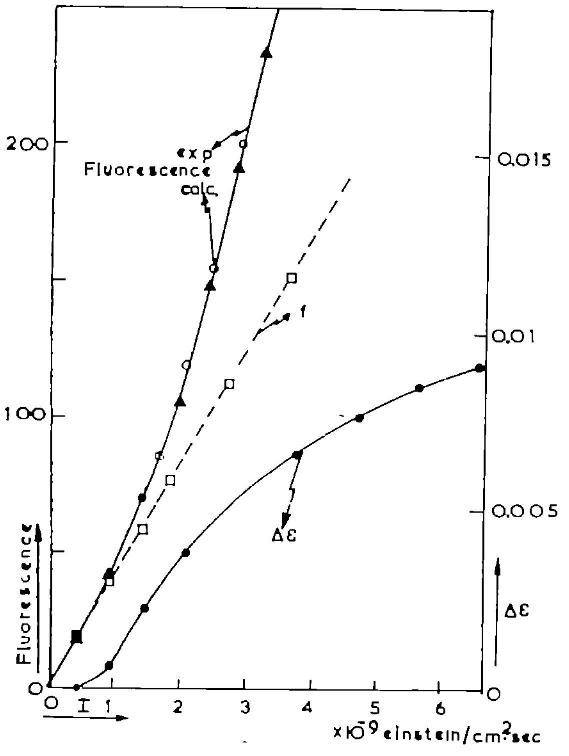

Fig. 3. *Rhodospirillum rubrum*, suspended in malate medium. The change in absorption at 880 mμ and the level of fluorescence in the steady-state are plotted as a function of the actinic intensity, I, of a wave-length of about 590 mμ. The initial fluorescence intensity f is also plotted as a function I. The calculated fluorescence intensities (see text) are indicated by open circles. The amount of fluorescence (left scale) is expressed in arbitrary units. The absorption difference (right scale) is given in optical density units

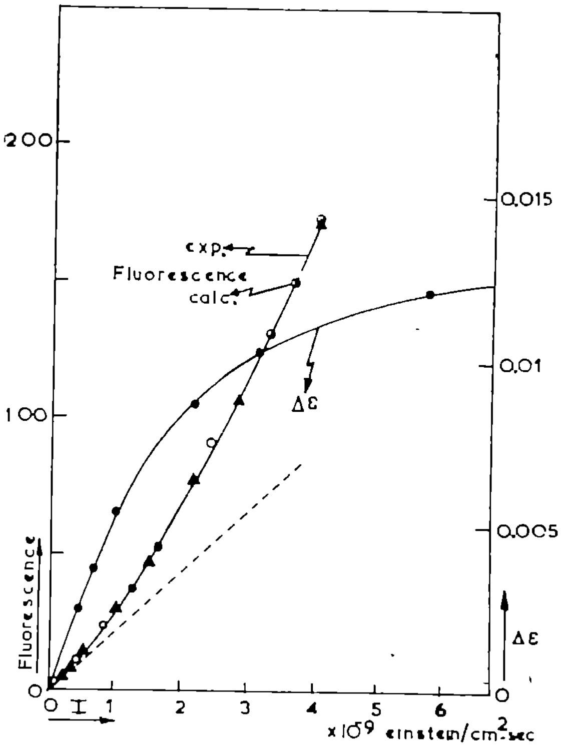

Fig. 4. *Rhodospirillum rubrum*, suspended in distilled water. The meaning of the symbols is the same as in Fig. 3. The slope of the fluorescence versus intensity curve at $I = 0$ is given by the dashed straight line

At – 170° C the changes in absorption at 880 and 795 mμ still occurred on illumination. The reactions were reversible: in the dark the original steady-state was again reached. For dried bacterial extracts this reversibility has been observed by Arnold and Clayton at 1° K (ref. 11).

We found that at – 170° C both the absorption spectrum and the absorption difference spectrum show a shift of the maximum at 880 mμ of about 20 mμ to longer wave-lengths. This shift provides an additional argument for the assumption that the change in absorption around 880 mμ is due to the bleaching of a pigment similar to B 890. It has been reported that in *Rhodospirillum rubrum* the fluorescence band of B 890, which has a maximum at 900 mμ, shifts about 20 mμ to longer wave-lengths on cooling to liquid nitrogen temperatures[12].

The quantum requirement for P 890 bleaching was measured for an aerobic aqueous bacterial suspension, to which in most experiments 10^{-3} M phenylmercury acetate was added in order to minimize the rate of P 890 restoration in the dark. The quantum requirement was calculated from the measured initial rate of the absorption change at 880 mμ, the intensity of the actinic light (590 mμ) and the absorbance of the suspension. It was assumed that the specific absorption coefficient of P was equal to that of bacteriochlorophyll at the infra-red maximum ($\epsilon = 9{\cdot}6 \times 10^{4}$ l. mol^{-1} cm^{-1} (ref. 13)), and that the absorption coefficient of P_{ox} was zero. The quantum requirements calculated from the initial rates measured at two intensities ($I = 0{\cdot}2$ and $0{\cdot}4$) for samples taken from the same culture were 3·3 and 3·1 (bacteria suspended in water to which phenylmercury acetate had been added), 3·1 and 3·6 (bacteria washed and suspended in water) and 3·2 and 3·2 (bacteria washed and suspended in water to which phenylmercury acetate had been added). These numbers are lower if the absorption coefficient of P_{ox} is not zero.

It seems that the observed correlation between increase in B 890 fluorescence and P 890 bleaching can be quantitatively described by the following hypothesis. Excitation energy is transferred from B 890 to P 890. On excitation of P 890 this component is bleached, which prevents further transfer of energy from excited B 890, causing an increase in the fluorescence of B 890; P 890 is assumed not to fluoresce at the wave-length of measurement. We postulate that the excited bacteriochlorophyll, $[B^*]$, looses its energy in 3 different ways: (1) fluorescence; (2) internal conversion; (3) transfer of energy to P 890. The change in B^* concentration, $d[B^*]/dt$ is then given by:

$$\frac{d[B^*]}{dt} = c_1 I - (k_1[B^*] + k_2[B^*] + k_3[B^*]\,[P]) \qquad (1)$$

where I is the intensity of exciting light and c_1 and the k's are rate constants for absorption, fluorescence, internal conversion and energy transfer; $[P]$ is the concentration of unbleached P 890. It is possible that other terms, containing variable parameters, should be added to the right side of equation (1). However, for the interpretation of the present experiments, the terms given appear to be sufficient. During quasi steady-state, that is if $[B^*]$ does not change appreciably in 10^{-8} sec ($k_1 \approx 10^{+8}$), $d[B^*]/dt$ is small compared with the other terms and we may put $d[B^*]/dt = 0$. This condition certainly is fulfilled at the relatively low intensities used. Solving for I we obtain:

$$I = (k + k'_3\,[P])\,[B^*] \qquad (2)$$

where $k = (k_1 + k_2)/c_1$ and $k'_3 = k_3/c_1$.

The intensity of fluorescence is given by:

$$I_{fl} = k_1[B^*] \qquad (3)$$

The fluorescence yield is:

$$\varphi_f = \frac{I_{fl}}{I} = \frac{k_1}{k + k'_3[P]} \qquad (4)$$

At zero intensity, all P 890 is in the non-bleached form: $[P] = P_0$. At high intensities, at which all P 890 is bleached: $[P] = 0$. The change in absorption is equal to:

$$\Delta\epsilon = c_2(P_0 - [P]) \qquad (5)$$

in which c_2 is a constant, equal to the difference in absorption coefficient of the unbleached and bleached forms of P 890. Eliminating P from equations (4) and (5) we get:

$$\frac{1}{\varphi_f} = \frac{k + k_3P_0}{k_1} - \frac{k'_3}{k_1c_2}\,\Delta\epsilon \qquad (6)$$

According to equation (6) $1/\varphi_f$ and $\Delta\epsilon$ are linearly related. We tested this by plotting $1/\varphi_f$ as function of $\Delta\epsilon$ in Fig. 5. Fig. 5 shows that $1/\varphi_f$ is in first approximation linearly dependent on $\Delta\epsilon$, which supports our hypothesis. The values $1/\varphi_f$ and $\Delta\epsilon$ for the same intensities were obtained from the experimental curves given in Fig. 3 and 4. The values of $1/\varphi_f$ at $\Delta\epsilon = 0$ is found by taking the slope of the fluorescence-versus-intensity curve at $I = 0$. In Figs. 3 and 4 calculated intensities of fluorescence are also given. These were calculated from the $\Delta\epsilon$ curves by substituting the experimental value of $\Delta\epsilon$ in equation (6). The two constants k'_3/k_1c_2 and $(k + k_3P_0)/k_1$ in the right side of equation (6) were obtained from each of the lines of Fig. 5. The first constant is equal to the slope of a line, the second is equal to $1/\varphi_f$ at $\Delta\epsilon = 0$. The experimental and calculated curves of fluorescence appear to be similar.

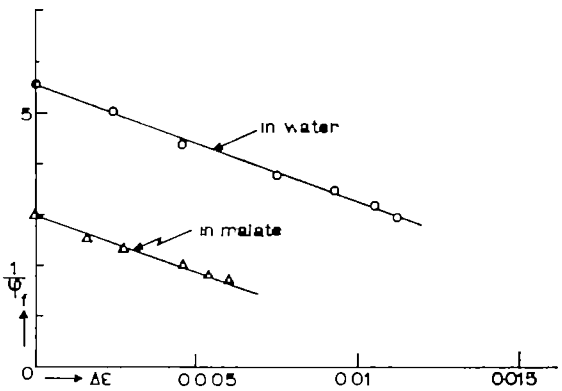

Fig. 5. The inverse of the fluorescence yield, $1/\varphi_f$, plotted as a function of the absorption change, $\Delta\epsilon$, for bacteria, suspended in growth medium (open triangles), and in water (open circles). The two curves are not comparable, since the fluorescence intensities were not measured absolutely

The quantitative correlation between fluorescence increase and P 890 bleaching, the low quantum requirement for this bleaching, and the fact that the bleaching occurs at very low temperature, strongly argue in favour of our hypothesis that the energy transfer from bacteriochlorophyll to P 890 occurs through inductive resonance.

The high efficiency for bleaching of P 890 indicates that P 890 may be an intermediate in bacterial photosynthesis. P 890 is suggested to be a pigment similar to B 890; it is, however, non- or weakly fluorescent and photochemically active; it may act as the photosynthetic reaction centre. It has been shown[1] that the transfer of energy with good efficiency to such a reaction centre is theoretically possible taking into account the concentrations and the fluorescence yield of bacteriochlorophyll *in vivo*.

Summarizing, we may say that the light-induced decrease in absorption at 880 mμ in the photosynthetic bacterium *Rhodospirillum rubrum* is quantitatively correlated with an increase in fluorescence yield of the bacteriochlorophyll type B 890. This correlation can be quantitatively explained by energy transfer from bacteriochlorophyll to a pigment P 890, present in a small amount, which pigment is bleached on excitation. The quantum requirement for P 890 bleaching was found to be about 3·2 or lower. The results indicate that the bleaching of P 890 is a primary photochemical process, and that P 890 acts as a reaction centre in bacterial photosynthesis.

After this manuscript was completed, Dr. R. K. Clayton kindly send us preprints of papers submitted for publication (*J. Photochem. Photobiol.*), giving evidence and conclusions in agreement with this and earlier papers from our laboratory. The main new evidence was that in an aqueous extract of an aged culture of a green mutant of the purple bacterium *Rhodopseudomonas spheroides* the optical density at the long wave-length maximum was reduced to about one-half on illumination; the difference spectrum was essentially similar to that of 'normal' purple bacteria[8]. This indicates that the specific absorption of these special bacteriochlorophyll molecules is reduced to one-half or less, and that thus in normal bacteria probably an appreciable change in absorption occurs in the few P 890 molecules, instead of a small change in all B 890 molecules.

DOES THE NEURONE SOMA ACTUALLY GENERATE ACTION POTENTIALS?

By YUTAKA OOMURA and TAKASHI MAÉNO

Department of Physiology, Kagoshima University, Japan

IT has been shown by Oomura *et al.*[1] that the neurone of a marine pulmonate mollusc, ***Onchidium verruculatum***, could generate the action potential in various sodium-free sea-waters, and that not sodium but calcium ions played an important part in the electrical activities. They also reported that the excitability in the soma was relatively low compared with that in the axon or axon–soma junction. With direct stimulation of the soma, it was assumed that the spike potential was initially generated in a remote triggering region, say, the axon or axon hillock, and electrotonically spread to the soma, then the action potential was generated in the soma membrane. It was still not certain, however, whether the electrical activity recorded in the soma was only a reflexion of the spike potential in a remote active region, and the soma membrane remained unexcited[2]. This uncertainty was tested as follows. (1) The excitability of the soma membrane was directly demonstrated in neurones which were ligated at the axon–soma junctional region; (2) indirectly evidenced by the transmembrane impedance measurements. The impedance measurements by means of the intracellular microelectrodes were first made on the neurones. With these techniques, we were able to demonstrate that the soma membrane was really excitable during activity.

Materials used were dissected œsophageal ganglion cells of a marine pulmonate mollusc, ***Onchidium verruculatum***. In the ligature experiments the neurones were tied with single silk filaments at the axon–soma junctional region. For the impedance measurements three microelectrodes were inserted into a single neurone. The first microelectrode (*Rr*) was for recording transmembrane potential, the second one (*Rc*) served as an arm in an a.c. impedance bridge, and the third one was for polarizing the membrane and connected to an electronic stimulator through a high resistor (Fig. 1). The resistances of the microelectrodes utilized in the impedance experiments ranged from 10 to 20 MΩ. For the voltage clamp experiments a feedback amplifier was inserted between the first and the third electrodes[3].

Ligature experiments. Ligated soma showed some signs of injury. The resting potentials of about 40 mV were obtained which were somewhat smaller than those of unligated neurones. Spontaneous firings, observed frequently on penetration of the electrodes in the latter, were usually absent in the former. The ligated neurones never responded synaptically or antidromically. This indicates that the nervous function in the region of the axon hillock was satisfactorily blocked by the ligature. By direct transmembrane stimulations the action potentials could be generated in the soma, although their thresholds were higher than those of unligated ones. Shapes of the action potentials were quite indistinguishable from those in the unligated neurones, especially when the threshold of the latter was slightly increased by an application of a hyperpolarization (Fig. 2*A* and *C*).

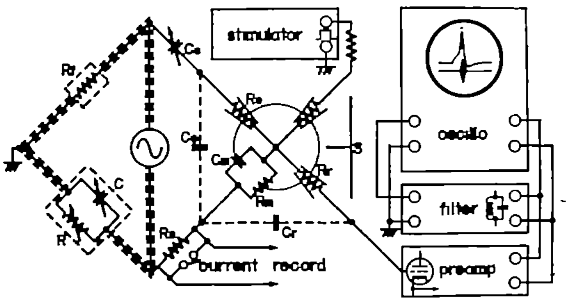

Fig. 1. Schematic presentation of the impedance circuit. *R* and *C*, variable resistor and capacity; *Rc* and *Cc*, resistance and capacity of the microelectrode in the bridge arm; *Rm* and *Cm*, membrane resistance and capacity; *Rr* and *Cr*, resistance and capacity of the recording microelectrode, respectively. *Cc*, variable air condenser (max. cap. 50 pF); *Rf*, fixed resistor (100 kΩ); *Rs*, current monitoring resistor, shunted in impedance measurements; *S*, shielding plate

Despite the similarity of the action potentials between two preparations, a marked difference was clearly demonstrated in the voltage clamp experiments as shown in Fig. 2*B* and *D*. In the unligated neurones under the voltage clamp condition, the inward membrane current appeared in the all or none manner. Moreover, the time course of the current showed close resemblances with that of the action potential. In the ligated neurones, on the other hand, the time course of the membrane current was much different. Similar to the results obtained by Hagiwara and Saito[4], the inward current was followed by a slowly developing outward current. Low intensity of the inward current and slow time course of the outward current might be attributable to an injury in the membrane. These results will be discussed elsewhere.

Impedance experiments. Frequencies of alternating currents applied to the bridge were 0·2–2 kc/s (adequate frequencies 0·5–1·2 kc/s). Impedance changes during

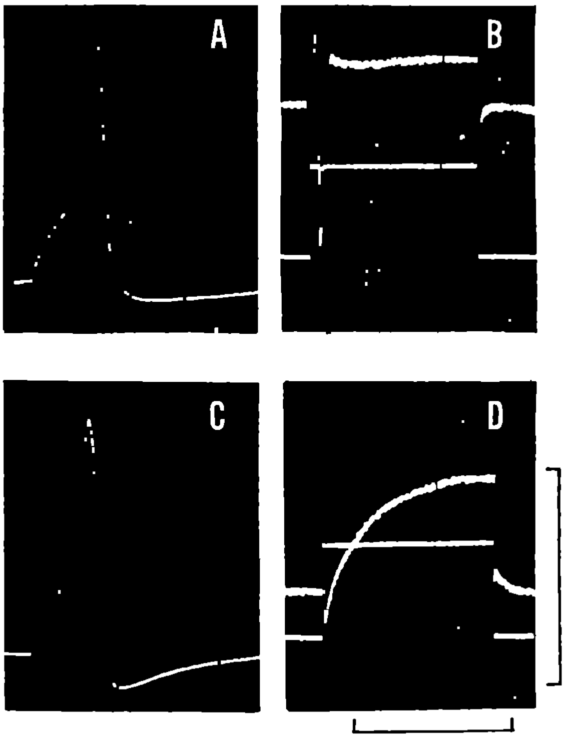

Fig. 2. Intracellular recordings from unligated (*A* and *B*) and ligated soma (*C* and *D*). *A* and *C*, action potentials initiated by short current pulses; *B* and *D*, relationships between the membrane currents (upper beams) and potential (lower beams) under voltage clamp condition. The resting potential of the unligated neurone was artificially increased. Note the difference in time courses of the membrane currents when the membrane was depolarized. Current gains are not identical. Upward and downward deflexions represent outward and inward currents, respectively. Resting potential, 40 mV; voltage scale, 100 mV; time scale, 100 msec for *A* and *C*, 400 msec for *B* and *D*

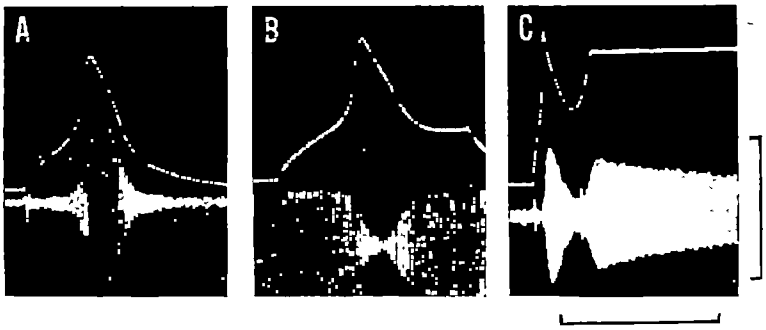

Fig. 3. Impedance changes during the action potentials. *A* and *B*, the bridge is balanced at the resting state and near the peak of the action potential, respectively; *C*, markedly prolonged action potential. Voltage scale, 100 mV, time scale, 100 msec for *A* and *B*, 400 msec for *C*

neuronal activities could not be detected by frequencies higher than 2 kc/s. Relatively large value of the membrane time constant (Cm 0·02 μF × Rm 5 MΩ) and presence of stray capacities (Co and Cr) decreased the accuracy of the measurements by the a.c. bridge in higher frequencies. After the bridge had been exactly balanced for the membrane impedance at the resting state, a suprathreshold outward current pulse was passed through the membrane. Considerable lack of balance of the bridge was recorded simultaneously with the action potential (Fig. 3*A*). Precise balancing of the bridge during the activity was also obtained at various stages of the action potential adjusting appropriate values of C and R (Fig. 3*B*). Time course of the impedance changes were more clearly demonstrated when the action potentials were prolonged by an administration of barium ions into the sea-water[1] (Fig. 3*C*).

These results suggested that the membrane impedance diminished considerably during the action potential. Although a quantitative analysis of the data was complicated by the presence of stray capacities of the electrodes, calculations indicated that the membrane resistance was reduced to about 100 kΩ and the capacity remained nearly unchanged. Now let us assume as follows: (1) the ratio of the area of the soma to that of the axon hillock is 20; (2) at the peak of the activity the membrane resistance might decrease to 1/100 of the initial value. If the active area is restricted within the axon hillock, the total resistance during activity might fall to about 1/5 of its resting value (about 1 MΩ). However, more marked reduction in the membrane resistance was obtained. It appears, therefore, unlikely that the membrane of the soma remains inexcitable and that the action potential recorded in the soma is the potential spread electrotonically from the axon or the axon hillock. We conclude that the soma of the giant neurones of *Onchidium* is excitable and generates the action potential.

This investigation was supported by a grant from the Ministry of Education and from the Muscular Dystrophy Associations of America, Inc.

UREASE AND CITRASE OF PATHOGENIC AND SAPROPHYTIC FUNGI

By Dr. H. SENECA, P. PEER and R. NALLY

Department of Urology, Columbia University College of Physicians and Surgeons, Presbyterian Hospital, New York, 32

FUNGI, like bacteria, are very ubiquitous in their distribution throughout the world. Many saprophytic types play very essential parts in the biological cycles involving organic matter such as the decomposition of hemicellulose, lignins, etc., but are also involved in the synthesis of complex organic compounds. Their most important function is the breaking down of complex molecules and the synthesis of useful ones, both for the animal and plant kingdoms. There are numerous species of fungi in Nature, mostly saprophytic in their biological behaviour, and only about 50 species are capable of causing diseases in man and animals, some producing fatal infections such as *Coccidioides immitis*, *Histoplasma capsulatum*, *Cryptococcus neoformans*, *Candida albicans*, etc., while the vast majority give rise to chronic systemic or skin diseases. Fungus infections are very serious among birds and insects.

The outlook of systemic mycotic infections was very gloomy in the past, but with the introduction of the sulphonamides, tetracycline and penicillin in actinomycosis, nystatin in candidiasis[1], 'Amphotericin *B*' (ref. 2) in serious systemic mycoses and griseofulvin in dermatophytoses and deep mycoses[3,4], the overall prognosis is at present very favourable.

Moulds, yeasts and fungi are extensively used in fermentation in industry, in the dairy industry, the manufacture of citric acid, ascorbic acid, antibiotics and even steroids. They also produce ammonia from urea. Somehow, the enzymatic activities of pathogenic fungi have been utilized to a very limited extent in their biochemical studies. Lactic acid, ethanol, acetic acid and formic acid are formed from glucose by *Actinomyces bovis*[5] and acid phosphatase is produced from some strains[6]. *Cryptococcus neoformans* does not ferment sugars, assimilate potassium nitrate nor reduce nitrates into nitrites. The carbon of glucose, maltose, sucrose and galactose is utilized but not that of lactose, and urea may be split[7]. *Nocardia asteroides* did not liquefy gelatin nor coagulate milk, but nine out of eighteen strains of *Nocardia brasiliensis* coagulated milk, nine liquefied gelatin and three reduced nitrates to nitrites[8]. *Streptomyces* and *Nocardia* produced penicillinase[9]. On the basis of the fermentation of glucose, maltose, sucrose and lactose, *Candida* is classified into seven species. *C. albicans* produces acid and gas in glucose and maltose, acid in sucrose and has no effect on lactose. *C. tropicalis* produces acid and gas in all, but fails to ferment lactose. *C. pseudotropicalis* produces acid and gas in all except maltose. *C. krusei* and *C. parakrusei* produce acid and gas only in glucose. *C. stellatoidea* produces acid and gas only in glucose and maltose and *C. guilliermondi* causes no change in sugars[10]. *C. immitis* liquefies gelatin, coagulates milk, utilizes carbon from sugars, alcohols, amino-acids, organic acids, and amides; and nitrogen from peptone, amides, amino-acids, nitrate ions and ammonia ions, but these biochemical reactions do not help in its identification[11]. In *Sporotrichum schenkii* the sugar reactions are of no value. Nitrogen of amino-acids, urea and ammonium nitrate were utilized, and no amino-acid was an essential growth factor[12–14]. Nothing is known about the fermentative propensities of *Hormodendrum compactum*, but *Phialophora verrucosa* produces acid in dextrose and dextrin, but has no effect on milk and does not produce indol[15].

The aforementioned references indicated that very little work has been done concerning the enzymatic activities of pathogenic fungi, and that very little use of this enzymatic activity has been applied towards the identification of fungi. Since enzymatic studies have been very fruitful in the identification of pathogenic bacteria and there is the possibility of using the enzyme profiles of bacteria in the chemotherapy of infections, a proper analysis of the enzyme profiles of fungi may be promising.

On the basis of the urease and citrase profile of pathogenic bacteria, they have been classified into seven profiles. Profile 1 produces urease and citrase and includes *Proteus vulgaris*, *P. rettgeri*, *P. mirabilis* and *P.* OX_2. Profile 2 produces only urease and includes *P. morganii* and 69 per cent of *Staphylococcus*. Profile 3 produces urease aerobically and also citrase and includes the *Klebsiella aerobacter* group and 77 per cent of *P. aeruginosa*. Profile 4 may or may not produce urease and/or citrase and includes *P. OX K* and *P. OX* 19. Profile 5 may or may not produce citrase, and has *P. inconstans*. Profile 6 produces only citrase and has *Pseudomonas* (26 per cent), *Alcaligenes fecalis*, *Salmonella*, *Vibrio cholerae*, and *Escherichia intermedia*. Profile 7 fails to produce urease and citrase and has *Escherichia coli*, *Salmonella paratyphi*, *S. gallinarum*, *S. pullorum*, V. el Tor, *Staphylococcus* (31 per cent), *Enterococcus*, *Streptococcus pyogenes* (Lancefield *A*), *Shigella*, *Pneumococcus*, *S. viridans*, *Neisseria*, *Brucella*, *Pasteurella*, *Lactobacillus*, and *M. tuberculosis*[16].

The protozoa have no urease: *Trypanosoma cruzi*, *Leishmania donovani*, *L. tropica*, *L. brasiliensis*, *Trichomonas vaginalis* and *T. foetus*[17]. On the basis of Krebs's cycle substrates, pathogenic bacteria are grouped into eleven profiles. Profile 1 has no effect on these substrates and includes *Streptococcus pyogenes* (Lancefield *A*) *Pneumococcus* and *Enterococcus*. Profile 2 utilizes only the carbon of oxaloacetic acid and includes *Staphylococcus*. Profile 3 is *Shigella*, utilizing the carbon of acetate, and malate. Profile 5 is *Escherichia*, utilizing the carbon of acetate, *cis*-aconitate, oxalosuccinate, fumarate and malate. Profile 6 is *Alcaligenes*, which utilizes the carbon of acetate, citrate, ketoglutarate, fumarate and malate. Profile 7 is *Salmonella*, which utilizes the carbon of acetate, lactate, citrate, *cis*-aconitate, ketoglutarate, fumarate and malate. Profile 8 is *Pseudomonas*, which utilizes the carbon of lactate, acetate, citrate, oxalosuccinate, fumarate, malate and oxaloacetate. Profile 9 is *P. morganii*, which utilizes the carbon of all except citrate, succinate, oxaloacetate and pyruvate. Profile 10 is *Klebsiella aerobacter*, which utilizes the carbon of all substrates except isocitrate, succinate and pyruvate. Profile 11 is *P. vulgaris*, *P. rettgeri* and *P. mirabilis*, which fail to utilize the carbon of succinate and pyruvate[18].

Pathogenic bacteria which are active urease and citrase producers are either drug-resistant or they mutate to become drug-resistant when exposed to these therapeutic agents[19]. It was this interest concerning the urease and citrase propensities of pathogenic fungi which motivated these investigations.

Urease is a macroglobulin with a molecular weight of 473,000, has 37 sulphydryl groups, with an optimum *p*H of 7·2–7·5, is dialysable, adsorbed on the Seitz filter, but filterable through the 'Millipore *HA*', does not permeate through the bacterial cell wall, and catalyses the hydrolysis of urea into ammonia and carbon dioxide through the mechanisms of sulphydryl groups. It is inactivated by silver, mercury, copper, cadmium, lead, fluorides, halogens, borates, quinones, formaldehyde and hydrogen peroxide, is rapidly digested and inactivated by pepsin and papain hydrogen sulphide at *p*H 4·3. Jackbean contains 16 times more urease than soybean. Inactivation by mercury can be reversed by cysteine. Urease activity is expressed as the amount of urease which will form 1 mg of ammonia nitrogen from ureaphosphate at *p*H 7 at 20° C in 5 min. Crystalline urease has about 133,000 U/g. Pasteur observed urease activity in *Torula ureae*.

Thunberg in 1910 [20,21], observed an enzyme which oxidized citric acid. It occurred in animal tissues, moulds, cucumber seeds, bacteria, etc. Recent investigations indicate that such an enzyme did not exist. Citric acid is first converted into *cis*-aconitic acid by aconitase and then changed into isocitric acid, then dehydrogenation occurs and the enzyme is isocitric dehydrogenase. This enzyme is found in heart muscle, muscle, liver, kidney, adrenals and other animal tissues and plant tissues[22,23]. There may be two isocitric dehydrogenases in yeasts, one requiring DPN and the other TPN as coenzymes: isocitric dehydrogenase requires manganous or magnesium ions. Pyrophosphate inhibits the enzyme because these ions are removed. Iodoacetic acid also inactivates by reacting with apodehydrogenase[24,25]. The enzyme can be extracted with water and is concentrated by fractionation with ammonium sulphate and ethanol at low temperatures[26].

Most of the pathogenic and saprophytic fungi were given to us by Dr. M. Silva, mycologist in the Department of Dermatology at the Medical School, Columbia University. Our stock cultures were also included in this investigation. A total of 190 cultures constituting 46 genera of pathogenic and saprophytic fungi are reported in this work.

Culture media	Mycological urea	
	Mycological agar (Difco)	35 g
	Distilled water	900 ml.
	Boil to melt and sterilize in the autoclave.	
	Urea c.p. Merck	20
	Phenol red	0·012 g
	Distilled water	100·00 ml.
	Stir to dissolve urea, and sterilize by filtering through the Seitz filter	

After cooling the mycological agar to 45° C, the sterile urea solution was added to the medium with constant stirring. If the temperature of the agar is high urea will be broken down and the medium cannot be used. Mycological agar urea is then tubed and solidified in a slanting position. The *p*H is 7 and the colour of the medium is straw or pale orange. The tubes are then ready for inoculation.

Simmon's citrate (Difco) is prepared by boiling 24·2 g of the medium in 1,000 ml. of distilled water. It is then tubed, sterilized by autoclaving, and slanted to solidify. The colour of the medium is green. If the carbon of citrate is utilized, growth is due to the presence of the enzyme, and the colour of the medium becomes blue. One pellet of Herbox Bouillon (obtained from the Pure Food Co., Inc., Mamaroneck, New York) cubes is added to 250 ml. of distilled water. It is then heated to dissolve the cube. 5 g of Nobel agar are added and the mixture boiled to dissolve. The *p*H is about 4, but it is adjusted to *p*H 7 by adding 10 per cent sodium hydroxide. It is then tubed, autoclaved and slanted to solidify.

190 cultures, comprising 46 genera, split urea. They were active urease producers in live cultures, when incubated at room temperature for 10–15 days. The following cultures failed to show urease activity in 48-h growth: two of seven *Beauveria*, one of three *Oospora*, three of thirty-nine *Candida*, one of four *Trichosporon*, two of four *Monosporium*, one of two *Neurospora* and one each of *Dipodascus*, *Emmonsia* and *Sclerotium*.

The utilization of citrate apparently indicates the presence of an enzyme which is probably citrase or isocitric dehydrogenase. The following genera failed to utilize the carbon of citrate or lack the enzyme: *Microsporon*, *Coccidioides*, *Oidium*, *Saccharomyces*, *Eremascus*, *Dipodascus*, *Hormiscium*, *Hansenula*, *Thamnidium*, *Emmonsia*, *Rhizopus*, *Sclerotium*, *Sporoblastomyces*, *Neurospora* and *Schizosaccharomyces*.

The following genera actively utilize the carbon of citrate and apparently have the enzyme which promotes growth: *Streptomyces*, *Paracoccidioides*, *Blastomyces*, *Beauveria*, *Pityrosporium*, *Aspergillus*, *Syncephalastrum*, *Mucor*, *Penicillium*, *Coniophora*, *Trichosporon*, *Phoma*, *Gymnoascus*, *Cephalosporium*, *Verticillium*, *Fusarium*, *Isaria*, *Choenophora* and *Pythium*.

The intermediate group constitutes those genera which may or may not utilize carbon in citrate, that is, three of eight *Nocardia* failed to utilize carbon in citrate, fourteen of fifteen *Cryptococcus*, four of ten *Trichophyton*, nine of thirty-nine *Candida*, nine of eleven *Geotrichum*, one of five *Phialophora*, one of three *Fonsecaea*, one of three *Sporotrichum*, two of three *Histoplasma*, one of three *Oospora*, one of two *Cunninghamella* and one of four *Monosporium*.

190 fungi were cultured on 'Herbox' agar medium of pH 7·00. The growth on this medium was compared with that of mycological agar (Difco). The following genera of fungi grow just as well on this medium as on mycological agar, in other words, the growth is very abundant or luxurious: *Trichophyton, Candida, Microsporon, Phialophora, Fonsecaea, Sporotrichum, Paracoccidioides, Blastomyces, Coccidioides, Beauveria, Cryptococcus, Saccharomyces, Pityrosporium, Thamnidium, Aspergillus, Cunninghamella, Mucor, Coniophora, Phoma, Cephalosporium, Gymnoascus, Verticillium, Fusarium, Neurospora, Isacria, Pythium* and *Choenophora*. 27 of 46 genera studied grew very abundantly on Herbox agar medium.

'Herbox Bouillon' cubes are ready made and are inexpensive. If this medium proves to be an adequate medium for the growth of fungi, it will save time and be very economical.

URICOLYTIC ENZYMES IN SOIL

By MARGARET MARTIN-SMITH

Soil Bureau, Department of Scientific and Industrial Research, Wellington, New Zealand

ALTHOUGH much work has been done on enzymes in soil, I have been unable to trace any report of the occurrence of uricolytic enzymes. The work reported here has been carried out in an attempt to ascertain whether detectable quantities of uricolytic enzymes are present in soil. News of Durand's[3] paper reached me only when this work had been finished.

Samples of garden soil (Waikanae silt loam) were taken at a depth of 0·5–3 in. immediately adjacent to a fowl run, which, with uric acid so readily available, could reasonably be expected to have correspondingly high uricolytic activity. The fresh soil was sieved through a 2-mm sieve, and stored at – 15° C. The pH of all samples of this soil was 6·6, and the moisture content varied from 17 to 19 per cent. Unless otherwise stated, soil extracts were prepared in the following manner.

Ten-g portions of soil were placed in 250-ml. stoppered conical flasks, and 15 ml. of buffer solution and 10 drops of toluene were added. The flasks were left without shaking for about 16 h at 24° C, and then filtered through a Whatman No. 32 paper. Both increase in temperature and in duration of extraction were found to increase the yield of enzymatic activity extracted from the soil, but for the purposes of this work the procedure already outlined was found suitable.

Two-ml. aliquots of the clear soil filtrate were incubated in 250-ml. conical flasks without shaking for approximately 24–48 h with sodium urate solution (~ 1 mg uric acid/ml.) and toluene. Control systems containing boiled soil extract, urate and toluene were incubated at the same time. Figures in Tables 1 and 2 show the difference between the amount of uric acid remaining in the control and that remaining after incubation with the soil extract which had now been boiled. Figures in Table 3 were calculated from results so obtained. Plating of the extracts on nutrient agar and microscopic examination showed that 0·5 ml. of toluene in the incubated systems suppressed bacterial growth. The uric acid concentrations were estimated according to Brown[1].

During initial experiments, it was found there was a very appreciable non-enzymatic breakdown of uric acid. Cupric copper has been shown to catalyse the auto-oxidation of uric acid in phosphate buffer, other bivalent metals being ineffective[2,3], and care was taken afterwards to exclude extraneous copper by using acid-washed glassware and glass-bidistilled water. Reasonably reproducible results could thus be obtained. Copper extracted from the soil could, however, have influenced results if boiling of the soil extract had changed its activity.

Preliminary experiments using 0·1 M buffers of pH 7·2 showed that efficiency of extraction varied in the ascending order: borate < *tris* < carbonate < phosphate. Accordingly, samples of soil were extracted at 37° C with 0·1 M phosphate buffers over the pH range 6–8·4 for 16 h, and with 0·1 M *tris*-acetate buffers over the pH range 7·5–9·5 for 64 h. A typical set of results appears in Table 1.

Table 1. EFFECT OF 0·1 M *tris* AND PHOSPHATE BUFFERS ON EXTRACTION OF URICOLYTIC ACTIVITY IN SOIL

Buffer used in extraction	pH	Fall in uric acid content (mg)
0·1 M phosphate	6·0	0·09
	6·6	0·65
	6·8	0·80
	7·0	1·25
	7·2	0·20
	7·6	0·15
	8·0	0·32
	8·4	0·88
0·1 M *tris*	7·5	0·19
	8·0	0·13
	8·5	0·33
	9·0	0·09
	9·5	0·05

2 ml. of soil filtrate, 2 ml. sodium urate solution, 2 ml. 0·5 M phosphate buffer of pH 7·0, and 0·5 ml. toluene were incubated without shaking for 48 h at 30° C.

Two pH optima for extraction were obtained at about pH 7·0 and 8·5, suggesting the possibility of the presence of two uricolytic systems.

Soil was extracted with phosphate buffers of pH 6·8 and molarities 2, 1, 0·5, 0·1, 0·05 and 0·01 M for 16 h at 37° C, and 2-ml. aliquots of each filtrate incubated with 2 ml. of urate solution and 0·5 ml. of toluene for 50 h at 30° C. There was little difference in the efficiency of extraction of uricolytic activity with buffers of concentrations between 2 M and 0·1 M, but at still lower molarities the amount of activity extracted fell markedly. This may, however, have been also a direct influence of salt concentration on the enzymatic reaction, not only a difference in extraction efficiency.

Two-ml. aliquots of soil extracts obtained in 0·1 M phosphate buffers of *p*H 7·0 and 8·4 were incubated with urate solution, toluene, and 2-ml. aliquots of 0·5 M phosphate buffers of different *p*H. The *p*H optima of both enzymes appeared to lie about *p*H 7·0. The temperature optima of the enzymes extracted in phosphate buffers of *p*H 7·0 and 8·4 appeared to lie at 30° C.

An examination of the thermal stability of the enzyme extracts was made by preheating the extracts for 15 min at each temperature (Table 2).

Table 2. EFFECT OF HEAT PRETREATMENT ON THE ACTIVITY OF ENZYMES EXTRACTED IN PHOSPHATE BUFFER OF *p*H 7·0 AND 8·4

Temperature of preheating (°C)	Fall in uric acid content (mg) Enzyme extracted at *p*H 7·0	Enzyme extracted at *p*H 8·4
20	0·487	0·345
30	0·553	0·497
37	0·751	0·894
40	0·894	0·959
45	1·530	1·300
50	0·748	0·748
60	0·163	0·244
70	0·00	0·00

Experimental details as for Table 1.

The activity of both the enzymes extracted at *p*H 7·0 and 8·4 rose to a maximum when they had been preheated at 45° C, and fell thereafter. This effect may be a result of activation of the enzymes, or of inactivation of some inhibitor.

A study of the stability of the enzymes extractable with phosphate buffer at *p*H 7·0 and 8·4 showed that when the soil was stored at − 15° C the amount of activity remained reasonably stable over the period of one month; extracts in 0·1 M phosphate buffer stored under the same conditions, however, lost some 50 per cent of their activity.

The effects of some metal chelators, sulphydryl compounds and sulphydryl reagents on the enzymes extracted with phosphate buffers of *p*H 7·0 and 8·4 were investigated (Table 3).

Table 3. EFFECT OF SOME INHIBITORS ON THE ENZYMES EXTRACTED IN PHOSPHATE BUFFER AT *p*H 7·0 AND 8·4

Inhibitor	Concentration in system (M)	Per cent inhibition Enzyme extracted at *p*H 7·0	Enzyme extracted at *p*H 8·4
Sodium cyanide	$2 \cdot 1 \times 10^{-3}$	100	14
Sodium azide	$3 \cdot 4 \times 10^{-4}$	100	86
Sodium diethyldithiocarbamate	$1 \cdot 3 \times 10^{-4}$	98	15
Sodium ethylenediamine tetraacetate	$7 \cdot 6 \times 10^{-4}$	52	20
Cysteine	$1 \cdot 8 \times 10^{-4}$	21	20
2,3-Dimercaptopropanol	$1 \cdot 8 \times 10^{-4}$	53	65
Sodium monoiodoacetate	$3 \cdot 6 \times 10^{-4}$	13	86
p-Hydroxymercuribenzoate	$1 \cdot 4 \times 10^{-4}$	27	93
Mercuric chloride	$1 \cdot 6 \times 10^{-4}$	80	72

2 ml. of soil filtrate, 2 ml. of sodium urate solution, 2 ml. of 0·5 M phosphate buffer of *p*H 7·0 and 0·5 ml. of toluene were incubated without shaking for 48 h at 30° C with 0·1 ml. of inhibitor solution. Controls of the same composition but with boiled soil extracts were incubated at the same time.

The two enzymes differed markedly in their behaviour with the metal chelators sodium diethyldithiocarbamate, sodium ethylenediamine tetraacetate, and sodium cyanide, and the sulphydryl group reagents sodium monoiodoacetate and *p*-hydroxymercuribenzoate.

A brief comparison has been made with the uricolytic activity of soil under permanent pasture. A sample of Taita soil, *p*H 5·2, at a depth of 0·5–3 in. from under grass–clover pasture, and the garden soil were extracted with 0·1 M phosphate buffers of *p*H 7·0 and 8·4 for 18 h at 37° C. Two-ml. aliquots of each filtrate were incubated with 2 ml. of urate solution, 2 ml. of 0·5 M phosphate buffer *p*H 7·0, and 0·5 ml. of toluene for 48 h. Under these conditions, and allowing for the different moisture contents, the pasture soil had approximately one-sixth the uricolytic activity of the garden soil.

It might possibly be concluded that the uricolytic activity in soil is due to organisms producing uricase, and that such organisms are likely to be more plentiful in a soil frequently or continuously supplied with urate.

I thank Dr. D. J. Ross, of Soil Bureau, Dr. R. Truscoe, of Victoria University of Wellington, and Dr. K. Strzemienski, of Soil Bureau, for advice.

SOURCES OF ERROR IN THE WHEAT CYLINDER BIOASSAY FOR AUXIN

By DR. K. E. COCKSHULL and PROF. O. V. S. HEATH, F.R.S.

Horticultural Research Laboratories, University of Reading

WALKER, Hendershott and Snedecor[1] carried out a statistical investigation of the various sources of random variation in the bioassay of growth-substances separated from tissue extracts by paper partition chromatography. Their bioassay method utilized wheat coleoptile sections, placed in a small, corked assay tube with a chromatogram segment and 1 ml. of sucrose-buffer solution—a method similar to that of Hancock and Barlow[2] as used in this department[3,4].

They reached the following important conclusions:

(1) Variation between coleoptile sections within tubes provided a gross underestimate of experimental error; true replicate samples of the plant material should therefore be used.

(2) The failure of known or unknown growth substances to run consistently with the same R_F in a particular solvent made the greatest contribution to experimental error.

(3) Measurements of coleoptile growth should be used as data, without being transformed to percentages of the 'control' growth.

(4) Reducing the number of coleoptile sections per assay tube from the usual 10 or 5 to 2 or 1 and increasing the number of samples, greatly reduced the variance of the mean and gave the greatest information per hour of work. These last conclusions were based partly on calculation and partly on comparisons between different experiments.

In previous work here (Clark and Heath[4]), estimates of experimental error have been based on triplicate chromatograms, rather than on replicate samples of a rather limited supply of experimental plant material, using the mean of 5 coleoptile sections (from one tube) for each chromatogram segment. We have recently followed Walker *et al.* in examining the effects of using different numbers of sections per assay tube but with known concentrations of the growth regulator, indolyl-3-acetic acid (IAA—sodium salt) instead of segments from chromatograms of tissue extracts. Thus we were able to compare within single experiments the mean growth obtained with different numbers of sections. These experiments at once revealed large and unexpected effects of number of sections, both on the amount of 'control' growth without added auxin and the responses to a range of concentrations of IAA.

Statistical analysis of some of these data showed a highly significant ($P < 0{\cdot}001$) interaction between number (1, 2 or 5 sections per tube) and IAA concentration (0, 0·01, 0·1, 1, 10 or 100 p.p.m.). This took the form that while the single sections gave their greatest growth at 10 p.p.m., with little less at 100 p.p.m., and the pairs grew most at 1 p.p.m., the peak for 5 sections occurred at 0·1 p.p.m. after which the curve fell away to show practically no growth promotion at all at 100 p.p.m. This was later shown to be a consequence of the sections being enclosed in the assay tube, for the responses to IAA concentrations were found to be very similar with different numbers of sections when these were placed in uncorked assay tubes (each with a band of paraffin wax at the mouth to prevent spilling). Further research, to be described in a paper to be submitted to the *Journal of Experimental Botany*, has indicated that accumulation of respiratory carbon dioxide is the major factor causing the interaction found between number of sections and IAA concentration in corked assay tubes.

Heath and Clark had already shown, in their researches on chelating agents, that variations in technique and in sources of wheat seed could alter the pattern of response of coleoptile sections to growth regulators. We have therefore examined the response of a second strain of the variety 'Eclipse', obtained from Wye College, and of a different wheat variety, namely, 'Thatcher', to 0 and 100 p.p.m. IAA when 5 sections were grown in both corked and uncorked tubes. The results of these experiments (which were conducted on separate occasions) are summarized in Table 1.

Table 1. SECTION-LENGTH (CM) AFTER GROWTH FOR 24 H AT 25° C IN 0·5 ML. OF THE SOLUTIONS INDICATED

Initial section length, 1·0 cm. Means of two occasions; four replicate tubes per occasion

Variety	Eclipse (Reading)		Eclipse (Wye)		Thatcher	
Dates	1.9.60 and 11.9.60		24.4.61 and 26.5.61		12.9.60 and 13.9.60	
IAA p.p.m.	0	100	0	100	0	100
Corked	1 89	1·93	1·91	1·87	2·03	1·91
Uncorked	2·02	2·34	2·07	2·52	2 05	2·46

It was clear, therefore, that this effect was a result of variations in technique alone as it could be reproduced with other varieties of wheat. It was also of interest to know whether the effect on final section length of corking the tubes was paralleled by an effect on uptake of IAA by the sections. Measurements were made of the quantity of IAA remaining in 100 p.p.m. solutions after they had supported the growth of different numbers of sections for 24 h. Two methods of colorimetric estimation were used on different occasions; in one the IAA remaining in the solution was estimated 30 min after the addition of a Salkowski reagent[6] and in the other the solutions were partially resolved by paper partition chromatography before the addition of the reagent[6]. The results obtained by these two methods were consistent and in close agreement (Table 2).

Table 2. PERCENTAGE OF IAA REMAINING IN THE ASSAY TUBES; INITIALLY 0·5 ML. OF 100 P.P.M., EQUIVALENT TO 50 µG IAA

Means of two occasions

	Corked tubes		Uncorked tubes	
Sections/tube	5	1	5	1
Resolved solution	44	27	0	5
Unresolved solution	43	29	0	5

The reduced growth of 5 sections in corked tubes was accompanied by a reduced disappearance of IAA at 24 h, but apart from this there was little correlation between IAA disappearance and final section length. In the uncorked treatments (irrespective of whether 1 or 5 sections were present) almost no residual IAA could be detected, which indicated that we were in fact testing the effect of a known quantity of IAA rather than the effect of a maintained external concentration. (If this were incorporated into the section and if it then remained as free IAA, the internal concentration at 24 h, for single sections in uncorked tubes in the 100 p.p.m. IAA treatment, would be greater than 1 g IAA/kg fresh weight of coleoptile tissue.) As the method was developed for the assay of growth substances in small quantities of tissue extracts it is undesirable to increase the volume of solution used.

The main object of the investigation was to determine which was the most sensitive and useful method for assaying growth substances, and therefore concentration-response curves were obtained for each number of sections in both corked and uncorked assay tubes. For each number of sections (1, 2 or 5) a separate factorially designed experiment was carried out in 5 blocks of occasion; on each occasion 6 concentrations of IAA (ranging from 0 and 0·01 p.p.m. to 100 p.p.m.) were tested in both corked and uncorked assay tubes with four replicate tubes. The results for the two extreme cases (1 and 5 sections) are

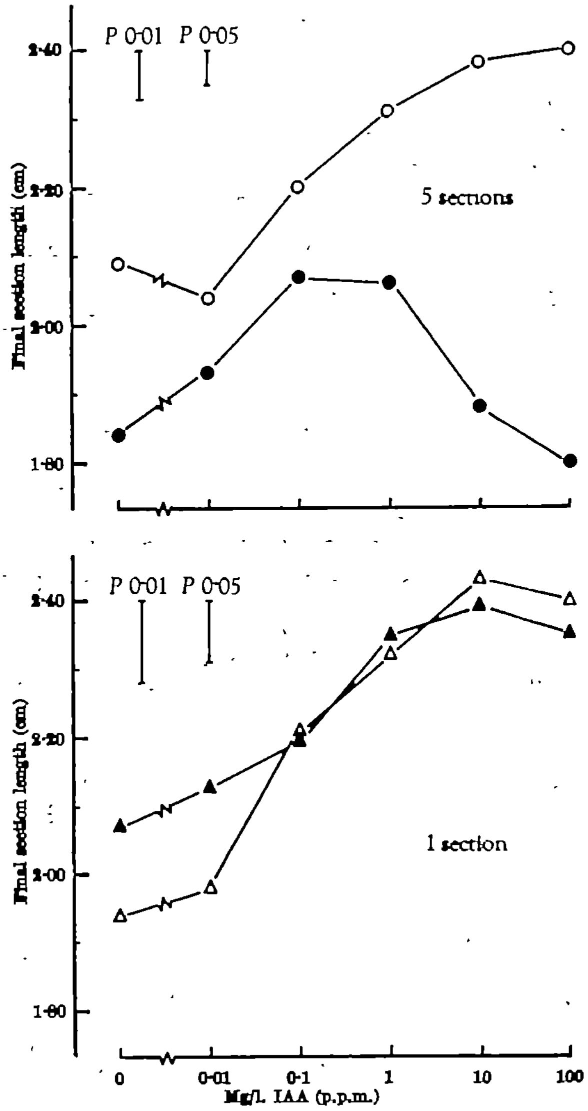

Fig. 1. The responses of 1 (▲ △) or 5 (● ○) sections to a range of IAA concentrations, in corked (▲ ●) and uncorked (△ ○) assay tubes after 24 h at 25° C. Initial section-length was 1·0 cm. Each point represents the mean of five occasions (between September 20, 1960, and November 16, 1960) with four replicate tubes on each. Least significant differences between two means are shown for P 0·05 and P 0·01

presented in Fig. 1. The results for 2 sections were intermediate in character but corresponded more closely to the curves for 1 section than to those for 5 sections. It is apparent that the range of growth-promoting concentrations is increased by the use of either uncorked tubes or fewer sections in corked ones. Walker *et al.*, on the basis of statistical considerations, recommended the use of fewer sections in each assay tube and on empirical grounds we also have reached this conclusion. The choice therefore is between 1 or 2 sections in either corked or uncorked assay tubes.

We have found that the accumulation of carbon dioxide can affect the growth response to IAA and it is evident from Fig. 1 that it can also affect the 'control' growth but in a more complex manner, for example, the respiratory carbon dioxide from a single section can give rise to a significantly greater section-length at 24 h, when it is allowed to accumulate in a corked tube. This effect reduced the magnitude of the IAA-induced growth in excess of the 'control'.

The main disadvantages of uncorked tubes would appear to be that the sections are exposed both to fluctuations in the composition of the atmosphere of the room in which the assay is performed, and to a slowly diminishing solution volume due to evaporation. This last should tend to maintain the external IAA concentration, which is not constant but is decreasing due to disappearance of IAA, presumably into the sections. Statistical analyses of the data showed that the error variance was no greater for uncorked tubes and when single sections were used the error variance was significantly less than in corked ones ($P < 0.05$).

From the significance-levels shown in Fig. 1 it can be seen that there is some loss of accuracy with single sections, but this can be improved, as Walker *et al.* pointed out, by increasing the number of replicate tubes. They recommended that either four replicate tubes with 2 sections in each or five replicate tubes with 1 section in each should be used at the discretion of the individual. We would endorse this view but would add that in our particular method the most sensitive technique would utilize single, 10-mm long sections in each replicate uncorked tube.

In certain circumstances it may be necessary or more convenient to use techniques in which the free diffusion of gases is restricted, for example, in either corked assay tubes or covered Petri dishes. In such techniques the quantity of carbon dioxide accumulated could be reduced by utilizing either shorter sections or shorter assay periods in conjunction with more accurate measuring techniques; by conducting the assay at a temperature lower than 25° C; by opening the vessels at intervals or by increasing the volume of enclosed air. Varying any of these factors could conceivably lead to considerable differences in response of coleoptile sections to growth regulators and such variations in technique may account for some of the observed discrepancies between different authors' results.

Of relevance in this connexion are the data of Barlow and Hancock[7], who observed effects on growth, with corked or uncorked tubes and 5 sections, essentially similar to those reported here. They concluded, however, that the relative effects of IAA concentration on final length or growth rate were similar in both corked and uncorked tubes. The data published in their Fig. 4 do not seem to support this statement, although the magnitudes of the differences were smaller at their lower assay temperature of 20° C.

EFFECT OF ANTI-PLATELET ANTIBODIES ON THE *IN VITRO* UPTAKE OF 5-HYDROXYTRYPTAMINE BY BLOOD PLATELETS

By DR. J. M. BRIDGES, M. BALDINI, C. FICHERA and W. DAMESHEK
Blood Research Laboratory, Pratt Clinic—New England Center Hospital and Department of Medicine,
Tufts University School of Medicine, Boston

IT has long been known that blood platelets are antigenic and that anti-platelet antibodies produce shortening of the platelet life-span *in vivo* and agglutination and lysis of the platelets *in vitro*[1–3]. Further manifestations of platelet injury by antibody have more recently been shown by inhibition of clot retraction and by reduction of thromboplastin generation[4]. These have been important additions to the study of the various actions of antibodies on the platelets and have led to a better understanding of thrombocytopenic disorders in human beings. They have provided, however, but little knowledge of the profound biochemical changes that occur in the platelets when these are attacked by antibody. Investigations on this subject have begun in our laboratory. It is known that *in vivo* as well as *in vitro* blood platelets take up 5-hydroxytryptamine (5-HT, 'Serotonin') rapidly by an active transport mechanism partially linked to their content of adenosine triphosphate (ATP) (refs. 5–8). It was thought that antibodies acting on the platelets might inhibit this phenomenon. This article describes the results of experiments designed to test this hypothesis.

In these studies, an *in vitro* system was used in which various antibody-containing sera were added to samples of normal human platelet-rich plasma and incubated at 37° C in the presence of 5-HT labelled with carbon-14. Platelet radioactivity was determined at various intervals and taken as the measure of the platelet uptake of 5-HT.

The effect of anti-human-platelet serum prepared in the rabbit was first tested. The platelet agglutinin titre of this serum was 1/200 when measured by the technique of Dausset *et al.*[9]. The serum was added in the amount of 0·2 ml. to each aliquot of 1·8 ml. of citrated human platelet-rich plasma (platelet count 350,000–400,000/mm^3). (All platelet counts were done by the technique of Brecher and Cronkite[10].) After the subsequent addition of 0·2 ml. of a saline solution of labelled 5-HT (5-hydroxytryptamine (β-aminoethyl-β-C^{14}) (creatinine sulphate complex), Nuclear Chicago) (50 µg of ^{14}C-5-HT/ml. saline), the samples were incubated for various intervals at 37° C. Platelet buttons were obtained by centrifugation, washed once with normal saline, and re-suspended in 2 ml. of distilled water. The platelets were then disrupted by repeated freezing and thawing and the debris deposited by centrifugation. Aliquots of 1·5 ml. of the supernatants were dried on steel planchets and their radioactivity measured in an end-window gas-flow counter. Two sets of controls were prepared by replacing the heterospecific antiserum either with equal amounts of (1) serum from

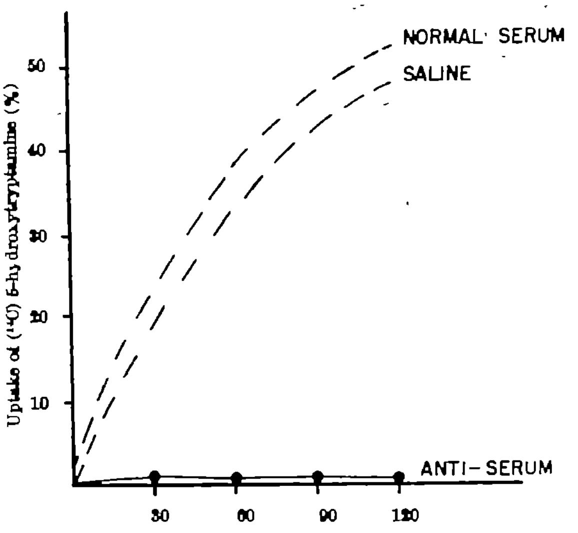

Fig. 1. The *in vitro* uptake of 5-hydroxytryptamine labelled with carbon-14 by normal human platelets was blocked by the action of a heterospecific antiserum

non-sensitized rabbits, or (2) saline. The platelet uptake of 5-HT in test samples and controls was derived from the platelet radioactive-counts and expressed in per cent of the total radioactivity added.

The platelet uptake of 5-HT in the controls increased progressively reaching the maximum average value of 47 per cent (41–52 per cent) between 90 and 120 min. In the controls containing 0·2 ml. of saline, platelets had similar values of 5-HT uptake as in the controls prepared with 0·2 ml. of normal rabbit serum. When, however, the heterospecific antiserum was used, the platelet uptake of 5-HT was consistently less than 1 per cent. One of such experiments is illustrated in Fig. 1.

The factor present in the heterospecific antiserum which was capable of blocking the *in vitro* uptake of 5-HT by normal human platelets was sensitive to dilution. When 0·2 ml. of progressively diluted samples of antiserum were used, the inhibiting effect was progressively reduced and no inhibition of 5-HT uptake was noticed when the total dilution of the antiserum in the system reached 1/880. Furthermore, these experiments showed that agglutination of the platelets at the end of the incubation period could be seen under the phase-contrast microscope only in the test samples with higher concentrations of antiserum (1/11–1/110). With dilutions of 1/220–1/440 there was no agglutination of the platelets, while there was still a marked reduction of the 5-HT uptake (11–29 per cent uptake).

The specificity of the reaction between the antiserum and the platelets was later demonstrated. Five absorptions of the antiserum with 'pure' preparations of normal human platelets almost completely removed the 5-HT inhibiting factor. (The saline platelet suspension used for the absorption of the antiserum contained 8·2 × 10⁶ platelets/mm³ while the contaminating white cells were less than 25 and the red cells less than 100/mm³. Each absorption of 1 ml. of antiserum was done with 0·25 ml. of platelet suspension.) This demonstration was necessary since it is known that antigen–antibody reactions not directed towards the platelets can cause release of 'Serotonin' from the platelets[11].

From these experiments it was concluded that since depression of 5-HT uptake by normal human platelets in contact with heterospecific antiserum occurred even in the absence of visible platelet agglutination, it was therefore not the consequence of platelet clumping but rather the expression of a specific metabolic damage produced by the antiserum directly on the platelets.

A second series of experiments was performed by the use of serum from four patients who had received multiple blood transfusions. It is known that multi-transfused patients often become iso-sensitized to blood platelets[12]. Iso-sensitization to platelets in the four patients was demonstrated by the remarkable shortening of the survival-time of isologous platelets as measured by the chromium-51-labelling technique[13], while the patients themselves had either a normal platelet count or had amegakaryocytic thrombocytopenia (Table 1). The experimental system used in the examination of the human sera differed somewhat from that adopted in the investigations with heterospecific antiserum. 1 ml. of patient's serum was added to each 1 ml. aliquot of normal platelet-rich plasma obtained by differential centrifugation of citrated venous blood from healthy donors. (In each 'Serotonin' experiment, platelets from the same donor were used as for the platelet survival study.) After addition of 0·2 ml. of the solution of 5-HT labelled with carbon-14, the samples were incubated at 37° C for various intervals. Two sets of controls were used, one in which the patient's serum was replaced by donor's serum, and the other in which the donor's platelet-rich plasma was replaced by the patient's own platelet-rich plasma.

Results of these experiments are summarized in Table 1. The serum from all four of these sensitized patients demonstrated a variable, but often marked effect in depressing the *in vitro* uptake of 5-HT by donor's platelets, while when in one experiment the patient's serum was used with the patient's own platelet-rich plasma, no depression in 5-HT uptake was observed. It was therefore evident that the 5-HT inhibiting factor present in the serum from multi-transfused patients behaved as an iso-antibody, being effective on the donor's platelets and ineffective on the patient's own platelets. Furthermore, it was demonstrated that the serum factor inhibiting the 5-HT uptake by donor's platelets could be removed almost completely by three absorptions with donor's platelets. (For the absorption experiments platelet concentrates in saline were used containing 5·9 × 10⁶ platelets/mm³ with a white cell count of less than 25/mm³ and a red cell count of less than 100/mm³. 1 ml. of serum was absorbed each time with 0·25 ml. of platelet concentrate.)

In all the experiments performed with the sera from the iso-immunized patients, no agglutination of the platelets could be seen under phase-contrast microscope, and no lysis of the platelets occurred as demonstrated by the unchanged platelet counts in the various samples before and after incubation. Furthermore, when the above four sera were tested for platelet iso-agglutinins by the method of Dausset *et al.*[9] a positive result was obtained with only two sera. This finding indicated a high degree of sensitivity of the 5-HT method in the detection of platelet iso-antibodies.

Further experiments were performed using sera from six patients with acute or chronic idiopathic thrombocytopenic purpura. The bone marrow in all six patients was abundant in megakaryocytes, while the platelet counts were greatly reduced (8,000–62,000/mm³). These cases are considered by many observers to be auto-immune.

Table 1. SEROTONIN UPTAKE TEST WITH SERA FROM MULTI-TRANSFUSED PATIENTS

Patient	Disease	Platelet count/mm³	No. of blood trans.	Uptake of 5-HT (per cent) Donor platelet-rich plasma Patient serum	Donor platelet-rich plasma Donor serum	Patient platelet-rich plasma Donor serum	Patient platelet-rich plasma Patient serum	Survival time of donor platelets in patient* (h)
L. C.	Aplastic anæmia	20,000	22	18·6	42·3	—	—	30
M. B.	Leukæmia	45,000	17	28·0	44·2	—	—	16
M. L.	Blood loss anæmia	340,000	29	9·8	40·2	39·0	37·6	8
S. Q.	Refractory anæmia	60,000	12	25·2	34·3	—	—	22

* Normal value 8–10 days.

Table 2. Serotonin Uptake Test with Sera from Idiopathic Thrombocytopenic Purpura Patients

Patient	Platelet count/mm^3	Uptake of 5-HT (per cent) Donor platelet-rich plasma: Patient serum	Uptake of 5-HT (per cent) Donor platelet-rich plasma: Donor serum
T. G.	8,000	35·6	32·9
J. M.	40,000	37·3	38·9
B. F.	10,000	42·4	44·0
A. M.	24,000	32·7	35·1
H. M.	38,000	33·5	36·1
S. M.	62,000	40·9	48·1

with auto-antibodies attacking the platelets in the circulation and resulting in shortening of the platelet life-span[14,15]. The serum from these patients, presumably containing an anti-platelet auto-antibody, exerted no effect on the 5-HT uptake of normal donor's platelets (Table 2). The negative result was repeatedly confirmed with platelets from various donors. It was concluded, therefore, that the anti-platelet factor presumed to be present in the serum of patients with idiopathic thrombocytopenic purpura injured the platelets through a different mechanism than did hetero- and iso-antibodies, or resulted in the development of thrombocytopenia by some other more indirect process.

It is believed that the inhibiting effect induced by specific hetero- and iso-antibodies on the *in vitro* uptake of 5-HT by blood platelets may be a useful indicator in further studies on the complex biochemical changes produced by antibodies on blood platelets.

ETHYLENE PRODUCTION BY SUBCELLULAR PARTICLES FROM RAT LIVER, RAT INTESTINAL MUCOSA AND *PENICILLIUM DIGITATUM*

By Dr. G. RAM CHANDRA and Prof. MARY SPENCER

Departments of Plant Science and Biochemistry, University of Alberta, Edmonton, Canada

It has been reported that all fruits, without exception, give off ethylene[1]. While the production of ethylene by fruits and certain micro-organisms has been the subject of extensive investigation over the past twenty-five years, the possible role of this compound in the metabolism of animals has been virtually ignored. Recently, Kakanov[2] provided evidence that both normal rats and pig ascarids produce ethylene. Although no attempt was made to remove ethylene from air supplied to the respiratory chambers or to maintain aseptic conditions, Kakanov's experiments were nevertheless interesting, particularly since rats with transplanted subcutaneous sarcoma, subcutaneous abscess or which had received a subcutaneous injection of aluminium oxide exhaled more ethylene than healthy rats.

With knowledge of the site of ethylene production in fruit[3,4] and a method for activation of the ethylene-producing system[4], a more direct approach to the question of ethylene production by animals and micro-organisms was made in our laboratory by attempting *in vitro* preparations capable of evolving the gas. In this article, mass spectrometric and gas chromatographic evidence of ethylene production by particulate fractions from rat liver, rat intestinal mucosa and *Penicillium digitatum* is given.

About 50–60 g fresh weight of liver or 2·5–3·5 g intestinal mucosa pooled from 4–6 rats were used in each experiment. The Wistar rats were killed by decapitation prior to the experiments. A 10-cm loop of the small intestine posterior from the pyloric sphincter was dissected, washed with demineralized water and blotted dry. The mucosa was squeezed from the gut with a spatula.

Penicillium digitatum (Sacc.) NRRL 1203 was grown in stationary culture under aseptic conditions. The growth medium[5] contained glucose (25·7 g), ammonium nitrate (4 g), potassium dihydrogen phosphate (13·61 g), magnesium sulphate (1·23 g), ferric nitrate (5 mg) and 1 ml. of Pratt's micro-element solution[6], dissolved in 1 litre of distilled water. The *p*H of the medium was 4·4. After two weeks, the growth (about 25 g wet weight) was gathered and either used immediately or frozen. The *p*H of the medium when gathered was 4·2.

To prepare subcellular particles from rat liver and intestinal mucosa, the tissues were homogenized in ice-cold 0·88 M sucrose (1 g wet weight per 10 ml. suspension) at low speed in the Servall 'Omnimixer'. The *p*H of the homogenate was maintained at 7·0–7·2 by the addition of 0·1 N potassium hydroxide. Particles from *Penicillium digitatum* were obtained from a homogenate of the fungus in 0·5 M sucrose–0·1 M potassium dihydrogen phosphate buffer of *p*H 7·0 (1 : 10 w/w). All homogenates were centrifuged at 4,000*g* for 7 min. The sediment was rejected and from the clear supernatant particles were separated by centrifugation at 12,725*g* for 15 min. The particles were carefully suspended in 25 ml. of reaction mixture (Table 1) and tested for ethylene production over 2- and 18-h periods at 25° C by gas chromatographic and mass spectrometric methods described earlier[4]. When particles were sonically treated, they were exposed for 4 min at 2° C to a Raytheon sonic oscillator (10 kc/s) tuned to 1·1 amp. Microscopic examination of the particulate fraction from *Penicillium digitatum* revealed the presence of intact spores and some incompletely fragmented mycelia in these preparations, which were found to be viable. Untreated particles from the animal tissues were stainable with janus green *B*.

Table 1. Ethylene Production by Subcellular Particles from Rat Liver, Rat Intestinal Mucosa and *Penicillium digitatum*
(μl. × 10^6/mg nitrogen/2 h)

Run No.	Treatment	Rat liver	Rat intestinal mucosa	*Penicillium digitatum*
1	Untreated	5·0	15·2	12·5
2	Untreated	8 0	16·2	—
3	Sonically treated	9·5	25·8	13·2
4	Sonically treated	13·0	13·8	31·6
5	Sonically treated	—	12·5	23·6

Female rats, 10 weeks old, were used.

Reaction mixture: 0·5 M sucrose, 0·125 M KH_2PO_4, 0·05 L-malic acid, 10^{-3} M $MgSO_4$, 10^{-3} M $MnSO_4$; 1·93 × 10^{-3} M adenosine triphosphate and 3 3 × 10^{-4} M diphosphopyridine nucleotide were added after sterilization of the mixture; sonication was performed prior to ATP addition; *p*H was adjusted to 7 with sodium hydroxide.

The results of our initial trial experiments with tissues from female Wistar rats, 10 weeks old, and *Penicillium digitatum* are given in Table 1. It is evident that particles separated at 12,725*g* from rat liver, rat intestinal mucosa and the fungus produced ethylene. Many steps in the preparation of these fractions could not be performed quantitatively and variation in nitrogen content of particulate fractions from different runs occurred. Thus, quantitative duplication of results from different runs was not to be expected. These initial experiments, along with mass spectrometric analyses which confirmed the identity of the gas as ethylene, served to show that subcellular fractions from sources other than the tissues of higher plants produce ethylene.

In our earlier work[4] with subcellular particles from tomatoes, we had shown that production of ethylene was related to the disintegration of the structure of the mitochondria. In the experiments reported here, to test the applicability of this finding to animal and fungal tissues, comparisons were made, within a single run, of ethylene production by particles which were untreated, sonically treated or aged *in vitro*. It should be noted first that some fragmentation of the particles probably occurred when the tissues were originally ground in the 'Omnimixer'. This is consistent[7] with the observed lack of lag-period in carbon dioxide production by the particles. Ethylene was also produced by a fraction separated at 40,210*g* for 15 min, which would contain fragments of both mitochondria and endoplasmic reticulum. It is evident from Table 2 that ageing of the untreated particles or sonic treatment of them increased ethylene production. Thus, as with tomatoes[4], ethylene production by subcellular particles from rat liver, rat intestinal mucosa and *Penicillium digitatum* appears to be stimulated by disintegration of the particles.

Table 2. EFFECTS OF *in vitro* AGEING AND SONIC TREATMENT ON ETHYLENE PRODUCTION BY SUBCELLULAR PARTICLES FROM RAT LIVER, RAT INTESTINAL MUCOSA AND *Penicillium digitatum*

		Ethylene (μl. × 10^{6}/mg nitrogen)						
		Rat Liver		Rat intestinal mucosa			*Penicillium digitatum*	
Treatment	Time (h) Run No.	1	2	3	4	5	6	7
Untreated	0–2	2·2	2·0	5·6	5·3	Trace	Trace	7·2
Untreated	2–18	2·7	4·3	12·4	11·8	7·6	10·5	8·0
Sonically treated	0–2	5·1	4·8	36 4	15·9	38 0	22·7	18·0
Sonically treated	2–18	2·2	2·2	52·4	23·5	15·0	31·0	24·0

Male rats, 16 weeks old, were used.
Reaction mixture as in Table 1.

The foregoing experiments, together with others[8] in which we have observed the presence of ethylene in exhaled gas from human subjects, lead us to suggest that the production of ethylene may be a general phenomenon of life processes and that its metabolic role may be a question of fundamental importance.

This work was supported by a grant-in-aid from the National Research Council of Canada.

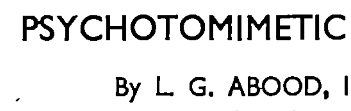
A POSSIBLE MECHANISM OF ACTION OF CALCIUM AND SOME PSYCHOTOMIMETIC AGENTS ON MEMBRANES

By L. G. ABOOD, I. KOYAMA and H. KIMIZUKA

Departments of Psychiatry and Biochemistry, University of Illinois College of Medicine, Chicago

IN the course of investigating the mechanism of action of a group of anticholinergic psychotomimetic agents, it was observed that the agents seemed to influence those properties of excitable tissues that were particularly sensitive to a depletion of Ca^{2+}. The importance of Ca^{2+} in the maintenance of excitability in nerve and muscle has been recognized since 1883 [1], but it was only recently that there has been a revival of interest in it, following the observation of Hodgkin and Keynes[2] that an increased influx of Ca^{2+} accompanied excitation of the squid giant axon. This article discusses the types of Ca^{2+}-dependent systems in excitable tissues which are influenced by the agents, and the possible mechanisms involved.

The chemistry and pharmacology of the agents concerned within the present study are described elsewhere[3]. They encompass a wide variety of esters of heterocyclic imino and di-imino alcohols and substituted glycolic and other carboxylic acids. An example of this class, and that utilized in the present investigation, is *N*-methyl-2-pyrrolidyl methyl *cyclo*pentylphenyl glycolate (PMCG):



Resting potentials were recorded in single fibres of freshly dissected frog sartorius muscles with the glass capillary microelectrode (Ling–Gerard type) filled with 3 M potassium chloride and having a resistance of 20 megohms. A pair of muscles were first soaked in Ringer's solution for 30 min before the resting potentials of each muscle were determined. One muscle was then transferred to a solution of calcium-free Ringer's solution and the resting potentials were measured after spontaneous twitching ceased 40 min later.

The experimental muscle was simultaneously transferred to a calcium-free Ringer solution containing 10^{-4} M PMCG and the resting potential also recorded 40 min later. Comparable experiments were conducted in calcium-free Ringer's containing 4 mM EDTA. A set of experiments was performed where 10^{-4} M PMCG was present in the test solution prior to the immersion of the experimental muscle.

When frog muscles are transferred from a Ringer's to a calcium-free solution, there is a rapid drop in the intrafibrillar resting potential which results in spontaneous twitching, or fasciculation, of the muscle. Both the decrease in the resting potential and the fasciculations can be prevented if the calcium-free solution contained PMCG (Table 1). In the presence of the drug, the resting potential could be maintained at almost normal levels. After the resting potential has dropped 50 per cent in a calcium-free medium, it could be restored to almost normal by the addition of 10^{-4} M PMCG to the calcium-free medium. In this respect, the action of PMCG in restoring the resting potential is similar to that of Ca^{2+} and other bivalent alkali cations. It should be mentioned that similar effects could be demonstrated with a large number of homologues of PMCG.

The action of PMCG and Ca^{2+} appear to be similar in a number of respects. Both cations can form poorly dissociable salts with such acids as EDTA, phosphoric, and

Table 1

		Drug at zero time		Drug present 40 min later	
		Resting potential (−mV)	% Diff.	Resting potential (mV)	Reversal (%)
Ringer's	C	90 ± 3	—	91 ± 3	—
	PMCG	89 ± 3	−1	91 ± 4	0
Ca-free	C	65 ± 5	—	70 ± 6	—
	PMCG	80 ± 4	23 (89)	82 ± 5	12 (91)
Ca-free	C	44 ± 6	—	45 ± 5	—
EDTA	PMCG	74 ± 5	67 (82)	55 ± 5	22 (61)
NaCl	C	60 ± 3	—	61 ± 4	—
	PMCG	81 ± 4	29 (90)	74 ± 3	47 (82)

The effect of PMCG on the intracellular potential of frog sartorius muscle exposed to various solutions. The results are expressed as the mean ± standard deviation. The values in the parentheses refer to the per cent of the normal resting potential (−90 mV). The concentration of PMCG at zero time was 10^{-4} M and, when added 40 min later, 10^{-4} M.

citric, as evidenced by the fact that the acids interfere with the adsorption of the cations to a variety of substances including frog nerve, muscle and skin, as well as brain mitochondrial membrane and lipid monolayers. The adsorption of both Ca^{2+} and PMCG to frog sartorius muscle increases experimentally as the pH increases between 4 and 10. When freshly dissected sartorius muscles are exposed to isotonic saline, they immediately begin to fasciculate, while the lactate production increases five-fold. On the gradual addition of either Ca^{2+} or PMCG at equimolar concentrations to the saline solution, a similar pattern of decrease in the concentration-activity curve is obtained for both the frequency of twitching and lactate production.

On the basis of such studies with various biological preparations it seemed likely that one was dealing to a large extent with surface phenomena; so that it might be possible to demonstrate a similarity in the action of Ca^{2+} and PMCG on the physical properties of interfacial films. Preliminary studies have been conducted with lipid interfacial films, while more extensive studies involving complexes of phospholipids and crystalline proteins are in progress. The addition of 10^{-4}–10^{-6} M PMCG to a monolayer of either stearic acid or dipalmitylphosphatidyl choline will increase the rigidity of the monolayer in a manner similar to Ca^{2+}. At higher concentrations (10^{-3} M) the surface active properties of PMCG become manifest so that the effect is one of dispersion of the monolayer and reduction in the surface pressure resulting from the interaction of PMCG and the monolayer. It is of significance that the concentration range in which PMCG acts like Ca^{2+} on the monolayer is the range in which it restores the resting potential of sartorius muscle fibres. PMCG at concentrations in excess of 10^{-4} M will inhibit the adsorption of Ca^{2+} to monolayers of lecithin, and the inhibition appears to be of the competitive type.

The dispersity of anionic lipophilic colloidal suspensions is increased by the loss of divalent cations; and the preservation of a normal colloidal state in biological systems is dependent on a balance of monovalent and divalent cations. The ability of Ca^{2+} to impart rigidity to colloidal dispersions consisting of proteins and phospholipids is to a large extent attributable to its capacity to combine with acidic carboxylic and phosphate groups[4]. The addition of even trace amounts of polyvalent metals to monolayers of stearic acid and other substances containing carboxylic acid groups will impart rigidity by occupying two or more end groups[5]. Under certain conditions this effect can be antagonized by monovalent cations.

Harkins[6] has shown that crystalline proteins, such as catalase and cytochrome c, will form a monolayer of spherical or ellipsoidal molecules with barium stearate. In the absence of Ba^{2+} or a similar cation such a monolayer is incapable of forming. Interactions between lipids and proteins can occur through van der Waals forces between the non-polar hydrophobic residues of the fatty acids and similar functional groups in the hydrophobic face of the protein molecule. Combination can also occur as a result of hydrogen bonding, electrostatic attraction between oppositely charged groups of proteins and lipids, and adsorption of the hydrated polar molecules on to the highly hydrated protein molecules.

The lipophilic hydrocarbon residues of an air/water interfacial lipid film are arranged in closely packed parallel arrays, normal to the surface, while the hydrophilic polar tail is projected into the aqueous medium. Despite the length of the hydrocarbon chain and the restricted translational freedom, there exists considerable freedom of rotation about the long axes of the molecules[7]. In addition to diminishing the hydrophilia of the polar tails Ca^{2+} or Ba^{2+} can, by combination with adjacent acidic groups, restrict rotational freedom. There is a third factor which may be involved in explaining the increased cohesiveness Ca^{2+} imparts to the interfacial film, and that is the diminution in repulsion of adjacent molecules brought about by the neutralization of anionic groups. Finally, the van der Waals attraction between adjacent units in the monolayer is increased since the molecular weight of the repeating units is doubled.

It has been postulated that during membrane depolarization there is a loss of Ca^{2+}, along with various phosphates, and that the displacement of Ca^{2+} from the lipoprotein membrane results in the structural rearrangement responsible for altering membrane permeability to such ions as Na^+ and K^+ (ref. 8). If it is assumed that surface Ca^{2+} forms complexes with the phosphates groups of phospholipids or ATP-protein complexes, the replacement of the poorly hydrated Ca^{2+} by the well-hydrated Na^+ would increase the hydrophilic character and diminish the rigidity of the biomolecular lipophilic structure of the membrane. Simple displacement of Ca^{2+} from bound sites could result in a net inflow of water since the dissociated Ca^{2+} is more than twice as greatly hydrated as Na^+. Removal of Ca^{2+} with complexing agents such as EDTA and citrate leads to an analogous situation. The addition of numerous bivalent alkali earth metals as well as agents such as PMCG will restore a depolarized calcium-deficient membrane to its resting, electrically excitable state. Agents such as PMCG may act by virtue of their ability to complex with phosphate groups of both lipids and proteins with the net result that the cohesiveness and the lipophilic-hydrophilic balance of the membrane is partly restored. It must be pointed out, however, that it has not been possible as yet to duplicate the present experimental findings when frog spinal nerve roots or ganglion cells were used in place of sartorius muscle. Whether or not this difference is largely a matter of technique or is due to the more complex nature of nervous tissue is not known.

The interaction of PMCG with an excitable membrane, however, must obviously be quite different from that of Ca^{2+} since the polar–nonpolar aspects of the drug would permit a diversity of interactions with a complex lipoprotein membrane not possible with Ca^{2+}.

The objective of this investigation has been to explore the similarity and interrelationship of the two substances, and it remains to determine the unique physico-chemical properties of this class of agents underlying their mechanism of action. It is hoped that such investigations may not only help elucidate the mechanism of action of the drugs but also aid in the investigation of the properties of excitable membranes.

LETTERS TO THE EDITOR

PHYSICS

Particle Structure

It has been shown[1,2] that an empirical model of Nature exists in which many natural constants equal functions of π. The dimensional units are defined by the equations $C = 1$ and $\bar{\lambda} = \lambda_e = 2$ (λ_e is the Compton wave-length of the electron). Charge squared then equals $2a$ (a is the fine structure constant) and $M\lambda$ equals 4π (M is mass).

Particle structure can be described in terms of the properties of the particle and the constants characterizing the particle. In this suggested model the formation of the electron ($\mp\ \mp$) and the positron ($\pm\ \pm$) involves the combination of three units of rest mass π and field $2\exp - \pi^2/2$ to give a particle with rest mass 2π and a charge squared equal to $2\exp(-\pi^2/2 + 2\exp(-\pi^2/2 + 2\exp - \pi^2/2))$ or $2a$ (ref. 2). The energy of combination equals π. There are now two components each contributing a mass of π and a charge squared of a. Rest mass and energy are interconvertible but charge is constant and therefore conversion of energy to rest mass will only increase the rest mass of a component.

In the formation of the charged π meson the mass of the components equals $M\lambda/e^2 = 4\pi/2a$:

$$4\pi/2a + 4\pi/2a \rightarrow (8\pi/2a - 2\pi) + \text{energy}\ (2\pi)$$

Energy of combination equals 2π, indicating meson formation corresponds to a strong interaction similar to that involved in electron formation.

If components of opposite sign for charge and mass combine the result is a particle of zero mass and zero charge or a neutrino.

The charged π meson decomposes into a muon and a neutrino. The neutrino formed could have meson components or it could be a double neutrino since it has unique properties[3]. The masses involved are:

$$(8\pi/2a - 2\pi) \rightarrow (6\pi/2a + 2\pi) + 2(\pi/2a - 2\pi)\ \text{energy}$$

There appear to be two neutrino components or two neutrinos as indicated by the energy term.

Formation of the neutral π meson involves components of opposite charge:

$$(\mp) + (\pm) \rightarrow (\mp\ \pm) = \pi^0\ \text{meson}$$

$$4\pi/2a + 4\pi/2a \rightarrow [8\pi/2a - (1/2a - 2\pi)] + \ \text{energy}\ (1/2a - 2\pi)$$

Loss of energy on particle formation involves the charge factor since charge neutralization occurs.

Resonances may correspond to rest masses, for components, which are multiples of $4\pi/2a$. Combinations of these components may give particles of high mass and a very short life.

Elementary particles may combine to give higher mass particles. Helium is an example. The charged K meson may be a similar combination:

$$4(8\pi/2a - 2\pi) - (4\pi/2a - 1/2a)\ \text{energy} = K\pm$$

The neutral K meson has two distinct lifetimes involving two particles of slightly different masses. This suggests the dual formulation:

$$4(8\pi/2a) - [4(\pi/2a - 2\pi) - (1/2a \pm 2\pi)]\ \text{energy} = K^0$$

There are alternative possibilities, but this shows the various mesons can be accounted for with little deviation from accepted ideas. In all cases the calculated and observed rest masses differ by less than one electron mass. The model can be extended to hyperons[1]. The life of the particles may be related to the mass terms representing the particles, thus making possible extension of the model to these constants.

A simple model of Nature exists which is in good numerical agreement with many observations and which is readily expandable to include other observations.

Neutron Capture in the Samarium Isotopes and the Formation of the Elements of the Solar System

Recent theories concerning the formation of the elements are based on neutron capture, and are subject to quantitative experimental tests through radiative capture measurements[1-3]. This communication reports 30 keV neutron capture measurements for the isotopes of samarium. 2–20-g samples of electromagnetically separated samarium isotopes as Sm_2O_3 were used with the *ORNL* 3-MV pulsed Van de Graaff, providing the neutrons via the lithium-7 (p,n) reaction. A Moxon-Rae counter detected the capture γ-rays as in an earlier tin isotope measurement[3].

The isotopes samarium-150 and -148 are shielded from r-process[1] production by stable neodymium-150 and -148. Thus the s-process only should have contributed to their creation in stars, and the products of their neutron capture cross-sections near 30 keV and their natural abundances should be nearly equal. From the measured cross-sections we find the ratio (Table 1, col. 5) to be 0·94 with a relative uncertainty estimated at 10 per cent. Combining additional data for the ratio only, we get 1·02 (± 6 per cent). The expected average ratio in the mass region 120–200 is perhaps a 1 per cent decrease per mass unit[4], or 0·98 for this case. The results thus strongly confirm the s-process nucleosynthesis prediction. The r-process abundances derived for the other isotopes are in reasonable agreement for the odd and even isotopes separately but show an unexpectedly large odd–even effect. The number (N_r) for samarium-152 was derived ignoring the minor s-process branch (β^- decay of 93 yr. samarium-151); however, a large but uncertain percentage of the branch returns to samarium-152. Thus the r-process abundance given in Table 1 for samarium-152 could be increased by a few per cent. resulting in even closer agreement with N_r of samarium-154.

The samarium-149 precursor of samarium-150 in the s-process additionally has one of the few extremely large thermal neutron cross-sections (40,800 barns at 0·0254 eV). That for samarium-147 is about 500 times smaller (90 barns). This ratio is even larger in the neighbourhood of the 0·1 eV resonance. The ratio remains greater than 400 for neutron temperatures up to 2,000° absolute. Thus the present results leave little possibility for significant neutron exposure in solid[2] or even molten bodies of solar system material either terrestrial or, as Murthy and Schmitt have recently shown[5], for representatives of the chondrites, carbonaceous chondrites and achondrites.

If we assume $N_s\sigma_c$ to be constant from atomic weight A = 148 to A = 150 the selective depletion (via thermal neutron capture) of samarium-149 should be apparent in the residual abundance assigned in Table 1, column 7, to the r-process. As the thermal cross-sections of samarium-148 and samarium-150 are comparable with that of samarium-147 or smaller[4], perhaps a

Table 1. NEUTRON CAPTURE IN THE ISOTOPES OF SAMARIUM

Samarium isotopes at 30 (±7) keV

A	N(Atom %)	Class	σ_c(mb)	$N_s\sigma_c$	N_s	N_r	A
144	2·87	p(m)	119 ± 55				
147	14·94	rs	1,173 ± 192	(2,850)	2·4 ± 0·4	12·5 ± 0·4	147
148	11·24	s–0	258 ± 48	2,900 ± 540			
149	13·85	rs	1,622 ± 279	(2,850)	1·8 ± 0·3	12·1 ± 0·3	149
150	7·36	s–0	370 ± 72	2,770 ± 535			
152	26·90	rs	411 ± 71	(2,850)	6·9 ± 1·0	20·0 ± 1·0	152
154	22·84	r–0	325 ± 61	0	0	22·84	154

The production process (column 3) is from ref. 1. The r-process abundances are derived by assuming $N_s\sigma_c$ constant for all the isotopes of samarium

more sensitive indicator is found in the $N\sigma_c(150)/N\sigma_c(148)$ ratio. First, the r-process is shielded, and secondly the abundance of samarium-150 is only about half that of samarium-149. The samarium-149 depletion is then:

$$\frac{\Delta N\,(149)}{N\,(149)} = \frac{7{\cdot}36}{13{\cdot}85}\,[(1{\cdot}02 \pm 0{\cdot}06) - 1]$$

which gives an upper limit of 4 per cent for selective depletion, applicable to solar system material as discussed here. It should be mentioned[7] that inclusion of minor secondary processes such as (p,γ) and (γ,n) reactions and neutron resonance effects can increase the uncertainties in this limit by perhaps a factor of two.

In summary the following conclusions may be drawn from the samarium results.

(1) The near equivalence of $N\sigma_c$ for samarium-148 and samarium-150 is in excellent agreement with the predictions of Burbidge *et al.*[1].

(2) At the same time these results provide some constraints for nucleosynthesis models[1,2].

A New ²Π–X²Π Band System of Nitrogen Sulphide

THE spectrum of nitrogen sulphide is excited by means of a micro-wave oscillator of 2,450 Mc/s in sealed quartz discharge tubes containing a few mm of nitrogen and traces of sulphur. Besides the β- and γ-bands, a number of hitherto unassigned bands, degraded to the red, are recorded in the region 2650–2850 Å. These are photographed on a 6·6-m concave grating spectrograph in the second order at a dispersion of 0·57 Å/mm. Rotational structure of seven bands has been analysed and the results are reported in the present communication.

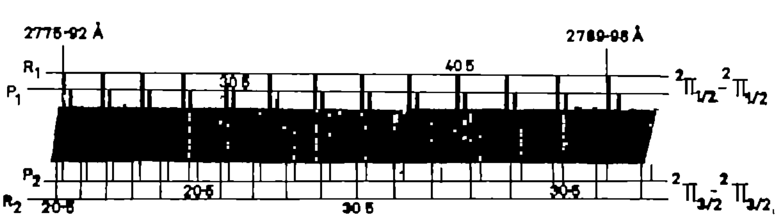

Fig. 1. (v' + 1) – 0 band of the new ²Π–X²Π system

Each band consists of two sub-bands with an average separation of 107 cm⁻¹. One such band at 2775 Å is shown in Fig. 1, where the rotational structure of the two sub-bands extends towards the longer wave-lengths as indicated by leading lines. The sub-band shown at the top in the spectrogram has two P and two R branches while the other sub-band with leading lines drawn below has only single series of P and R branches. Such a doubling in the case of P and R branches of only one sub-band is obtained in the $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ component of a $^2\Pi$–$^2\Pi$ transition with an appreciable Λ-type doubling in the $^2\Pi_{1/2}$ states while in the $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ component the Λ-doubling is negligible.

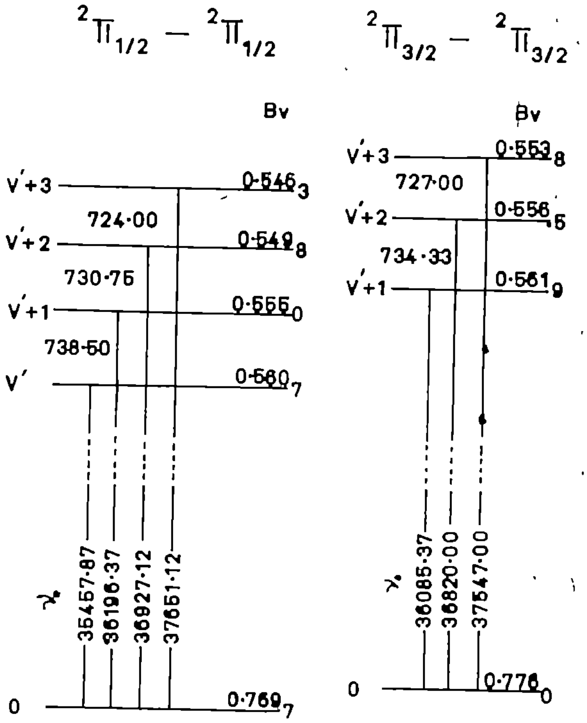

Fig. 2. Energy-level diagram of the vibrational levels of the ²Π–X²Π band system

Four bands of $^2\Pi_{1/2}$–$^2\Pi_{1/2}$ and three of $^2\Pi_{3/2}$–$^2\Pi_{3/2}$ transitions have been analysed and their respective vibrational levels are given in an energy-level diagram in Fig. 2. It is found that all the bands arise from different initial vibrational levels to the v'' = 0 level of the final $^2\Pi$ state. The band system belongs to a $^2\Pi$ (a)–$^2\Pi$ (a) transition with large spin-splitting in both the states. A comparison of the $\Delta_2F''_1$ (J + 1/2) and $\Delta_2F''_2$ (J + 1/2) values, that is, $R(J - 1) - P(J + 1)$, of the $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$ sub-states of the final $^2\Pi$ level with those obtained for the v'' = 0 of final levels of the β- and γ-systems[1,2] shows good agreement, thereby indicating that all the three band systems have the $^2\Pi$ ground state as the common final level.

Comminution: a Modified Logistic Growth Function

HOLMES's equation[1] rewritten in terms of specific surface area, S, can be derived from the differential equation:

$$\frac{dS}{dE} \propto S^{1-r} \tag{1}$$

where E is energy input per unit volume and r is Kick's law deviation exponent[1]. Equation (1) reduces to Kick's equation[2] when $r = 0$, Bond's third theory[3] when $r = \frac{1}{2}$ and Rittinger's equation[4] when $r = 1$. These equations suggest that material of unlimited fineness can be produced by milling.

A consideration of the expenditure of energy on the material under comminution, and the utilization of energy in causing fracture, indicates that: (*a*) the rate of change of the energy which can lead to fracture with energy input diminishes as energy input increases; (*b*) as the particles decrease in size, their resistance to fracture increases; (*c*) S reaches an upper asymptote, S_∞, as energy input increases. These lead to a differential equation which, reduced to its simplest form, becomes:

$$\frac{dS}{dE} = k\,\frac{S(1 - S/S_\infty)}{E} \tag{2}$$

where k is a parameter. Strictly E refers to net energy, defined as the difference between the gross energy and the energy required to maintain the mill in operation without relative movement. Equation (2) is a modified form [due to E in the right-hand side] of the Verhulst–Pearl–Reed logistic growth function[5,6]. The method involved here can be developed for differential grinding, which is analogous to competing populations.

Integrating equation (2) between non-zero limits gives:

$$E^k = A\,\frac{S}{1 - S/S_\infty} \tag{3}$$

where A depends on the initial values of S and E, which in turn depend on the material under comminution and its previous history. However, equation (3) may be used with confidence if the initial values of S and E are small; in most instances the experimental curves of S versus E will appear to extrapolate through the origin.

If values of S_x, S_{x+1} . . . corresponding to values of E_x, E_{x+1} . . . in geometrical progression:

$$\left(\frac{E_{x+1}}{E_x} = \text{constant} > 1\right)$$

are interpolated from the experimental data then:

$$\frac{1}{S_{x+1}} - \frac{1}{S_\infty} = \left(\frac{E_x}{E_{x+1}}\right)^k \left(\frac{1}{S_x} - \frac{1}{S_\infty}\right) \tag{4}$$

which has as its solution $S_x = S_{x+1} = S_\infty$. Thus, the value of $1/S_\infty$ is obtained from the point where the line of $1/S_{x+1}$ against $1/S_x$ intercepts the line at 45° to the axes through the origin. This method of finding an unknown asymptote has been used in other applications[7-9].

A plot of $\frac{S}{1 - S/S_\infty}$ versus E on a log log grid, or a plot of S/S_∞ versus E on a logistic log grid, will give a straight line if equation (3) is applicable. If S_∞ is so large that S/S_∞ can be neglected equation (3) reduces to a power form as with Holmes.

Fig. 1 shows some data[10] treated in this manner; excellent agreement is evident. In this example $k = 1$. The value of S_∞ could depend on the material under comminution, the conditions of breakage, mill dimensions and power input.

I thank Prof. H. J. King, Dr. A. Jowett and Mr. O. C. Dell for discussions.

OCEANOGRAPHY

Occurrence of Abnormally High Fluoride Concentrations at Depth in the Oceans

DURING the course of an investigation in these laboratories of the constancy of ionic composition of sea-water and in particular of the distribution of fluoride ion in the oceans, unusually large variations in the fluoride/chlorinity ratio have been found.

A new method[1] for the determination of fluoride in sea-waters has been applied to the analysis of more than 300 samples collected from the surface and from depth. The surface samples showed no significant geographical variation in the fluoride/chlorinity ratio (mean value about 6·7 × 10^{-5}), except for a few samples of high chlorinity water from the Mediterranean, in which the ratio averaged about 6·4 × 10^{-5}, a phenomenon probably associated with precipitation of calcium. No significant change of the ratio with depth was found in the Pacific and Indian Oceans. In the deep waters from some other localities, however, much higher fluoride/chlorinity ratios were found, frequently amounting to a 30 per cent increase.

Particularly pronounced were the fluoride/chlorinity (parts per thousand) ratios of the deep-water samples from the North and South Atlantic west of the mid-

Table 1. FLUORIDE/CHLORINITY RATIOS OF SEA-WATER AT DIFFERENT DEPTHS

Atlantic Ridge (Table 1). The high fluoride/chlorinity ratios found in deep waters may be caused either by submarine volcanic activity or by dissolution of fluoride minerals. The latter explanation seems likely for the samples from the North Atlantic since cryolite deposits are found on the east coast of Greenland. It is debatable, however, whether or not these Atlantic deep water masses would remain sufficiently unaffected by upwelling and other processes to retain their high fluoride content as far south as 53° S.

Many more samples will be needed before the significance of these results can be fully interpreted, but it is felt that the existence of these water masses having high fluoride/chlorinity might prove useful in the study of deep water circulation in the Atlantic.

We thank the many oceanographical institutions which have supplied water samples, and particularly Dr. R. Cox of the National Institute of Oceanography for arranging the collection programme.

Size Analyses of Turbidity Current Sediment

SEDIMENT cores were obtained from the Iberia Abyssal Plain and the Biscay Abyssal Plain[1] on a cruise of R.R.S. *Discovery II* in 1958 organized by the Department of Geodesy and Geophysics of the University of Cambridge. These cores consist of beds of sediment deposited by turbidity currents, which are sometimes only a few cm thick but are more often 50–100 cm thick, and alternating with these beds is normal pelagic sediment, not thicker than about 40 cm. These cores have characteristics similar to those of abyssal plain sediments elsewhere described by Ericson and others[2].

Size analyses were made on two of the beds of sediment which had been deposited by turbidity currents to see how the grain size of the sediment varies with the depth in the bed. Such an investigation is necessary if quantitative studies are to be made on the settling of sediment from a turbidity current. Analyses made by other workers[2] have been only of the fraction of the sediment in which the particles are larger than 74μ. The analyses reported here are of sediment the size of which is in the range 2μ–64μ. The results of the analyses of one of the beds are given here. The position of the core from which the bed came and a summary of its lithology are presented in Table 1.

Table 1. DETAILS OF CORE 3742

Position	41° 22′ N., 14° 32′ W.	
Depth	2,919 fathoms	
Area	Iberia abyssal plain	
Lithology		
	0–26 cm	Brown pelagic sediment
	26–73 cm	Dark grey turbidity current deposit. Sharp contact
	73–100 cm	Light grey ooze, mottled colouring, disturbed. Passes with no sharp break into sediment beneath
	100–242 cm	Dark grey sediment grading down the core to a fine sand-turbidity current deposit

The analyses were made with a Coulter counter which was calibrated with pollen grains of known diameter[3]. The accuracy was estimated from repeated analyses of one sample of sediment. The Coulter counter measures the volume of sediment coarser than a given size with the assumption that all the grains are spherical and these values have been converted to weight per cent by assuming a specific gravity of 2·65. The instrument will disregard all sediment below a certain size; in the work described here the lower limit was for spherical grains having a diameter of 2μ so the results show size analyses for that part of the sediment which has a diameter greater than 2μ.

Two sets of analyses were made; in both sets the sediment was dispersed with sodium oxalate and in the second set carbonates were dissolved with hydrochloric acid. The results are shown in Figs. 1 and 2. Fig. 1 shows the percentage of sediment which is coarser than 10μ and the depth down the bed. The points (*a*) are for samples which were dispersed only, and the points (*b*) for samples which are carbonate-free. Fig. 2*a* shows histograms of the size analyses of the samples in which the carbonates remain and Fig. 2*b* of the samples which are carbonate-free. The percentage of calcium carbonate in three samples from this bed ranged from 23 to 24 per cent by weight.

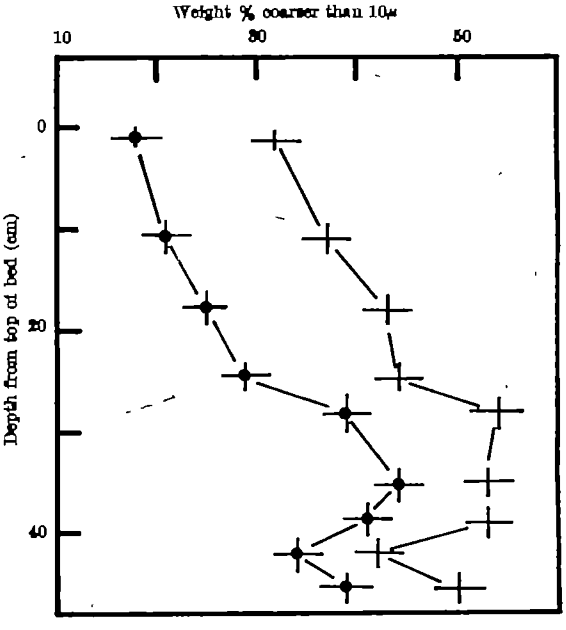

Fig. 1. Weight per cent coarser than 10μ and the depth from the top of the bed (cm). The right-hand curve (*a*) refers to samples which were dispersed only. The left-hand curve (*b*) refers to samples which are carbonate free. The vertical bars show the length of core from which the sample was taken and the horizontal bars represent two standard deviations

These results show that the sediment in the size range above 2μ diameter has a bimodal distribution in most of the samples with carbonates present and in some of the carbonate-free samples. The treatment with acid removes a part of the coarser size fractions. The sediment becomes coarser in grain size for a part of the way down the bed but the changes in size are less regular in the lowest 20 cm. This last feature was also observed in another turbidity

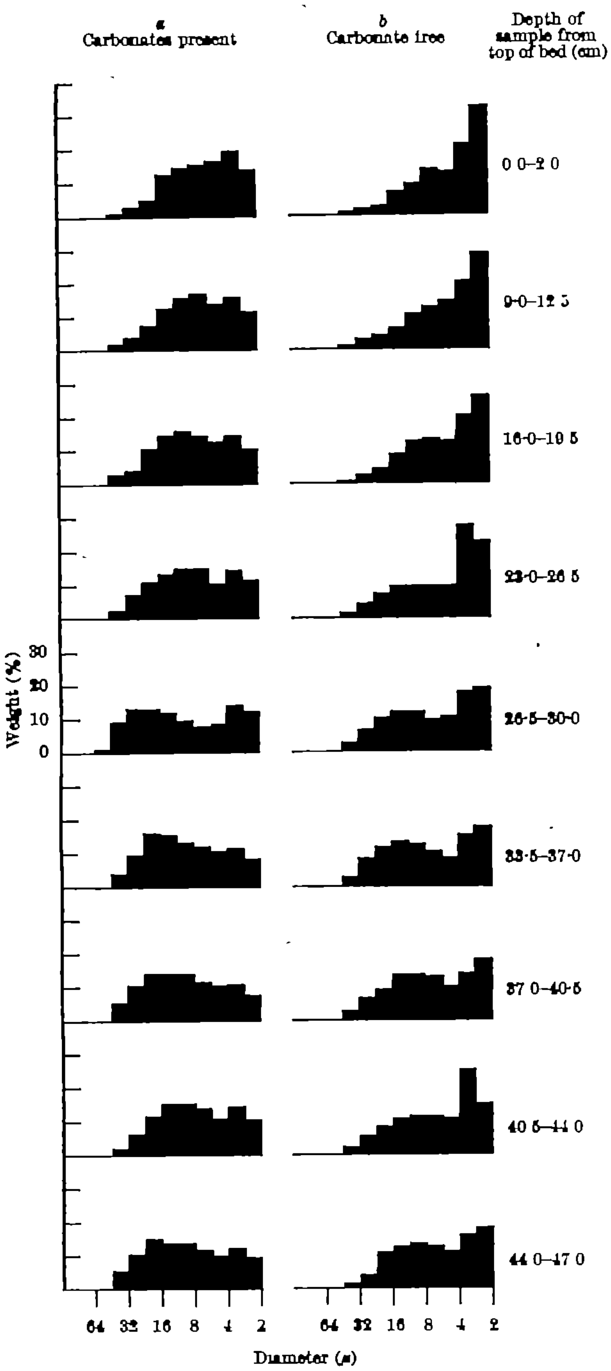

Fig. 2. Histograms of sediment size distribution. (a), Carbonates present; (b) carbonate-free. These histograms are for that part of the sediment coarser than 2μ (see text). They are arranged in order of depth from the top of the bed

current deposit from a second core nearby, analysed in the same way. Pipette analyses and water content determinations in several other beds deposited by turbidity currents also show it. It would be reasonable to expect such a feature if a turbidity current were turbulent at the time that settling of the constituent sediment started, for the change of the size distribution when successive increments were first deposited would not then be regular. If turbulence ceased then the change in size distribution with time would be regular and a graded deposit would result. Particles of 8μ diameter take approximately one month to fall freely through 100 m of water and the time to fall a certain distance increases as 1/diam.[2]; if 100 m is a reasonable figure to take for the thickness of a turbidity current before settling commences then it would seem there is time for any turbulence to cease.

METALLURGY

Hydrocarbons in the Gases evolved from Steel in Vacuum Extraction at 600°C.

THE conventional method of determining hydrogen in steel is vacuum extraction at 600°–700° C. Small specimens are heated, and the gases evolved are pumped off and collected in a suitable measuring system. It is generally accepted that the bulk of the hydrogen present in the steel is evolved under these conditions and that hydrogen is the principal component of the gases. Initially, separation of hydrogen from other gases was considered unnecessary[1], but it has become common practice to pass the hydrogen through a palladium tube or to oxidize it with cupric oxide. The composition of the other gases, which may constitute 10–40 per cent of the total, is unknown. and there are considerable variations in analytical practice with regard to the elimination of moisture by freezing or reduction over ferro-manganese.

Hydrogen may react with carbon in the steel to form methane or other hydrocarbons; such reactions have been postulated within the steel to account for some embrittlement phenomena[2], and at the surface during vacuum extraction analysis to account for decarburization of hydrogen-charged specimens as well as the parallel increase of 'other gases' with hydrogen content in pickling or cathodic charging[3]. Small amounts of methane have been found in the gases evolved at room temperature, especially from welded specimens and at 400° C from pickled specimens[4], but on the rare occasions that the gases evolved at 600°–700° C have been analysed for methane, only about 3–6 per cent was present[5].

In this context it is of interest to record some evidence for the presence of hydrocarbons in the gases evolved in vacuum extraction at 600° C. The equipment used is based on apparatus developed by Bach, Dawson and Smith[6], in which the hydrogen is separated from the other gases by a heated palladium tube. It has two additional features which are of importance here: the gases can be circulated at will over heated ferro-manganese, and there is a freezing cell in the measuring system. Specimens of commercial mild steel wire (¾ in. long, ⅛ in. diam.) were pickled for 24 h in 50 per cent hydrochloric acid, washed, dried, and introduced into the apparatus through a mercury leg. The results for three parallel specimens are given in Table 1.

Evidently, the 'other gases' condense at – 79° C and are decomposed, reduced, or cracked by passage over ferro-manganese, yielding only hydrogen and non-volatile products. Since the volume of hydrogen formed is roughly four times that of the other gas it seems reasonable to postulate a hydrocarbon with 8 hydrogen atoms in the molecule.

Batches of similar specimens were analysed without circulating the gases over ferro-manganese, using the freezing cell in some cases and not in others; the results are summarized in Table 2.

When the freezing trap is not in use, the analysis yields appreciable quantities of 'other gases'; in addition there

Table 1. Vacuum Extraction at 600° C

The difference is significant at 2 per cent level.

is an increase in the hydrogen yield, which suggests partial, and evidently somewhat erratic, cracking of the hydrocarbons in contact with the hot palladium tube.

It can be concluded that hydrocarbons are formed during vacuum extraction analysis for hydrogen in steel, and that precautions must be taken to ensure their complete decomposition, or the hydrogen figures will be too low.

Reactivity of Deformed Metal Surfaces

For the understanding of both boundary lubrication and the effect of environment on mechanical properties, it is important to know what increase, if any, occurs in the reactivity of metal surfaces when they undergo deformation. If an increase in reactivity greater than that due to changes in surface area is observed, it is reasonable to attribute it to the generation of point defects and dislocations in the metal. The relative importance of changes in surface area, point defects and dislocations is still largely speculative and an investigation is being made here to elucidate this.

Small tensile specimens (0·25 in. wide × 0·02 in. thick) were formed from rolled sheets of high-purity copper, iron and aluminium. These were annealed in an argon atmosphere, then etched for a standard time, copper and iron in aqueous nitric acid and aluminium in aqueous hydrofluoric acid. After etching the specimens were washed in water and dried before use. During each experiment the test specimen was extended to a linear strain of 15 per cent in five strain-increments of 3 per cent while immersed in a solution of either stearic acid labelled with radioactive carbon-14 or elemental sulphur labelled with the radioisotope sulphur-35. *Cyclo*hexane was chosen as the solvent because of its low solubility for oxygen; stearic acid and sulphur are typical boundary lubricants. The experiments were generally carried out at a strain rate of 10^{-3}/sec, although some experiments with aluminium were carried out at a strain rate of 10^{-4}/sec. After each increment of extension the test specimen was allowed to interact with the solution for ten minutes and was then

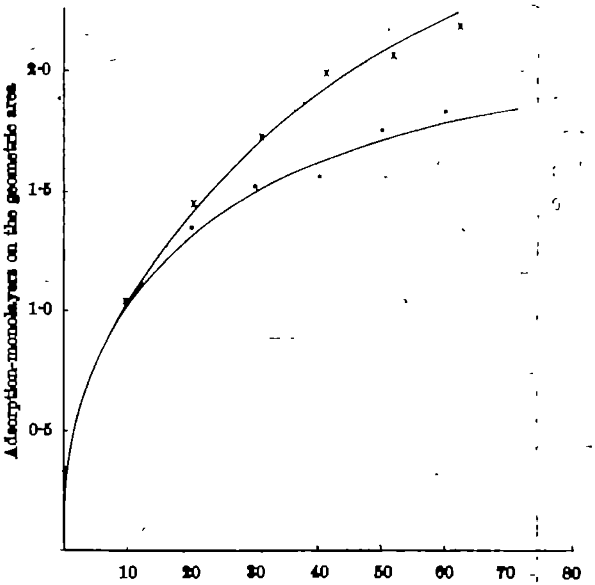

Fig. 1. Adsorption of stearic acid on copper versus time (including extension time). ●, Unextended; ×, extended at 6 per cent/min for 5 periods of 0·5 min

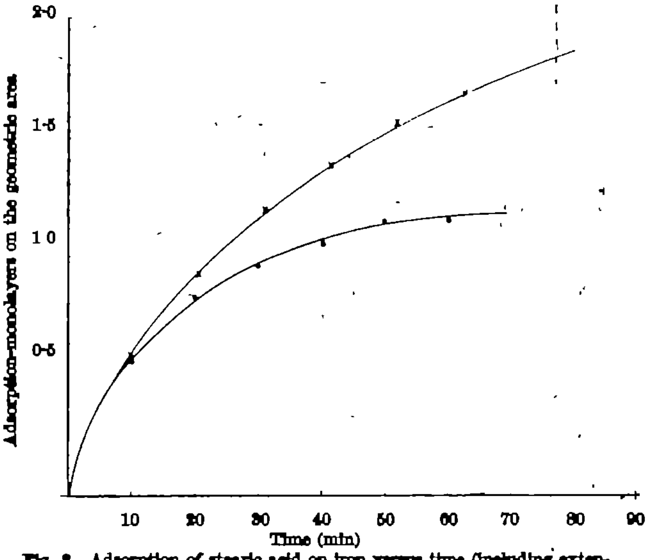

Fig. 2. Adsorption of stearic acid on iron versus time (including extension time). ●, Unextended; ×, extended at 6 per cent/min for 5 periods of 0·5 min

washed in benzene. The amount of reaction or adsorption which had taken place after each extension was determined by measuring the radioactivity on the surface of the specimen. This measurement was made in the centre of the specimen using an end-windowed Geiger-Müller counter of 0·2 in. diameter. Only the results obtained with stearic acid will be discussed here.

Fig. 1 shows the effect of deformation on the rate of adsorption of stearic acid on copper. The increased rate of adsorption on the deformed surface can be seen. Fig. 2 shows the effect of deformation on the rate of adsorption of stearic acid on iron. The increased rate of adsorption on the deformed surface is again evident. All three metals showed enhanced reactivity resulting from deformation and there was an approximately linear relation between the increase in adsorption on the deformed surfaces and the amount of deformation. In the experiments with aluminium the increase in reactivity was most marked if the deformation was carried out at the smaller rate of strain, due perhaps to the development of coarser slip in the metal under these conditions.

The increase in reactivity was not observed in specimens which were extended and then annealed before being allowed to interact with the solutions; the effect is thus not simply one of increased surface area resulting from deformation. Nor was increased reactivity observed in specimens which had been quenched from 600° C into cold water before allowing them to interact with the solutions. Such specimens would contain a large number of point defects; the effect is, therefore, not due to the creation of point defects in the deformed metals.

The effect is similar to that reported by Uhara *et al.*[1], who showed that the ability of copper wire to catalyse the decomposition of diazonium salts was enhanced by torsional deformation. They attributed this to a higher dislocation content of the deformed metal. It seems probable that the increased reactivity found in the present experiments is also due to a higher dislocation content.

CRYSTALLOGRAPHY

Charge-Transfer Complex Crystal Growth at a Solution–Solid Interface

ORIENTED intergrowth (epitaxy) of organic compounds has been reported in many hundreds of cases[1]. Although some examples seem to involve van der Waals forces exerting an orienting effect[2], a more generalized description might be that on a solid surface anisotropic short-range forces can exist which will cause orientation of molecules on this surface.

In an attempt to deposit from solution oriented crystals of an electron donor, 1,4-diaminodurene, on an electron acceptor single crystal, *p*-chloranil, it was found that crystals of the 1 : 1 charge-transfer complex[3,4] were deposited instead. For example, when 6·8 × 10^{-3} M diaminodurene in petroleum ether is placed in contact with a chloranil crystal at 25°, small crystals of the complex are observed to grow first on the surface of the crystal and then on one another. Exhaustion of the amine is substantially complete in one day. Concentrations of amine 5–10 times higher lead to a deposit of amorphous complex; solutions 10 times as dilute gave some colour in solution but no deposit on the crystal.

Similar crystal growth occurs when compacted disks (0·5 g compacted at 3,000 atm. in a 13 mm die) of the amine and the quinone are placed a few mm apart in a poor solvent such as petroleum ether, the residual chloranil tablet becoming covered with a dense network of weakly held, randomly oriented needles of the complex in a few days. A beard-like stubble of crystals appeared on the edge of the chloranil tablet within minutes of submerging the pellets. Nucleation continued, first on the remaining chloranil surface and then by crystals growing on one another.

These observations all suggest that crystal growth is occurring in a small concentrated zone near the least soluble component in solution, but that there is some tendency for orientation to occur on the surface of that component.

In principle, this constitutes a novel technique of growing crystals in a controlled manner. In light of the difficulty of obtaining even small crystals of charge-transfer complexes which are regular enough for structural and electrical investigations[4], this technique of crystal growth is being further investigated. Thus far it appears that the early stages of growth seem to be quite regular but the crystal ends have a distinct tendency to grow two or more parallel spikes, that is, one crystallographic direction is favoured for growth.

CHEMISTRY

Heterogeneous Recombination of Free Atoms

RECENT work by Reeves *et al.*[1] has shown that, under certain conditions, electronically excited molecules of O_2, N_2, NO, etc., can be formed by the heterogeneous recombination of free atoms on a metal surface. In these experiments light emission was observed from the gas just above the metal surface, showing that the molecules formed were desorbed in an excited electronic state. This evidence, and data on the kinetics of heterogeneous recombination[2,3], suggest that this desorption process is very rapid and that the molecules liberated may have excess kinetic energy. In this communication we report on an unsuccessful attempt to obtain evidence for such excess kinetic energy, by comparing the pressure exerted by a mixture of atoms and molecules on a surface where recombination takes place with the pressure on a surface where recombination is negligible.

The apparatus used consisted of metal foil 3 cm long, 1 cm wide and 0·1 mm thick mounted on a thin vertical glass or quartz fibre. Half of each face of the vane was coated with clear glyptal resin, which has a low coefficient for recombination of atoms, the coating being applied so that any differences in apparent pressure on the two types of surface would result in a couple on the vane. Deflexions of the vane were observed by means of a small galvanometer mirror mounted on the centre of the vane. The products of an electrodeless radiofrequency discharge through oxygen, nitrogen or hydrogen flowed vertically past the vane. Total pressures between 0·5 and 2 mm mercury were used, and atom concentrations of up to 20 per cent corresponding to atom flows of up to 8 μmole/sec were obtained.

The atom concentrations were determined by gas phase titration[4,5], and the fraction of atoms recombining on the vane, which was typically 80 per cent, was determined by comparing the intensities of the chemiluminescent emissions associated with the O + NO (ref. 6), N + N (ref. 7) or H + NO (ref. 8) reactions above and below the vane. The sensitivity of the suspension was determined by calculating the moment of inertia of the vane and measuring its period of oscillation when mounted on the fibre. It was possible to detect a difference of pressure of 0·05 dyne/cm^2.

Vanes of silver, copper, nickel and platinum were used; in no case could a deflexion attributable directly to atom recombination be detected, but in all cases there was a slow deflexion with a time constant of about 5 sec (the natural period of the vane-fibre system was about 0·5 sec). This deflexion increased with the atom concentration (but not linearly) and was independent of the total pressure for a given atom concentration. It was concluded that this deflexion was associated with unequal temperatures of the surfaces of the vane due to the heat released by recombination on the uncoated surface of the vane. Such effects have been discussed in connexion with the 'Crookes radiometer'[9,10]. The time constant of the deflexion corresponded to the time for the vane temperature to reach a steady state.

Since the smallest force which could be detected was equal to the force exerted by the atoms which hit the active surface and remained on the surface to recombine, it was concluded that molecules of oxygen, nitrogen and hydrogen formed by recombination on silver, copper, nickel and platinum surfaces do not leave the surface with an average of more than twice the normal thermal velocity.

Heat of Formation of the Difluoromethylene Radical

Majer and Patrick[1] have recently reported a value for the heat of formation of CF_2 which differs appreciably from that reported by Margrave *et al.*[2] and regresses toward values from the older literature. This heat has been deduced from electron impact studies on $C_6H_5CF_3$ and $C_6H_4FCF_3$ and involves the appearance potentials of the $C_6H_5F^+$ and $C_6H_4F_2^+$ ions, respectively. Since those ions are not formed directly from the parent molecules, it is obviously dangerous to utilize appearance potentials for thermochemical calculations of any except the most qualitative nature, and a detailed consideration of the data seems to indicate that − 17 kcal/mole is only a positive limit for the heat of formation of CF_2.

A spontaneous unimolecular rearrangement of $C_6H_5CF_2^+$ to yield $C_6H_5F^+ + CF_2$ in large yield seems improbable but, if this happens, it must involve an excited state of the ion. A cyclic intermediate (7-membered ring) would require the breaking of two carbon–carbon bonds and no doubt a considerable activation energy. If the first step in the fragmentation reaction of $C_6H_5CF_3$ were:

$$C_6H_5CF_3 + e \rightarrow C_6H_5CF_2^+ + F + 2e \qquad (1)$$

and the second step were either a spontaneous unimolecular rearrangement:

$$C_6H_5CF_2^+ \rightarrow C_6H_5F^+ + CF \qquad (2)$$

or an ion-molecule process (highly improbable at the low pressures used):

$$C_6H_5CF_2^+ + F \rightarrow C_6H_5F^+ + CF_2 \qquad (3)$$

then the appearance potential of $C_6H_5F^+$ will be essentially that of $C_6H_5CF_2^+$ since the second and third reactions are undoubtedly exothermic. Majer and Patrick[1] did not consider the possibility of CF as a product. In either case, there seems little chance that the energy liberated in the second spontaneous step could be utilized to help make the first step to go in the normal ionization chamber.

One would estimate the energy needed for ionization of typical fluorocarbons to fall in the range 9–10 eV, and for breaking a C–F bond to fall in the 4–5 eV range[3-5]. The sum of these factors (13–15 eV) compares favourably with the 13·35 eV appearance potential for $C_6H_5F^+$ from $C_6H_5CF_3$, the 13·15 eV appearance potential for $C_6H_4F_2^+$ from *p*-$C_6H_4FCF_3$ and the 13·75 eV appearance potential for $C_6H_4F_2^+$ from *m*-$C_6H_4FCF_3$ as reported by Majer and Patrick[1], and thus tends to support the postulate that the apparent energy required for forming these ions is primarily determined by a reaction like (1) and that the exothermicities of reactions like (2) and (3) or those involving a cyclic intermediate are not being properly considered. Since the dissociation energy for a $C_6H_5{-}CX_3$ bond is approximately 10–30 kcal/mole less than for a $C_6H_5{-}X$ bond, one should correct the appearance potentials accordingly and this yields $\Delta H_f(CF_2) \approx -35 \pm 10$ kcal/mole, in good agreement with earlier work.

There seems to be little support for the 13·35 eV ionization potential of CF_2 reported by Reed and Snedden[6] since this would limit the C–C bond energy in C_2F_4 to a maximum of about 46 kcal/mole, which is much too low and incompatible with the properties of C_2F_4.

Another piece of evidence for a more stable CF_2 radical comes from the patent of Farlow[7], who prepared C_2F_4 from CF_4 and graphite in an induction-heated furnace. From these data, Stull[8] has calculated: $\Delta H_f^\circ = -46 \pm 5$ kcal/mole for CF_2.

Orientation of Benzoic Acid adsorbed on Nickel

THE concept of aromatic systems interacting with metal surfaces has been used to explain data obtained by a variety of techniques. Suhrman and Schulz[1], using thin-film electrical resistance measurements, concluded that electrons are transferred to a nickel adsorbant surface by adsorbed benzene, triphenylmethane and naphthalene. The relatively low heat of adsorption of benzene on nickel powder was interpreted by Yu *et al.*[2] on the basis of the energy needed to destroy the aromatic ring. Blomgren *et al.*[3], in investigating adsorption at the mercury-aqueous acid solution interface using the electrocapillary method, explained the amounts adsorbed as resulting from perpendicular orientations for straight chain aliphatic compounds and parallel orientations for planar aromatic substances. By determining the amount of adsorption from aqueous solution of various aromatic substances on to solid electrodes by bulk-phase depletion measurements, Conway *et al.*[4] concluded that the molecular orientation was probably flat.

Additional evidence to support the hypothesis of aromatic system-metal interaction is given in the present work. The amount of benzoic acid adsorbed per unit of apparent area of nickel surface was determined and used to calculate the molecular area of the adsorbed molecule. Adsorption measurements were also made with stearic acid, a material the orientation of which is assumed to be perpendicular, in order to calibrate the surface. 5×10^{-5} molar solutions of the carbon-14 labelled acids in spectranalysed carbon tetrachloride were prepared. Nickel planchets were then contacted with these solutions by floating them in 20-ml. beakers containing 10 ml. of the solution for a number of periods up to four days. They were then removed, drained, and immediately counted. A correction was made for material that deposited due to evaporation during planchet drainage. The counts were then converted to weights and the molecular areas calculated using these values and the apparent surface area.

The molecular area of the adsorbed acids at equilibrium was found to be 22 ± 3 Å^2 for stearic acid and 44 ± 7 Å^2 for benzoic acid (both at the 95 per cent confidence-level, 20 samples each). The molecular area of benzoic acid, using models[4], is 56 Å^2 at a planar orientation and 20 Å^2 at a perpendicular orientation. Thus, the data indicate an interaction between the aromatic ring and the metal surface even in the presence of the competing carboxylic acid function. It is interesting to note that while the aromatic system is adsorbed when on the same molecule with a carboxylic acid function it does not in any way impair the adsorption of stearic acid on to chrome plate from benzene[5].

Paper Chromatography of Organic Acids

THE identification of non-volatile organic acids on paper chromatograms is usually dependent on the use of a suitable pH indicator which is applied to the developed and dried paper by spraying[1]. This procedure is inconvenient and an even distribution of indicator on the paper is difficult to obtain.

Hartley and Lawson[2] incorporated the indicator in the developing solvent, and in this way obtained an automatically developed chromatogram by simply drying the paper. Of the acidic solvents used by Hartley and Lawson ethyl formate/formic acid/water (12 : 5 : 3) was found to be the best, but even this did not give sufficient separation of those acids commonly occurring in plant tissues (Table 1, col. *A*).

Table 1

Acid	R_F values (20° C) *A* (ref. 2) Ethyl formate/formic acid/water (12 : 5 : 3)	 *B* Butyl formate/formic acid/water (10 : 4 : 1)
Tartaric	0·67	0·21
Citric	0·71	0·24
Oxalic	0·76	0·40
Succinic	0·79	0·56
Lactic	0·84	0·64
Bromophenol blue	0·95	0·90

n-Butanol/acetic acid/water (30 : 5 : 10) has been used as a solvent for paper chromatography of organic acids[3]. In this solvent, however, oxalic acid streaks badly, and the possibility of esterification resulting from the presence of free butanol and acetic acid makes it unreliable.

A solvent in which esterification is not possible has been found to be more satisfactory. The best solvent was found to be *n*-butyl formate/formic acid/water (10 : 4 : 1). Commonly occurring plant acids were readily separated by this solvent (Table 1, col. *B*). It is fast flowing and bromophenol blue can be incorporated in it to give an automatically developed chromatogram.

Five typical plant acids—tartaric, citric, oxalic, succinic and lactic acids—were chosen as reference substances. 50 µg of each acid was spotted 1·5 in. from the edge of a sheet of Whatman No. 1 paper. The solvent was prepared by mixing 10 parts of *n*-butyl formate, 4 parts of formic acid (98 per cent) and 1 part of water by volume. To the solvent was added sodium formate[2] (0·05 per cent w/v) and bromophenol blue (0·02 per cent w/v). Development was by the ascending technique at room temperature. The paper was suspended in a tank, previously saturated by small paper strips dipping into solvent dishes, with the lower edge dipping into a trough of solvent. The development of the sheet took about 4 h, and it was not found necessary to equilibrate the paper in the tank before running.

After the solvent had run a sufficient distance the paper was removed and allowed to dry overnight at room temperature. The acids appeared as yellow spots against a blue background, and all produced well-defined spots with no streaking. Bromophenol blue had an R_F value high enough to show up all the acids examined.

This method has been found to be particularly suited to the identification of acids separated by silica-gel chromatography using gradient elution with *n*-butanol–chloroform. Acids which are eluted together from the column, as for example succinic and lactic acids, are readily separated by the technique. The solvent system is also applicable to many more naturally occurring acids.

Separation of Zirconium and Hafnium by Reversed Phase Partition Chromatography

THE technique of reversed phase partition chromatography is being increasingly used for the separation of metals of similar chemical behaviour. Siekierski and Fidelis[1,2] describe the application of this technique to the separation of the rare-earth metals, using tributyl phosphate absorbed on kieselguhr as the stationary phase, and nitric acid in various concentrations as the eluant. Pierce and Peck[3,4] use di-(2-ethylhexyl) *o*-phosphoric acid on polyvinyl chloride/acetate copolymer ('Corvic'), also for the separation of rare earths. Hamlin *et al.*[5] use tributyl phosphate on Kel-*F* for the isolation of uranium from many metals, while Pierce and Peck[6] use dithizone/carbon tetrachloride/chloroform on cellulose acetate[7] for the isolation of indium. Biochemical separations have also been described[8]. A number of metal separations are described by Cerrai and Testa[9] using trioctyl phosphine oxide on cellulose powder.

It has been shown that a partial separation of zirconium and hafnium can be achieved by solvent extraction from nitric acid solution using tributyl phosphate[10] and that the addition of inorganic nitrates such as sodium nitrate may improve the separation[11,12]. It seemed probable, therefore, that the technique used by Siekierski and Fidelis would give a separation of zirconium and hafnium, using the same stationary phase, tributyl phosphate on kieselguhr, and an eluant containing nitric acid and an inorganic nitrate.

The chromatographic column was prepared according to the method described by Siekierski and Fidelis, except that the dimensions were somewhat larger, namely, 1 cm diameter and 13–15 cm length, using 4·8 g kieselguhr and 3·0 ml tributyl phosphate (column I). Column II was also prepared, with a larger amount of tributyl phosphate (4·8 g kieselguhr and 6·0 ml. tributyl phosphate).

As this investigation was initiated with the object of determining hafnium in reactor grade zirconium (that is, < 100 p.p.m. hafnium) the separation of a small amount of hafnium from a larger amount of zirconium was investigated. 1·0 g hafnium-free zirconium nitrate was dissolved in 24 ml. of the chosen eluant, and 1 ml. of a hafnium solution containing 10 μg hafnium and about 1 μc ^{181}Hf tracer (Radiochemical Centre, Amersham) was added. 5 ml. of this solution was added to the top of the column, and after this had been run through at a flow-rate of about 1 ml./min, elution was continued with the chosen eluant, collecting each successive 10 ml. fraction, which was first counted for ^{181}Hf and then treated with ammonia solution to precipitate the zirconium (and also the hafnium, but the quantity of this is negligible).

Table 1

Eluant	Column No.	Hafnium in eluant fractions	Zirconium in eluant fractions	Separation
5% HNO_3 + 50% $NaNO_3$	I	0–10 ml. 42% 10–20 ml. 35%	2% at 0–10 ml. 10% at 10–20 ml. bulk at 20–30 ml.	some
12.5% HNO_3 + 50% $NaNO_3$	I	0–10 ml. 22% 10–20 ml. 30% 20–30 ml. 18%	10% at 20–30 ml. bulk at 30–40 ml.	some
5% HNO_3 + 50% NH_4NO_3	I	0–10 ml. 44% 10–20 ml. 43% 20–30 ml. 6%	1% at 0–10 ml. 3% at 10–20 ml. bulk at 20–30 ml.	some
10% HNO_3 + 50% NH_4NO_3	I	0–10 ml. 32% 10–20 ml. 33% 20–30 ml. 15%	2% at 0–10 ml. 10% at 10–20 ml. bulk at 20–30 ml.	some
12·5% HNO_3 + 50% NH_4NO_3	I	0–10 ml. 26% 10–20 ml. 47% 20–30 ml. 11%	5% at 20–30 ml. bulk at 30–40 ml.	reasonable
20% HNO_3 + 50% NH_4NO_3	I	0–10 ml. nil 10–20 ml. 93% 20–30 ml. 7%	10% at 10–20 ml. bulk at 20–30 ml.	some
20% HNO_3 + 50% NH_4NO_3	II	0–10 ml. 8% 10–20 ml. 66%.	2% at 20–30 ml.	good
25% HNO_3 + 50% NH_4NO_3	I	0–10 ml. nil 10–20 ml. 75% 20–30 ml. 18%	2% at 10–20 ml. 3% at 20–30 ml. bulk at 30–40 ml.	reasonable
25% HNO_3 + 50% NH_4NO_3	II	0–10 ml. 24% 10–20 ml. 44% 20–30 ml. 20%	1% at 10–20 ml. 2% at 20–30 ml. 5% at 30–40 ml. bulk at 50–60 ml.	good

Table 1 shows the eluants investigated, and the amounts of hafnium and zirconium in the different fractions. It can be seen that quite promising separations of zirconium and hafnium can be achieved, particularly with column II. Quantitative recovery of hafnium does not, however, occur so that any analytical application is limited. It should, however, be possible to use an isotope dilution technique, ascertaining the recovery of hafnium by the addition of ^{181}Hf tracer, and then determining the hafnium spectrographically, after addition of a known small amount of specpure zirconium (for example, 5 mg) as standard and carrier. By this means the lower limit of detection of hafnium in zirconium by the spectrographic method should be reduced by an order of 10, that is, the precision at the normal impurity level (10–40 p.p.m. hafnium in reactor grade zirconium) should be considerably improved.

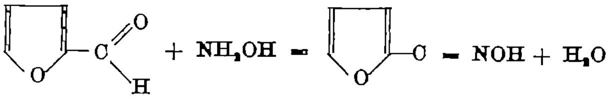
Polarographic Determination of Fural

A NUMBER of chemical and physico-chemical methods for the determination of fural have been devised. The most commonly used are gravimetric determination with phloroglucine[1], photometric determination with aniline[2] and with orcine[3], etc. Polarographic determination based on reduction of the aldehydic group present has also been described[4].

During an examination of potential utilization of some condensation reactions for determination of certain aldehydes significant in food technology[5,6] a new method of polarographic determination of fural was devised; this was based on conversion of fural to oxime, or as the case may be, to a semicarbazide. Fural reacts with hydroxylamine to form fural-oxime, which is very suitable for polarographic determination.



Fural-oxime is reduced on the mercury-drop electrode, and the waves are suitable for analytical evaluation. The condensation of fural with hydroxylamine occurs best in slightly acid medium/Britton-Robinson's buffer pH 1·98 in the medium of 1×10^{-2} N sulphuric acid. In the medium of this sort fural-oxime is reduced in one single well-developed and measurable wave. The half-wave potential in Britton-Robinson's buffer pH 1·98 is $-$ 0·73 V (standard calomel electrode).

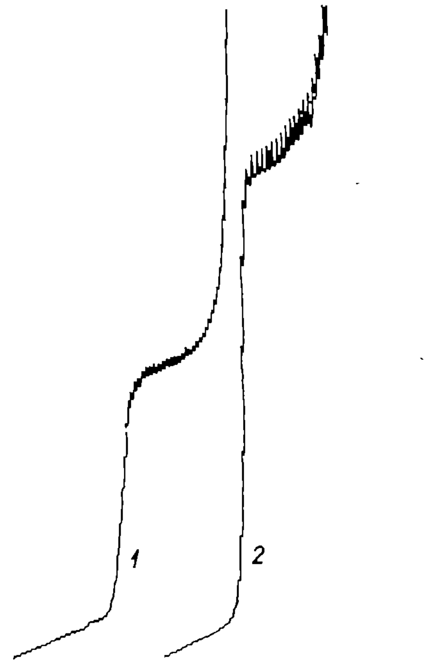


Fig. 1. Condensation of fural with hydroxylamine. (1) 1 ml., 1×10^{-3} N fural solution + 9 0 ml. phosphate buffer pH 7·20; (2) 1 ml. 1×10^{-3} N fural solution + 1 ml. 2 N hydroxylamine hydrochloride, 3 ml. 1×10^{-2} sulphuric acid + 5 ml. water. Mercurosulphate electrode, h, 60 cm, 4 V, sensitivity 1 : 20

The advantage of the method lies above all in that the oxime formed is reduced at a more positive potential in a four-electron wave, while in direct polarography the aldehydic group is reduced but in a two-electron wave. Hence, the method is doubly sensitive as compared with the direct polarographic method. This is of special advantage in analyses of samples with a low fural content, such as is the case with various food materials.

Composition of the Myristicin Fraction from Oil of Nutmeg

The aromatic ether fraction of oil of nutmeg has been previously shown[1] to consist of eugenol (I*a*), isoeugenol (II*a*), safrole (I*c*) and myristicin (I*d*). Vacuum distillation yields a fraction (b.p. 109°–112°/1 mm mercury; 60 g from 1 kg of 'W.I.' oil of nutmeg (George Lueders and Co.)) which consisted of a substance heretofore accepted both chemically[1,2] and pharmacologically[3] as the single compound, myristicin (I*d*).

	3	4	5
a	OCH$_3$	OH	H
b	OCH$_3$	OCH$_3$	H
c	O—CH$_2$—O		H
d	O—CH$_2$—O		OCH$_3$
e	OCH$_3$	OCH$_3$	OCH$_3$

The isomerization of this fraction with alcoholic potassium hydroxide yielded (*trans*) isomyristicin (II*d*), isolated by crystallization of the distilled reaction mixture. The mother liquors of this isolation, on analysis by vapour phase chromatography, provided the first indication of the complexity of the above 'myristicin' fraction. Of the four peaks observed (Fig. 1), No. 1 was easily identified as methyl isoeugenol (II*b*) by its infra-red spectrum and direct comparison to a commercial sample. Peak No. 3 was to a large extent *trans*-isomyristicin not removed by crystallization. The remaining two peaks were isolated using a Beckman Megachrome preparative V.P.C. instrument using a substrate of silicone 710, on firebrick at 220°. The presence of a methylenedioxy group (by nuclear magnetic resonance) and the absence of absorption in the 963–967 cm^{-1} region of the infra-red spectrum of peak 2 strongly suggested that the isomer might be *cis*-isomyristicin. That *trans*-propenyl aromatic ethers possess a characteristic absorption band in the above region (which is transparent for the *cis*-isomer) has been shown for isosafrole[4], anethol[5], isoeugenol, methylisoeugenol[6] and asarone[7]. Further, it has been shown recently[7,8] that the *cis*-isomer of the stereo-isomeric pairs invariably precedes the *trans*-isomer during vapour chromatography. This peak was verified as *cis*-isomyristicin by its conversion to *trans*-isomyristicin (II*d*) and its synthesis from myristicin, both with alcoholic potassium hydroxide.

The fourth peak was also isolated by preparative chromatography and showed the absence of a methylenedioxy group, but the presence of a strong band at 957 cm^{-1}. Isoelemicin (II*e*) was synthesized by the potassium hydroxide isomerization of elemicin[9] and was found to possess an identical infra-red spectrum.

Methylisoeugenol may be assumed to be in the propenyl form in the original sample of nutmeg distillate. There is an unresolved peak at this identical time in the original 'myristicin' fraction, and a search for the logical precursor, methyl eugenol, has been unsuccessful[1].

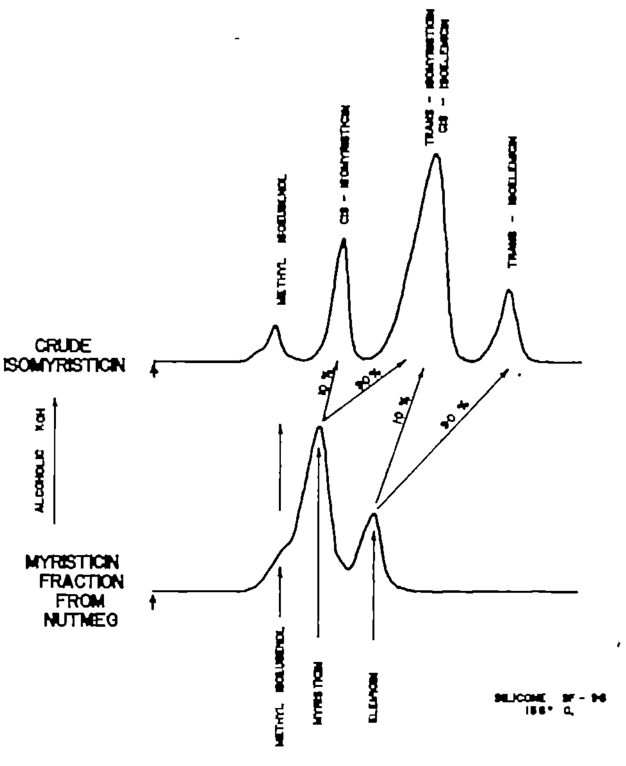

Fig. 1

The implied presence of elemicin (I*e*) in the original myristicin fraction was confirmed by the successful separation of it from myristicin by the low-temperature chromatography (158°, silicone '*SF*–96') as shown in the lower part of Fig. 1. Repeated fractional distillation was ineffective in increasing the myristicin content of this constant boiling fraction over 70 per cent. Consequently, in assigning chemical and biological properties to the substance as isolated from nutmeg allowance must be made for this congeneric contaminant.

Synthesis of some 3-Deoxy-heptulosonic Acids (3-Deoxy-2-keto-heptonic Acids)

A suitable synthesis for 3-deoxy-aldulosonic acids has been published by Kuhn *et al.*[1]. After successfully repeating this work, resulting in the isolation of crystalline 3-deoxy D- and L-*erythro*-hexulosonic acid[2], we investigated the synthesis of some 3-deoxy-heptulosonic acids.

Starting from D-glucose, we followed the procedure as described for the hexulosonic acids (Fig. 1).

By this method the compounds II and III were obtained, both characterized by their spectra. However, we were

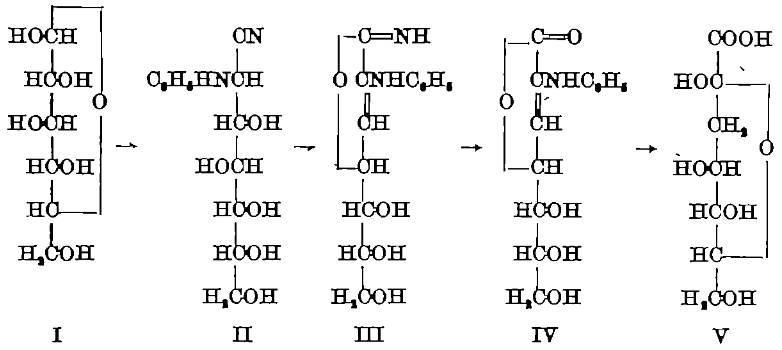

Fig. 1

unable to isolate the intermediate IV. We obtained a syrup in which the acid V was detectable by colour reactions. We did not succeed in preparing the acid in a pure form from this syrup.

After modifying the reaction conditions (treatment of compound III in water at 95°–100° C for 1 h) compound IV was obtained as a crystalline substance (melting point 158°–159° C). The structure was established by micro-analysis and by the infra-red and ultra-violet spectra. Stirring compound IV in water with 'Amberlite *I.R.* 120 H' at 70° C for 40 min afforded a crystalline compound with melting point 167° C (dec.), $[\alpha]_D^{23} = -5{\cdot}8°$ (H_2O; $C = 2{\cdot}8$).

This substance is the lactone of the keto acid (V), as was indicated by micro-analysis and by the absence of a strong acidic reaction. The keto group proved to be enolized, as was shown by potentiometric titration, which revealed the presence of a weak acid (equiv. weight 191·5; calc. 190·2). This agrees with the absence of the typical reactions of the 3-deoxy-2-keto acids, such as the coloration with *o*-phenylene diamine and the periodate–thiobarbituric acid reaction. Furthermore, the structure of the enol-lactone, as given in Fig. 2, was confirmed by ultra-violet and infra-red spectra, bromine consumption, colour reaction with ferric chloride, and consumption of 2 moles of periodate. The ultra-violet spectrum shows a maximum at 229·5 mμ ($\epsilon = 6{,}000$) in acidic solution, which shifts to 261·0 mμ ($\epsilon = 5{,}500$) at *p*H 8. In the infra-red spectrum (in methanol) absorption bands appeared at 1,761 cm⁻¹ (γ-lactone C=O, conjugated with C=C bond), 1,654 cm⁻¹ (C=C). No absorption band of a keto group was present.

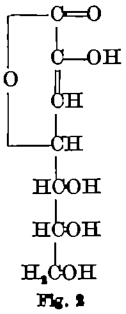

Fig. 2

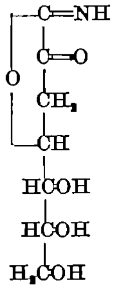

Fig. 3

For comparison we prepared 2,4-dihydroxy-crotonic acid-γ-lactone and its 4-propyl derivative by known methods[3]. These substances show the same characteristic bands in the infra-red (in methanol) and ultra-violet spectra and the same chemical properties. These spectral data are in accordance with reports on analogous compounds[4].

The enol-lactone was also obtained by treatment of the intermediate III with 'Amberlite *I.R.* 120H' in water at room temperature for 4 h. In this reaction a second crystalline substance could be isolated in addition. This material contains nitrogen and is no intermediate, because it could not be converted into the 3-deoxy-heptulosonic acid or its enol-lactone. It probably results from a side reaction. Micro-analysis and the infra-red spectrum showed the structure to be a 1-imino-2-keto-γ-lactone (Fig. 3). Absorption bands at 3,170 cm⁻¹ (N—H), 1,730 cm⁻¹ (C=O), 1,656 cm⁻¹ (C=N) in potassium bromide.

Starting from D-galactose we obtained only the corresponding 1-imino-2-keto lactone, as was established by micro-analysis and the infra-red spectrum.

We thank Dr. J. Bakker and Mr. H. M. van den Bogaert of the Philips Research Laboratory and Mr. F. van Deursen of these Laboratories for the measurement and discussion of the infra-red spectra.

BIOCHEMISTRY

A Sensitive Qualitative Test for Sulphoxides on Paper Chromatograms

A number of sulphoxides have been found to occur naturally in plants[1] (for example, alliin, *s*-methyl-L-cysteine sulphoxide, glucoiberin). To aid in the detection of sulphoxides on paper chromatograms, a specific sensitive test has been devised. The test, which is based on the reaction of sulphoxides with hydriodic acid to form iodine[2], is presented here.

The test is carried out by lightly spraying a chromatogram with an aqueous solution of soluble starch, sodium iodide and hydrochloric acid. The reagent solution is prepared by mixing ten volumes of a solution of soluble starch (5 per cent) and sodium iodide (0·5 per cent) (stable one week in the dark) with one volume of concentrated hydrochloric acid immediately before use. The chromatogram is quickly placed in a desiccator containing dry sodium hydroxide. The paper is supported in an unfolded condition with minimal contact to avoid uneven colour development and artefacts. The desiccator is evacuated with a mechanical pump for 30–60 min in the dark. Sulphoxides are revealed as brown spots which develop slowly in about 15 min. The contrast can be improved by a second spraying with a 5 per cent solution of soluble starch to yield a purple colour.

This procedure is reproducible and sensitive. Methylcysteine sulphoxide can be clearly detected at a concentration of 0·01 μmole per 20 μl. (covering about 3 cm² of Whatman No. 1 paper). Other sulphoxides tested (methionine sulphoxide and glucoiberin) have a similar sensitivity, which is comparable with that of the ninhydrin reaction. Even at high concentration these sulphoxides react slowly, giving a brown colour. The brown spots are stable for several weeks in the desiccator, but disappear within 24 h after removal. The purple colour obtained from the second spraying (5 per cent soluble starch) fades in a few hours.

The protein amino-acids and the common sugars gave no reaction. Neither thioethers nor sulphones gave a positive test. Colour formation with di-*n*-propyl thiosulphinate was consistent with a sulphoxide structure. Dimethyl thiosulphonate, diethyl thiosulphonate and toluene sulphinic acid formed a purple colour immediately (that is, without drying) with about one-tenth the sensitivity of sulphoxides (0·1 μmole/20 μl.). 'Cysteine disulphoxide'[3], which probably has a thiosulphonate structure[4], also reacted without drying, but could be detected only at a concentration of 1 μmole per 20 μl. These results agreed with the known reduction[5] of thiosulphonates with hydriodic acid. A weak positive test was obtained with sinigrin, but the explanation for this reaction is unknown. Strong oxidizing agents such as peroxides, peracids, permanganate and periodate form an immediate purple colour with the sulphoxide reagent. Low concentrations of oxidizing agents react at once or not at all. The test is specific for sulphoxides, since they are the only compounds that give a positive test and do not react immediately.

After chromatography, 0·01 μmole of methylcysteine sulphoxide can be detected on a small chromatogram (18 × 18 cm) and 0·05 μmole on a large chromatogram (56 × 56 cm). The type of solvent used did not affect the sensitivity of the test. However, after chromatography with either phenol/water (8 : 3) or *n*-butanol/acetic acid/water (9 : 1 : 2·5), methionine and methylcysteine spots gave a positive test owing to oxidation during evaporation of the solvent after chromatography. The same effect has not been observed with other thioethers or after the use of basic solvents. To avoid oxidation of methionine and *S*-methylcysteine during chromatography[6], they can be converted to their sulphoxides prior to chromatography[7].

More stable thioethers may be chromatographed as such and then detected as sulphoxides after chromatography by treating the chromatogram in a closed chamber with hydrogen peroxide vapours at room temperature for 30 min, followed by thorough drying.

Subsequent to a sulphoxide test, a ninhydrin reaction can be obtained after decolorization of the spots by placing the chromatogram in an ammonia atmosphere for 1 h. This test has already proved useful in the study of the *in vivo* conversion of *S*-methylcysteine to its sulphoxide in crucifers[8], and in the detection of sulphoxides in plant extracts.

We thank J. F. Carson and F. F. Wong for gifts of dimethyl thiosulphonate, diethyl thiosulphonate and di-*n*-propyl thiosulphinate and A. Kjaer for gifts of glucoiberin and sinigrin. Influence of 5-Bromosalicylhydroxamic Acid on Serum Cholesterol-level

This communication presents the results of clinical experiments on influence of 5-bromosalicylhydroxamic acid (BSH) on serum cholesterol-level. BSH was formerly suggested by one of us as an antitubercular agent[1].

W. Johnson *et al.*[2] have given clinical evidence that BSH is an effective inhibitor of isoniazide inactivation. It is known that this inactivation is the result of acetylation of isoniazide[3]. On the other hand, it is known that acetic acid is a precursor of cholesterol in the rat[4] and the biosynthesis of cholesterol can start from acetate[5].

These two facts led us to examine the activity of BSH on cholesterol-level in blood serum. The substance has been shown to be of low toxicity[1,6,7], and this encouraged us to carry out our experiments directly in clinics.

Twenty patients with high cholesterol blood level (above 200 mg) were given orally 4 g of BSH daily. Within twelve days 9 patients (45 per cent) responded favourably to the treatment, and cholesterol-level was reduced by 8–31 per cent (average 20 per cent) (Table 1).

Table 1

No. of patient	Initial cholesterol-level (mg per cent)	Cholesterol-level after twelve days of treatment (mg per cent)	Reduction of cholesterol-level (per cent)	Cholesterol-level ten days after the treatment (mg per cent)
1	238	174	26·9	212
2	272	193	29·1	220
3	220	193	12·3	—
6	248	212	14·8	212
7	193	138	28·3	—
10	248	171	31·0	264
14	287	264	8·0	287
18	248	217	12·5	230
20	207	172	16 9	241
Average	240 ± 9·9	192 ± 11·9	20 0	238 ± 10·5

Ten days after the end of treatment, the cholesterol-level was again examined in most of the patients and was found to be clearly higher than immediately after treatment. A typical example is given in Fig. 1. This seems to indicate that lowering of cholesterol-level was due to the treatment with BSH.

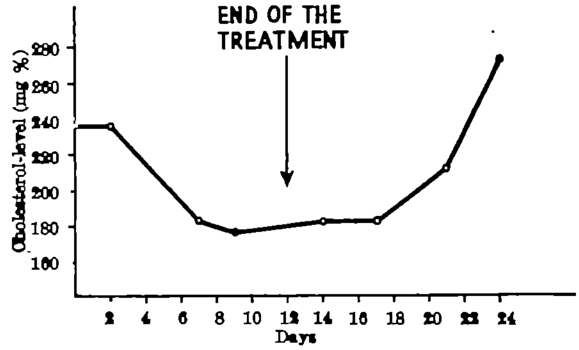

Fig. 1. Influence of BSH (4·0 g daily) on the cholesterol-level in serum

Further experiments will be carried out with the patients which did not respond to the treatment with BSH. In addition to these experiments a number of people with a normal serum cholesterol-level have been examined and their cholesterol, blood sugar and amino-nitrogen in plasma were determined.

The results are summarized in Table 2.

Table 2

No. of persons	Serum cholesterol (mg per cent)			Sugar in blood (mg per cent) (King's method)			Nitrogen of amino groups in plasma (mg per cent) (Frame *et al.* modified by Russel)		
	Hours after the application								
	0	2	4	0	2	4	0	2	4
12	154	167	170	93·5	74 1	78·1	5·1	5·4	5·0
S.E.	±13·3	±14·4	±13·3	±5·1	±2·6	±3·4	±0·17	±0·23	±0 12

It appears that BSH can also slightly raise the serum cholesterol-level in normal persons, and this indicates that

BSH definitely acts on the cholesterol-level, whether it is by reducing or increasing it. The latter seems to characterize cases with a normal cholesterol-level.

BSH certainly reduces the sugar content of blood and it appears that a little increase of amino-nitrogen is possible.

A sedative side-effect of BSH was also noticed in the course of experiments[8].

According to McIsaac and Williams[6] BSH is partly metabolized in the human body into 5-bromosalicylamide. We therefore also examined this substance from the point of view of its activity against hypercholesteraemia. Five patients were treated with 5-bromosalicylamide (2 g daily), but this did not seem to influence the cholesterol-level in blood serum.

Anthocyanins of the Squill

In the course of an investigation of the cardiotonic glycosides and flavonoid content in the squill (*Scilla maritima* L. or *Urginea maritima* Baker), several anthocyanins were identified, we believe, for the first time.

There are two principal varieties of squill: the red, and the white, with intermediate forms[1]. In the many samples examined, we found the following differences in colour: (*a*) completely white in both the innermost and outer tissues; (*b*) cream colour, yellowish or yellow-green; (*c*) red-brown; (*d*) red-violet. When the transverse sections are treated with 2 N hydrochloric acid the changes occur only in groups *c* and *d*; in the others only a few cells appear to be coloured. The changes in colour most frequently occur in the cells which are under the skin.

According to del Amo[2] the squill is distributed in the Iberian Peninsula and Balearic Islands, in populations the individuals of which belong to the same cariological type. We used for our investigation some 250 bulbs collected by him during 1957–60. Cariological determination gives the following distribution for the bulbs collected: 5 populations towards the north of the Ebro River on the coast of Cataluña which are triploid; 25 populations towards the south of the Ebro on the Mediterranean coast, central part of the Peninsula and Portugal which are all hexaploid; 20 populations collected in the Balearic Islands which are tetraploid. Anthocyanin content has also been examined in other related species: *U. undullata* (Desf.) Steinh., *S. obtusifolia* Moris, *S. lilio-hyacinthus* L., and *S. verna* Huds.

Extractions were carried out by immersing the scales in the presence of absolute ethanol, the final alcoholic concentration being 85 per cent; the dry weight of the bulb was approximately 17 per cent. This was repeated until no more colouring matter could be extracted. No hydrochloric acid was added to the extraction liquids; otherwise the anthocyanins can be altered in part, this being indicated by the appearance of a brown streak near the origin in the chromatogram[3]. A glucoside of pelargonidin which exists in some bulbs was also changed by hydrochloric acid. This does not conform with Lamort's views[4], who maintains that pelargonidin and its glycosides are very stable.

The extracts were concentrated in vacuum and banded on Whatman No. 3 paper, directly or after extracting the major part of the cardiotonic glycosides and flavonoids with ethyl acetate and mixtures of butanol/chloroform[5]. The banding was repeated three times for the isolation of the anthocyanins: first with butanol/2 N hydrochloric acid (1 : 1), afterwards with butanol/acetic acid/water (4 : 1 : 5) and finally with acetic acid/water (15 : 85). The anthocyanins were completely eluted with 70 per cent ethanol. For the identification of the anthocyanins, sugars and acylated residues the general techniques were used[6,7].

The most abundant anthocyanin found in the squill varieties examined was cyanidin-3-monoglucoside, free or acylated with caffeic acid. R_F of the acylated pigment: 0·27, 0·38, 0·42 respectively on the solvents mentioned λ_{max} methanol 0·01 per cent conc. hydrochloric acid = 527 mμ (Lange spectrophotometer II). In some cases other unidentified bands of cyanidin glycosides were found, with lower R_F values when alcoholic solvents were used; some of these glycosides seem to be acylated with *p*-coumaric acid. Two populations of tetraploid plants, examined in August, were found to contain a pelargonidin glycoside, in quantities of about 30–40 times less than those of the cyanidin. It ran in the paper as pelargonidin-3-monoglucoside isolated from the carnation, but was very sensitive to hydrochloric acid. The main difficulty for the identification of some of these pigments is due to the presence of lyophilic substances, which separate well in the chromatograms from the cyanidin-3-monoglucoside, and badly from the other pigments. We are trying to achieve this separation using cellulose powder columns with anhydrous solvents.

Table 1. Anthocyanin Content of Squill Varieties expressed as Chrysanthemin (mg/g Dry Weight)

Polyploidy	Date of determination	No. of populations	Chrysanthemin	
			In dark	In light
Triploid	Dec.–Jan.	5	0·00–0·03	1·16–1·76
	May–June	5	0·03–0·18	1·06–1·13
Tetraploid	Dec.–Jan.	8	0·19–1·22	0·57–3·55
	May–June	14	0·06–0·73	0·10–1·60
Hexaploid	Dec.–Jan.	7	0	0
	May–June	12	0	0·00–4·10

The quantitative estimation of the total anthocyanin content of the bulbs was carried out by a colorimetric method (colorimeter Zeiss Elko II, filter *S* 53). The aqueous solutions were made 0·1 N in hydrochloric acid, and the results expressed in cyanidin-3-monoglucoside (chrysanthemin), the same chromatographically isolated pigment used as reference standard. Table 1 records the results of two seasons: in winter when the plants still had leaves, and in late spring when all the leaves were dry. For each population three bulbs of different sizes were examined, immediately after being removed from the earth and after exposing the scales for one month to indirect daylight. When they were exposed to direct sunlight, the anthocyanins were altered after a short time and the scale assumed a brown colour.

Among the bulbs not exposed to light, the greatest content of anthocyanins was present in the tetraploids, which generally are those of greater weight and stronger colour. The triploids contained less and the hexaploids were completely white and contained no appreciable anthocyanins, although small bands of anthocyanins can be seen on the chromatograms. During the seasons mentioned some 60 hexaploid bulbs were examined recently pulled from the earth, only two of which, in the month of May, contained anthocyanins (0·2 mg/g). These results are not given in Table 1 because we have been unable to confirm the cariological determinations.

When the bulbs were exposed to daylight, the anthocyanin content generally increased with the red-violet colour; the white and cream bulbs acquired stronger yellow colour and occasionally yellow-green. From the bulbs examined in these conditions, the lesser increase in anthocyanin content corresponded to some tetraploids; while the relatively greater increase was observed in the triploids. Approximately half the hexaploids remained without offering appreciable quantities of anthocyanins; however, some bulbs examined in May presented the highest content on exposure to light.

No generalization can be made yet on the relation between anthocyanin content and cariological data; we can say that the collected tetraploids were rich in pigments; the hexaploids we found in the central part of Spain were the whitest and the poorest in anthocyanins; the Mediterranean hexaploids when exposed to light generally increased greatly in content of anthocyanins. We have been looking for leucoanthocyanins, but thus far no reactive spots were found when the paper was sprayed with *p*-toluenesulphonic acid.

When the bulbs of the three types were not completely submerged in the ground, or when they suffered some shock, anthocyanins appeared in appreciable quantities. In those exposed to the cold during the winter their frozen parts were red, and rich in anthocyanins including the whitest hexaploids.

Anthocyanins did not appear on the leaves in appreciable quantities, except in the plants grown in darkness, coinciding with the decrease in chlorophyll content. These results are in agreement with those of Kandeler[8], who increased the anthocyanin content in the shoots of red cabbage by the elimination of the chlorophyll with antibiotics. In the other species examined, anthocyanins did not appear, except in the *U. obtusifolia*, which had in the bulbs and in the leaves quantities similar to the tetraploid squills. These plants did not show the Liebermann reaction for cardiotonic glycosides.

We thank A. del Amo for the cariological determinations and for his collection of squill used in this work, and J. B. Harborne for his gift of several anthocyanins.

Neutron Activation Analyses of Snake Venoms: Presence of Copper

LITTLE is known about the mechanism of the spreading of snake venoms through the body of the victim. Duran-Reynals[1] postulated a "spreading factor" in snake venoms, which was identified by Chain and Duthie[2] as hyaluronidase. While the spreading of elapide venoms may be correlated to some extent to their hyaluronidase content, very little[3] or no hyaluronidase was found in viperide venoms.

An attempt was made to follow the spreading of snake venoms in experimental animals by the use of radioactivity techniques. So far *in vitro* labelling of venoms has been reported only with iodine-131 (ref. 4).

Recently, radioactive venoms of a relatively high specific activity were obtained at the Rogoff Medical Research Institute at Beilinson Hospital[5] by *in vivo* feeding of cystine labelled with sulphur-35 to specimens of *Vipera palestinae*.

Neutron activation was used for the detection of trace elements in different venoms, on the assumption that the presence of specific trace elements could be used for tracing and following the path of the venom, or part of it, through tissues of experimental animals.

The only trace element reported in snake venoms is zinc. Concentration in viperide venoms are in the range of 1,000–3,000 p.p.m. (for example, that of *Bitis arietans*, 1,100 p.p.m., and in elapide venoms, 3,000–5,600 p.p.m.)[6]. Since zinc is widespread in animal tissues, the search was directed towards other elements.

Small samples of venom were weighed, sealed in polyethylene vials and irradiated in *IRR*-1 (the Israel Research Reactor at Soreq). The γ-ray spectra of the irradiated samples were determined using a 3 × 3 in. sodium iodide (Tl) scintillation counter and a multichannel analyser. Under these conditions, the only activities observed were due to sodium-24 and chlorine-38. When the venoms were first dialysed several times against water to remove non-protein-bound electrolytes, the activities of sodium and chlorine were considerably reduced. Other γ-ray peaks were observed and their decay was followed. The major peaks were assigned to 5·1 min copper-66 and 12·8 h copper-64, both produced by (*n*,γ) reactions with copper. A more precise assay of the protein-bound copper was carried out by fast radiochemical separation with carrier and β-counting of the precipitated CuCNS. The decay of the β-activity also consisted of two components with half-lives of ~ 5 min and ~ 13 h, due to copper-66 and copper-64 respectively. Fast coincidence measurements of the γ-rays resulting from the annihilation of the positron emitted by copper-64 provided an additional method of analysis and confirmed the results. Since γ-ray spectrometry is hampered by the interference due to the activation of sodium, chlorine and other impurities, most analyses were carried out using chemical separation and β-counting, which has a sensitivity of better than 10^{-9} g copper.

When the relative copper contents of samples were to be compared, the faster, though less-sensitive, method by coincidence counting was used (sensitivity ~ 10^{-7} g copper). This method can be made specific and is non-destructive.

A summary of various results is given in Table 1.

Table 1. COPPER CONTENT OF VARIOUS SNAKE VENOMS

Venom	Treatment	Copper concentration (±10%) (p.p.m.)
Vipera palestinae	dialysed	800
Naja naja	dialysed	1,600
Naja naja	non-dialysed	1,100
Echis carinatus	dialysed	3,900
Bitis arietans	dialysed	3,900

For comparison, the copper contents of normal mammalian tissues range from 10 to 30 p.p.m.[7].

A check on the zinc concentration was carried out using dialysed *Vipera palestinae* venom, which was found to contain 670 ± 10 per cent p.p.m. The zinc was determined by chemical separation of the irradiated sample and counting the β-activity of 52-min zinc-69 in the $ZnHg(CNS)_4$ precipitate.

Variation of the duration of dialysis against distilled water, using different venoms, did not reveal any change in the copper concentration of the protein fraction, which indicates that the copper is firmly bound to the protein.

An ion exchange chromatographic separation of *Vipera palestinae* venom on DEAE cellulose yielded two protein fractions containing the neurotoxin and the hæmorrhagin of the venom respectively[8]. Copper assay of the two fractions, by the coincidence method, showed that the copper was mainly in the neurotoxic fraction.

Activation analysis was also used for the determination of the copper content in various mouse tissues. Attempts to detect an increase in the copper concentration in different organs after the introduction of venom were unsuccessful, due to the dilution of the small quantity of venom (about 1 mg, with copper concentration of about 1,000 p.p.m.), in the larger sample of animal tissue (about 100 mg containing ~ 10 p.p.m. copper). Since the variation in the distribution of the copper within the analysed tissues was about ± 50 per cent, it was difficult to detect extra copper due to the venom, even under optimal experimental conditions, when the muscle containing freshly injected venom was frozen with liquid nitrogen immediately after the injection.

Experiments to detect other trace elements in snake venoms as well as to study the bond strength of the copper in the venom and the distribution of copper in the different venom fractions are in progress.

Enzymatic Reduction of δ-Keto Acids to the Corresponding Optically Active Hydroxy Acids

OPTICALLY active lactones of δ-hydroxy fatty acids contribute considerably to the total character of natural butter flavour[1]. Investigations have shown that there are several micro-organisms capable of producing optically active γ- and δ-hydroxy acids from the corresponding keto-compounds. One of the most suitable micro-organisms for this conversion is *Saccharomyces cerevisiae* or normal bakers' yeast[2,3].

To examine the character of this conversion, the enzymology of the reduction of δ-ketodecanoic acid by *S. cerevisiae* was investigated, part of which is described here.

An acetone powder of *S. cerevisiae* was prepared by dehydrating normal bakers' yeast (Kon. Ned. Gist- and Spiritusfabriek, Delft) twice with 10 parts (v/w) of acetone at −25° C and filtering off the yeast. The last traces of acetone were removed from the yeast *in vacuo*. The powder, together with the keto acid, was incubated in phosphate buffer ($pH = 6·0$) in the presence of, respectively, NAD *, NADP, isocitric acid, fumaric acid, and combinations of the coenzymes and the acids mentioned (Table 1).

Table 1. REDUCING CAPACITY OF AN ACETONE POWDER OF *S. cerevisiae*

Co-factors/co-substrates added	Remaining keto acid (%)	Hydroxy acid found * (%)
Blank	92	3
NAD	95	—
NADP	74	16
NADP + Mg^{2+}	85	9
DL-Isocitric acid	95	?
Fumaric acid	96	—
NAD + DL-Isocitric acid + AMP	97	—
NADP + DL-Isocitric acid	66	22
NADP + DL-Isocitric acid + Mg^{2+}	83	8
NADP + fumaric acid	65	21

* As equivalent amount of keto-acid.

The reaction mixtures contained: 100 mg acetone powder, 0·25 mmole potassium phosphate buffer pH 6·0, 30 μmoles δ-ketodecanoic acid (potassium salt) and the coenzymes/co-substrates indicated here. Total volume: 5 ml. The amounts of co-factors/co-substrates added were: NAD, 1·5 μmoles; NADP, 1·5 μmoles; AMP, 10 μmoles; DL-isocitric acid (tri-sodium salt), 30 μmoles; fumaric acid, 40 μmoles; magnesium chloride, 1 μmole. The mixtures were incubated at 30° C for 3 h *in vacuo*.

After incubation the mixtures were acidified to $pH = 1$ and the keto- and hydroxy-acids extracted from the reaction mixtures with ether. The keto acid was determined spectrophotometrically as the 2,4-dinitrophenylhydrazone in alkaline solution at 530 mμ, and the hydroxy acid as the Fe-(III)–hydroxamic acid complex at 515 mμ.

Table 1 clearly shows the specific need for NADP and the stimulating influence of the DL-isocitric acid and fumaric acid on the reduction when NADP is also present.

A cell-free homogenate of *S. cerevisiae* was prepared by disintegrating bakers' yeast by means of a mechanical shaker of the same type as the destructor used by Nossal[4]; afterwards the intact cells and the cell debris were centrifuged off. The crude cell-free homogenate was fractionated by centrifugation and the various cell compounds (cell walls, mitochondria and 'soluble fraction') incubated with δ-ketodecanoic acid in phosphate buffer (pH 6·0) in the presence of DL-isocitric acid and NADP. These experiments showed that the δ-ketodecanoic acid reducing enzyme (enzyme system) is present mainly in the mitochondria. Experiments with dialysed mitochondria revealed which co-factors were specifically needed for the reduction of δ-ketodecanoic acid to δ-hydroxydecanoic acid. The following co-factors appeared to be absolutely necessary: NADPH, coenzyme-A, ATP and Mg^{2+} (or Mn^{2+}). Hence, the aforementioned reduction takes place via the coenzyme *A*-ester of the keto acid. Since NADPH cannot be replaced by NADH, the reduction appears to be NADPH-dependent. For the specific rotation of the δ-hydroxydecanoic acid lactone, obtained via the reduction of the corresponding acid with isolated yeast mitochondria, an $[\alpha]_D^{20} = + 55·5°$ (in methanol; lactone concentration: 29·3 g/l.) was found which is in agreement with that for the lactone obtained via the reduction with intact cells[2,3]. Hence, the reduction with isolated mitochondria is stereospecific, just as that with intact cells.

The ability to reduce δ-keto acids to the corresponding hydroxy acids, however, is not confined to micro-organisms only; extracts from pigeon liver and ox liver also possess this property so that it may be stated that the enzyme (enzyme system) in question occurs in preparations originating from quite different biological objects. Pigeon liver and ox liver were homogenized in 0·03 M phosphate–carbonate buffer (pH 9·0) at 0° C in a Bühler homogenizer for 30 sec at maximum speed. After filtration through muslin, the crude homogenates were first centrifuged for 15 min at 1,000*g*; afterwards the supernatants were centrifuged for 60 min at 100,000*g* (pigeon liver) and 20,000*g* (ox liver). Of both enzyme solutions obtained, 2-ml. portions were incubated *in vacuo* with 2 ml. 0·1 M phosphate buffer (pH 6·5), 30 μmoles δ-ketodecanoic acid (potassium salt), 1 μmole NADP, 15 μmoles DL-isocitric acid (tri-sodium salt), 0·4 μmole magnesium chloride, and 0·4 μmole manganese chloride, for 3 h at 38° C.

After incubation these pigeon- and ox-liver preparations contained, respectively, 67 and 77 per cent non-converted keto acid and 20 and 7 per cent hydroxy acid. The isolated hydroxy acid was identified by its lactone-flavour after heating the acid *in vacuo*, and by paper-chromatographic analysis of its hydroxamic acid in the systems benzene/isopropylalcohol/water/glacial acetic acid (5 : 2 : 5 : 1) and benzene/water/glacial acetic acid (5 : 5 : 1) both in accordance with Keeney's[5] method. In both cases the R_F-value of the hydroxamic acid spot was in agreement with that of the hydroxamic acid obtained from authentic δ-hydroxydecanoic acid lactone. Moreover, in both cases only one hydroxamic acid spot could be observed on the chromatograms. Although the foregoing is no absolute proof that the reaction product isolated is identical to δ-hydroxydecanoic acid, this is highly probable. Unfortunately, the amounts of lactone obtained were insufficient to determine its rotation.

This work was for the greater part carried out at the Biochemical Department of the Technological University, Delft, under the supervision of Prof. W. Berends.

Deoxyribonucleic Acid Base Composition of Kappa and *Paramecium aurelia*, Stock 51

CERTAIN stocks of *Paramecium* contain cytoplasmic particles called kappa[1]. Kappa-bearing *Paramecia* (killers) are capable of killing other *Paramecia* (sensitives) and are resistant to the toxic agent which they produce[1]. The killer trait requires both the cytoplasmic particles and the dominant *K* gene for the maintenance of kappa, and is one of the most extensively studied examples of nucleo-cytoplasmic relations on a biological level[2-5].

In stock 51, kappa is of two morphological types, the so-called bright particle (which contains a refractile *R* body) and a non-bright particle which lacks this body[4]. The bright particle is associated with its ability to kill sensitive *Paramecia*[4]; the non-bright particle with the ability to convert sensitive paramecia of the proper genotype to killer animals[5]. In different stocks of killer animals, different kinds of killing are exhibited, characteristic of a particular stock; in stock 51, the most extensively investigated killer, the affected animals show an aboral hump before death[1].

The origin and phylogenetic relations of kappa to other organisms, to paramecia, to other cytoplasmic particles of paramecia, and to other DNA-containing particles of other organisms needs to be investigated using as many traits as possible. Since the equivalence of base composition of DNA would seem to be a minimum requirement for extensive base sequence homology and therefore genetic compatibility[6], a knowledge of the average base composition of the DNA of both host and particle might serve as a valuable trait. The present study reports the determination of the base composition of the DNA of kappa, of killer and sensitive *Paramecia*, and of *Aerobacter aerogenes*, used in the cultivation of the *Paramecia*.

The DNA base composition were determined using the caesium chloride density gradient centrifugation technique. The buoyant density of DNA is linearly related to its mole per cent guanine plus cytosine (G + C) content and requires only 1–2 μg DNA in the purified state or as the cell lysate[6]. The samples were each centrifuged together with *Pseudomonas aeruginosa* ^{15}N DNA (used as a reference of known density) in approximately 7 M caesium chloride at 44,770 r.p.m. until equilibrium was obtained in the Spinco Model *E* analytical ultracentrifuge (22 h). The banded DNA was photographed using ultra-violet absorption optics and the negatives traced with a Joyce-Loebl microdensitometer. The results are given in Table 1.

Lysates of killer *Paramecia* showed at least three well-defined bands. Each preparation of kappa (purified by the method of Smith[7]), of the strain of *A. aerogenes* used, and of the sensitive *Paramecia* used (isogenic with the killer, but lacking kappa) gave only a single band. Three bands were found in the lysate of the killer organisms at buoyant densities of 1·715, a minor or 'satellite' band at 1·696, and a major band at 1·689 g/c.c. corresponding respectively to the buoyant density of the single bands of DNA of *A. aerogenes*, kappa, and *Paramecia* found when each was run separately. Using a stock 51 *Paramecia* bearing a mutant kappa particle 51_{m43} (ref. 8) the DNA band of the host (1·689 g/c.c.) appeared to be the 'satellite' band with respect to kappa DNA (1·696 g/c.c.). This is not surprising since these particles are known to reach an average concentration of 3,000 per animal.

Table 1. COMPARISON OF MEAN GUANINE–CYTOSINE CONTENT OF DNA OF KAPPA, *Paramecium aurelia* AND *Aerobacter aerogenes**

	Buoyant density of DNA (g/c.c.)	Percentage G + C	DNA preparation‡
Killer paramecia†	1 716, 1·696, 1·689	56, 36, 29	lysate
A. aerogenes	1·715	56	purified
Kappa	1·696	36	lysate
Sensitive paramecia†	1·689	29	part purified

* The mole per cent guanine plus cytosine content was estimated by density gradient centrifugation of DNA in caesium chloride, using ^{15}N-labelled *Pseudomonas aeruginosa* DNA as the reference (density, 1·742 g/c.c.).

† Stock 51, killer *Paramecia* were grown on 0·15 per cent infusion of baked lettuce plus 0·1 per cent calcium carbonate inoculated 1 day before use with *A. aerogenes* (ref. 12). The *p*H of the medium was adjusted to a value of 6·5–7·5 prior to use; the sensitive animals were cultured axenically (ref. 13).

‡ Lysates were prepared by suspending 1 × 10^{5} *Paramecia*, or 2 × 10^{6} kappa, in 0·1 M ethylenediamine tetraacetate (EDTA) plus 0 15 M sodium chloride, *p*H 8·0, and adding sodium lauryl sulphate to a final concentration of 3 per cent; DNA was purified by Marmur's method (ref. 14).

On the basis of the mole per cent G + C content predicted from the buoyant density of the DNA, the results indicate that the DNA of the *Paramecia* is sufficiently different from kappa that extensive base sequence homology seems unlikely. It should be pointed out, however, that the presence of unusual bases in the DNA could affect the relation of the buoyant density of the DNA and the base composition[6,9]. The possibility of an odd base has not been excluded.

The base composition of the DNA of the *Paramecia* studied was in agreement with the range of mole per cent G + C contents for related ciliated protozoa (22–35 per cent)[10]. The DNA base composition of kappa, which strains gram negative, is close to certain *PPLO* organisms[9] and the cytoplasmic particle (polar bodies) of the flagellate *Strigomonas oncopelti*[11]. Whether these similar base compositions are fortuitous or indicative of a close taxonomic relation is not known at the present time.

Effect of Cortisone on Collagen Formation in the Chick Embryo

CORTISONE given to adult animals decreases the amount of alkali-soluble[1] and neutral salt-soluble[2,3] collagen in the skin. In the urinary excretion of hydroxyproline, however, no effect has been found[4,5]. In the chick embryo, a marked increase in the content of free hydroxyproline occurs in the tissues 6–10 days after a single injection of

1 mg of cortisone acetate[6,7]. However, when cortisone is given to the pregnant rat, the contents of free and bound hydroxyproline in the tissues of the new-born young are decreased[8]. This discrepancy has been attributed to the fact that 1 mg of cortisone greatly reduces the weight of the treated chick embryos and hence the absolute amounts of free and bound hydroxyproline in the cortisone-treated embryos are lower than in the controls, although their content per unit of dry tissue is higher[7]. The present work indicates that cortisone also decreases the content of free hydroxyproline per unit of dry tissue, but when cortisone is given as a single injection, a marked increase later occurs in the content of free hydroxyproline.

In the present work the mode of action of cortisone on collagen formation in chick embryos is studied with respect to the following four fractions: (1) free hydroxyproline; (2) peptide-bound hydroxyproline soluble in 80 per cent ethanol; (3) hydroxyproline soluble in 1 M sodium chloride, insoluble in ethanol, designated as hydroxyproline of soluble collagen; (4) total hydroxyproline. The values for normal embryos and the methods of analysis have been presented in an earlier report[9]. In addition, the proline present in fraction (1) was determined by the method of Troll and Lindsley[10].

After a single injection of 100 µg or 300 µg of cortisone acetate on to the chorioallantoic membrane on the 10th day of development, a decrease in the content of free hydroxyproline and proline per unit of dry matter occurred during the following days (Fig. 1). This first stage is followed by a second stage with an increase in the content of free hydroxyproline. The free proline, however, does not exceed the level of the controls. To exclude the possibility that the increase in the free hydroxyproline might be due to a delay in reaching the maximum observed in the controls on the 14th day of development, a series was made, in which 300 µg of cortisone was injected on the 8th day of development. In this series the values were 55·5 µg per 100 mg of dry weight in the control embryos and 97·3 µg in those treated on the 14th day of development. When an increasing dose of cortisone correlated to the daily weight of the embryo was given daily from the 8th to the 15th day, the contents of free hydroxyproline and proline on the 16th day were less than that of the controls even with a daily dose of 3 µg/g embryo.

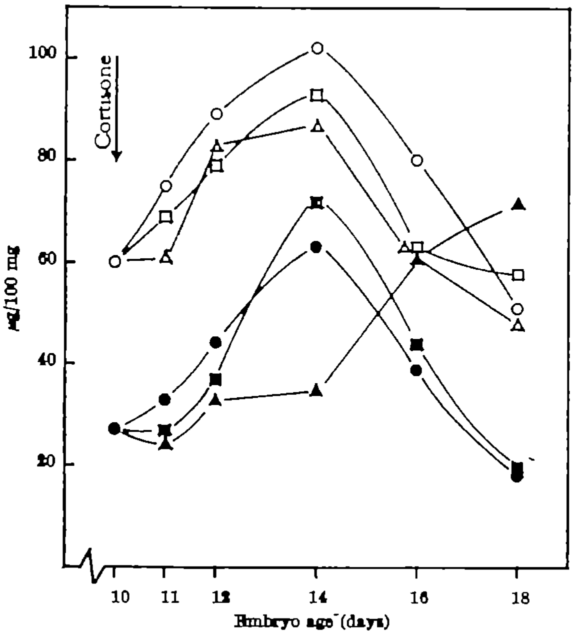

Fig. 1. Free hydroxyproline and proline in µg/100 mg dry substance of the embryo. Cortisone injected on the tenth day of development. Solid symbols, hydroxyproline; open symbols, proline;, ● ○, controls; ■ □, 100 µg cortisone acetate; ▲ △, 300 µg cortisone acetate

No marked change in the content of peptide-bound hydroxyproline was found after the administration of cortisone. Since this fraction was determined as the difference between the values before and after hydrolysis of the ethanol-soluble fraction, the methodical error was rather large. Therefore possible small changes in this fraction could not be detected.

The administration of cortisone as a single injection had no significant effect on the hydroxyproline of soluble collagen during the four following days when this was expressed per unit of dry matter. However, when this value was expressed as a percentage of the total hydroxyproline, a decrease was observed. When analysed six to eight days after the cortisone injection, the content of soluble collagen per unit of dry matter was increased, but this increase was much smaller than that of the free hydroxyproline. When cortisone was administered daily from the 8th to 15th day, the content of soluble collagen on the 16th day was below that of the controls even when expressed per unit of dry matter.

In all series the content of total hydroxyproline, expressed per unit of dry matter, increased after cortisone. Since even the smallest doses of cortisone used in this work slightly decreased the weight of the embryos, it seems possible, as suggested by Chvapil[7], that the increase is not real, but due to a decrease in the amount of substances other than collagen.

PHYSIOLOGY

A Common Pathway for Uptake of Glycine and Proline in Various Living Cells

COMPETITION experiments with various amino-acids suggested several pathways for re-absorption of these compounds in dog kidney tubules, namely, concerned with: (*a*) arginine, histidine and lysine; (*b*) leucine and isoleucine; (*c*) glycine transport, respectively[1].

From the excessive excretion of the basic amino-acids, ornithine, lysine and arginine, as well as cystine in human cystinuria, a common pathway in the human kidney was suggested for these analogues[2]. This concept was confirmed by intravenous injection of lysine into non-cystinuric subjects when an 'artificial' cystinuria ensued[3]. Intravenous glycine had no such effect[3].

From similar infusion experiments a second re-absorption pathway, shared by glycine, proline and hydroxyproline, has been inferred for human renal tubules. This system has a higher preference for the two imino-acids than for glycine itself[4]. The excessive excretion of most of the protein amino-acids in Hartnup disease, with the exception of glycine and proline[5], is compatible with this hypothesis, that is, the glycine–proline pathway is relatively unaffected in this hereditary condition but the transport pathways for other amino-acids are faulty in the renal tubules[6].

The experiments reported here were designed to examine the competition of proline in glycine uptake in another type of mammalian epithelium, that is, mucosa of small intestine. The everted sac *in vitro* technique[6] was used with male albino rats. Uptake of glycine was measured spectrophotometrically with ninhydrin[7]. Proline did not interfere with the glycine estimations under the experimental conditions. The concentration ratio was calculated as the fraction:

$$\frac{\text{Concentration of glycine on the serosal side}}{\text{Concentration of glycine on the mucosal side}}$$

that is, a ratio greater than 1·0 indicates active transport against a concentration difference.

Table 1. GLYCINE AND PROLINE UPTAKE BY EVERTED INTESTINAL SACS

Test compound	No. of sacs	Concentration ratio of glycine	Rate of transference of glycine (µM/100 mg fat-free dry wt./h)
Glycine (20 mM)	10	1·36 ± 0·06	4·21 ± 0·03
Glycine (20 mM) + proline (20 mM)	12	1·19 ± 0·07	2·65 ± 1·16

Uptake of glycine was reduced by the presence of L-proline when present in equimolar amounts (Table 1). The values reported were statistically significant at the 0·1 per cent level. Inhibition of glycine uptake by proline has been demonstrated previously with hamster intestine[8]. It is of interest that L-proline has the greatest affinity for the glycine uptake system of Ehrlich ascites tumour cells of all the compounds tested[9]. Hence this competitive effect is seen in three very different systems, namely, the renal tubules, intestinal mucosa and free-living tumour cells. Therefore, it seems likely that glycine and proline share a fundamental and primitive transport pathway in living tissues. In kidney at least the glycine–proline pathway is apparently under genetic control, transmitting as a recessive character[4,10].

Supersensitivity of Aqueous Outflow Resistance in Rabbits after Sympathetic Denervation

THE fall in intra-ocular pressure in patients with glaucoma simplex following topical epinephrine therapy has been noted repeatedly[1–3]. Recent tonographic analysis related this effect primarily to an increase in the facility of aqueous outflow although initially some small reduction in aqueous secretion may take place[4–6]. The mechanism by which the change in facility occurs is not known. Since tissues chronically deprived of their effector nerves develop an increased sensitivity to the neurohumoral transmitter, denervation experiments were performed to investigate the specificity of the response of outflow resistance to adrenergic influences.

Forty New Zealand albino male rabbits, weighing 2·0–2·5 kg, were subjected to right superior cervical ganglionectomy under thiopental sodium (Abbott) anæsthesia. One week later the animals were divided into three groups. The first group consisted of animals the eyes of which were given a 10-µl. injection of lævo-noradrenaline bitartrate in varying concentrations into each anterior chamber. The second group received a 10-µl. injection of lævo-noradrenaline bitartrate into each vitreous cavity. The third group consisted of saline-injected control animals. Injections were made with a calibrated Hamilton precision ground syringe and a 30-gauge needle. 2–3 h after injection, the intra-ocular pressure and outflow facility were measured after the technique of Sears[7] and Sears and Barany[8]. The animals were first anæsthetized with intravenous urethane (ethyl carbamate, Merck) and the eyes cannulated by means of a spring and trigger device[9]. Intra-ocular pressures were recorded using a Sanborn electromanometer system and the facilities of aqueous outflow were determined by measuring the steady-state increase in intra-ocular pressure caused by infusion of 2·0 µl./min of normal saline simultaneously into the anterior chamber of both eyes.

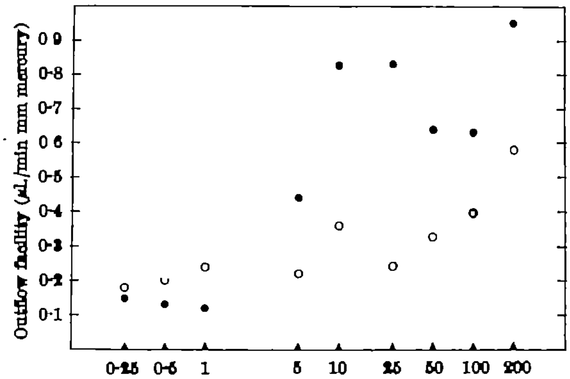

Fig. 1. Response of outflow resistance to adrenergic agents. ●, *RE*, denervates; ○, *LE*, normal

The effects of intra-vitreal injections of 1-noradrenaline on outflow resistance are indicated in the log dose response curve (Fig. 1). 3–6 animals were examined at each dose-level. In response to 1-noradrenaline there was a marked increase in outflow facility on the denervated side. A progressive increase in outflow facility occurred on the normally innervated left side. The latter effect was appreciable only at levels greater than 25 µg. On a molar basis, slightly higher doses were required to produce similar effects with 1-adrenaline. Isoproterenol was more effective (1·5 times) than either 1-noradrenaline or 1-adrenaline at lower doses. At higher levels of isoproterenol, the resistance-lowering effect was less marked on the denervated side, although greater effects were achieved on the normal side than with either 1-adrenaline or 1-noradrenaline. Intra-vitreal injections of 1·0 µg 1-noradrenaline bitartrate and less did not significantly affect the outflow resistance. At these levels the resistance on the denervated side was higher than on the normal left side as in the control saline injected animals (*RE* 0·16 ± 0·02, *LE* 0·24 ± 0·03 µl./min, mm mercury, $n = 6$, $p = 0·05$). Since no catecholamines could be recovered from the denervated eyes, while in control eyes the total catecholamines averaged 0·74 µg/g (ref. 10) iris and ciliary body, it is probable that the homolateral increase in outflow resistance noted one week after ganglionectomy is related to a decrease in (or absence of) the continuous release of adrenergic substances acting on the trabecular meshwork. Studies testing this hypothesis are in progress.

Anterior chamber injections could produce effects equal to those after vitreous injection in approximately 1/500 the intra-vitreous concentration. No definite resistance lowering effects were noted below 5·0 mµg with intra-cameral injection.

This work complements the studies of Barany[11], who noted that pretreatment with systemic reserpine prevented the resistance lowering effect resulting 24 h after superior cervical ganglionectomy. Further, α blockade accomplished by anterior chamber injection of phentolamine and phenoxybenzamine similarly reduced or prevented the 'ganglionectomy effect'. This finding suggested that the locus of action for 'α' active adrenergic material is on the trabecular meshwork. In the work reported here no effect was noted after an intra-vitreous injection of 1·0 μg of 1-noradrenaline bitartrate. By contrast, marked effects were noted with only 20 mμg after anterior chamber injection. Considerations of diffusion, protein binding, and degradation will of course necessitate high intra-vitreous dosage. The great sensitivity demonstrated with anterior chamber injection, however, would tend to exclude ciliary muscle and/or vascular effects to explain the resistance changes, and place the site of action in the trabecular meshwork.

Evidence for β or inhibitory adrenergic effects on the trabecular meshwork are inconclusive at the present time. Attempts to reproduce the elevated outflow resistance found one week after ganglionectomy using isoproterenol, a high β active material, showed that at low dose-levels isoproterenol acted more like noradrenaline, a strong α and a weak β stimulator. It is possible that at higher dose-levels, isoproterenol did have both β and α activity since the drop in outflow resistance was less than that which occurred with noradrenaline.

Parallel clinical studies of outflow resistance in patients with Horner's syndrome[12] also show a greater outflow facility on the homolateral side. The outflow resistance is further decreased after topical epinephrine bitartrate. Essentially similar results have already been reported by Krishna[13], who made a pharmacological denervation with topical guanethidine and noted a further reduction in intra-ocular pressure and outflow resistance when topical epinephrine was added.

Distribution of Precorticotrophin in Blood

IN previous communications[1–3] the existence of precorticotrophin—a precursor of corticotrophin—was demonstrated in the anterior pituitary tissue of the ox. Later, I[4] reported the presence of a material behaving like precorticotrophin in normal rabbit blood serum. Young[5] observed that the insulin-like activity of the serum or plasma from arterial blood, or from blood oxygenated *in vitro*, was higher than that of serum or plasma from comparable venous blood, or blood deoxygenated *in vitro*. In view of this, it appeared worth while to investigate the presence of precorticotrophin-like material in sera obtained individually from arterial and venous blood.

Blood collected from carotid artery and from jugular vein of normal male rabbit under 'Nembutal' anaesthesia was allowed to stand overnight in a refrigerator. Next day sera were collected and freeze-dried. Just before the experiment each serum sample was dissolved in distilled water such that 1 ml. of the solution corresponds to 1 mg of the sample. A portion of such solution was next treated with urea in such an amount that its concentration was 6 M with respect to its final volume. Corticotrophic activity of both portions of solutions, untreated and urea treated, was determined by the Sayers method as used in the previous investigation[4].

Table 1. MEAN SAYERS ACTIVITY OF ARTERIAL AND VENOUS BLOOD SERUM OF NORMAL RABBIT

Group	Treatment	Mean adrenal ascorbic acid depletion (mg/100 g) ± *S.E.*
A	Saline only	35·8 ± 10·45 (15)*
B	Standard ACTH† solution (10 mμ/ml.)	77·2 ± 15·91 (6)
C	Arterial serum	37·0 ± 10·08 (20)
D	Arterial serum urea treated	75·1 ± 8·74 (20)
E	Venous serum	62·7 ± 9·81 (12)
F	Venous serum urea treated	53·3 ± 14·22 (12)

* Figures in parentheses indicate total number of observations.
† Gift of standard ACTH from Dr. D. B. Ghosh, director, Central Drug Laboratory, Calcutta, is acknowledged.

Table 1 shows the results obtained in the Sayers test when the test animals were injected intravenously with different test solutions at a dose of 0·25 ml./100 g body-weight. It is found that the response produced in the Sayers test by the arterial serum (Group *C*) is of the same order as that produced by saline only (Group *A*). But the response produced by the urea-treated arterial serum (Group *D*) is significantly higher ($0·001 < P < 0·01$) than that produced by untreated arterial serum (Group *C*). This indicates the presence of a precorticotrophin-like material in the arterial serum. On the other hand, venous serum untreated (Group *E*) compared with the group on saline only (Group *A*) appears to possess slight, although not significant ($P < 0·40$), activity in the Sayers test; such activity is not enhanced further after treatment of the venous serum with urea (Group *F*). It therefore appears that the precorticotrophin-like material which was reported earlier to be present in circulation[4] is demonstrable only in arterial but not in venous blood serum. Further, it explains, at least partly, the controversy that exists regarding the presence of corticotrophin in blood.

I thank Prof. F. G. Young, who suggested this investigation, and also Dr. B. Mukerji and Dr. A. B. Kar, of this Institute, for their advice.

Preparation of Antisera to Human Follicle-stimulating Hormone

WE have previously reported the preparation of antisera to fractions of human pituitary follicle-stimulating hormone which inhibited the activity of homologous antigens in mice and agglutinated red cells coated with the antigens, but they were ineffective against human chorionic gonadotrophin in rats[1]. The antisera have since been found to cross-react with human chorionic gonadotrophin in the red cell technique and when absorbed with human chorionic gonadotrophin they no longer agglutinated red cells coated with follicle-stimulating hormone. The antibodies, therefore, are not specific for follicle-stimulating hormone and we have now prepared antisera to new fractions.

The method of fractionation was by starch-gel electrophoresis, which is described fully elsewhere[2]. The segment of gel containing the follicle-stimulating hormone activity was eluted in saline, mixed with bentonite and given intravenously to rabbits or intraperitoneally to mice. The total dose given to rabbits was equivalent in biological activity to about 12,000 mg of the reference preparation *HMG*24; the dose given to mice was about 1,500 mg equivalents.

In vivo experiments showed that doses down to 0·025 ml. of these antisera inhibited the activity of homologous antigens in mice. *In vitro* tests were performed by the hæmagglutination method using tanned sheep red cells coated with follicle-stimulating hormone. The titres of the antisera varied from 1/200 to 1/1,600 and were reduced only slightly after absorption with human chorionic gonadotrophin. This was in striking contrast to the behaviour of antisera prepared to the follicle-stimulating hormone before electrophoresis. The reaction between the absorbed antisera and red cells was now inhibited by preparations of follicle-stimulating hormone (down to 0·3 μg/ml., equivalent to 1 mg *HMG*24/ml.) but not by human chorionic gonadotrophin (highest level tried was 100 μg/ml. containing about 100 I.U./ml.).

It thus appears possible to produce antisera to follicle-stimulating hormone suitable for immunological assay. The correlation of results obtained by this method and by bioassay will be reported elsewhere.

Cholinesterase and Glutamic Decarboxylase Levels in the Brain of the Hibernating Hamster

LITTLE information is available concerning the biochemistry of the brain of the hibernating animal although a considerable amount of data has been reported concerning the electrophysiology. Hibernating animals respond to stimuli with cries, positional changes and arousal[1]; but conspicuous activity was reported to be absent in the electrocorticogram of the golden hamster (*Mesocricetus auratus*) during arousal until body temperatures reached 19°–21° (ref. 2). Recordings from sub-cortical areas showed electrical activity at lower temperatures to be largely confined to the limbic system[3], while in the awakening European hamster (*Cricetus cricetus*) there was a sequence of increasing electrical activity with rising body temperature from mesencephalon to neocortex[4]. Cortical and sub-cortical neuronal activity has been recorded in the ground squirrel during deep hibernation, but only at 10 per cent of the amplitude found in the awakened brain[1]. It therefore seemed of interest to determine whether changes in enzyme systems of particular significance to the nervous system, such as cholinesterase and glutamic decarboxylase, occurred in the hibernating brain concomitantly with these electrophysiological phenomena.

In the work reported here adult male golden hamsters were housed at 5° in individual cages with food and water *ad libitum*. After entering deep hibernation for at least the second time the hamsters were killed by decapitation, the brains removed and homogenized, and the enzyme assays performed. Control animals which had never hibernated were housed at 21°.

Enzyme assays were performed in duplicate on the homogenates. Cholinesterase was measured by Albers's modification[5] of Gal's acetylthiocholine method[6] in which the homogenate was incubated with acetylthiocholine chloride, the reaction stopped by the addition of four volumes of 6 per cent perchloric acid, the sample centrifuged, and the absorbancy of the supernatant solution measured at 227 mμ. Results are expressed as the mean of the differences between these values and non-incubated controls per mg of tissue protein after a standard dilution of the incubation mixtures. Glutamic decarboxylase was measured according to Albers and Brady[7] with the addition of 2×10^{-3} M arsenite to block catabolism via α-ketoglutarate. In this procedure the formation of $^{14}CO_2$ from glutamate-1-^{14}C was measured. Data are presented in terms of mean value of radioactivity in the recovered $^{14}CO_2$ above non-incubated controls per mg of protein. Protein was measured according to Lowry *et al.*[8]. Significance was determined by the Fisher *t* test.

Preliminary studies indicated that measured activity in a given preparation was proportional to the protein content of the homogenate within the range used in these investigations and that the rate of the reactions was roughly constant during the incubation periods.

Table 1. CHOLINESTERASE ACTIVITY IN BRAIN HOMOGENATES FROM HIBERNATING AND NON-HIBERNATING GOLDEN HAMSTERS

Condition of animals (and No.)	Incubation conditions Temperature	Duration (min)	Mean decrease in absorbancy at 227 mμ/mg protein	Significance
Hibernating (5)	30°	20	0·757 ± 0·112	$P < 0.05$
Non-hibernating (5)			0·863 ± 0·035	
Hibernating (5)	21°	45	0·990 ± 0·102	$P < 0.15$
Non-hibernating (5)			1·136 ± 0·144	
Hibernating (5)	10°	45	0·520 ± 0·104	$P < 0.01$
Non-hibernating (5)			0·712 ± 0·138	

Table 2. GLUTAMIC DECARBOXYLASE ACTIVITY IN BRAIN HOMOGENATES FROM HIBERNATING AND NON-HIBERNATING GOLDEN HAMSTERS

Condition of animals (and No.)	Incubation conditions Temperature	Duration (min)	Mean radio-activity of $^{14}CO_2$ produced/mg protein (c.p.m.)	Significance
Hibernating (5)	30°	20	164 ± 18	$P < 0.01$
Non-hibernating (7)			123 ± 22	
Hibernating (5)	21°	30	131 ± 42	$P < 0.05$
Non-hibernating (7)			86 ± 23	

Cholinesterase activity, assayed at 30°, was depressed 14 per cent in the hibernating brain (Table 1) while determinations at lower temperatures, where the scatter of the data was greater, gave roughly similar results. The decrease in activity, although small, is consistent with the relative electrical silence of the hibernating cortex[2], an area with a high concentration of cholinesterase in the non-hibernating animal[11]. Adaptive changes in brain cholinesterase activity have been demonstrated under other experimental situations[12,13]. Further, a recent study has shown a marked increase in sensitivity of hibernating hamsters to a cholinesterase inhibitor[14].

Glutamic decarboxylase activity, however, was 30 per cent higher in the hibernating brain (Table 2). The data were insufficient to determine whether this change was due merely to variation in enzyme concentration or to alteration of the energy of activation of the enzyme, as has been demonstrated with preparations from hibernating heart[9,10]. The product of glutamic decarboxylase, γ-aminobutyrate, has been implicated in the nervous system as an inhibitory agent and as a participant in energy metabolism through the γ-aminobutyrate shunt[15]. Examination of oxygen consumption and anaerobic glycolysis have shown little difference between brain slices from hibernating and non-hibernating golden hamsters[9], although conflicting results have been reported from other species[16,17]. The postulated role of γ-aminobutyrate as a regulator of neuronal activity[18], and its ability when administered topically to the cortex to augment certain electrical activity while repressing others[19], is compatible with the present findings.

Effects of Intracarotid Injection of Hypertonic Saline on Spinal Reflex Excitability

DURING the past few years[1] we have been able to demonstrate that increasing the extracellular osmotic pressure by subcutaneous injection of hypertonic saline not only induces thirst and drinking in the rat, which has been extensively studied by others[2], but also produces an increase in the responsiveness of the animal and a relatively intense facilitation of previously learned thirst-associated simple motor acts[3] like running through an enclosed alley. The purpose of the present series of experiments was to measure this facilitatory effect in terms of an electrophysiological change in the final common path involved in the expression of this behaviour.

Changes in the amplitude of the monosynaptic spike in the cut fifth lumbar ventral root reflex discharge in response to appropriate low threshold, fast conducting afferent stimulation in cut muscle nerves of the hind leg served as a measure of this effect as a function of time following intracarotid injection of small amounts of hypertonic saline. Rats were prepared under ether anaesthesia, fixed to a rigid supporting apparatus, and were then switched to 'Flaxedil', 2 mg/kg administered intravenously, to prevent movements and were maintained on artificial respiration. The experiments were carried out 2½–3 h later. A large portion of the back and the hind limbs were deafferented by cutting the lumbar spinal roots. Reflex discharges were recorded through silver wire electrodes under paraffin oil at a cord temperature 37·5° C in response to rectangular pulses, 0·01 msec in duration, applied to the appropriate afferents. Afferent input was monitored by recording from the dorsal root close to the spinal cord. Potentials were amplified and recorded by means of Tektronix 122 pre-amplifiers, a 532 four trace oscilloscope, and a Grass C4D kymograph camera. Blood pressure was monitored in the femoral artery by means of a Statham *P23 AC* pressure transducer and a Grass pre-amplifier and polygraph.

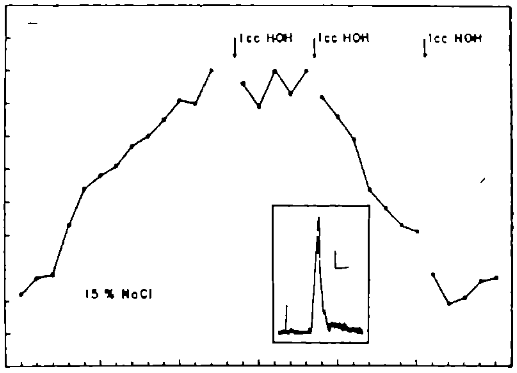

Fig. 1. Percentage change in lumbar (5) ventral root reflex discharges relative to the pre-injection mean value following a 1·0 c.c. intracarotid injection of 15 per cent sodium chloride, and successive 1·0 c.c. injections of distilled water. The lower tibial was stimulated ¼ sec and each point in the figure is the mean amplitude of 15 successive responses. The inset illustrates a typical monosynaptic reflex discharge. Calibration: 0·2 mV vertical, 1 0 msec horizontal

Results are presented in Fig. 1 where the percentage change in amplitude of the monosynaptic reflex discharge (relative to the pre-injection mean value) following a 1·0 c.c. intracarotid injection of 15 per cent sodium chloride, and successive 1·0 c.c. injections of distilled water, are plotted as a function of time in min. Solutions were injected at the rate of 0·02 c.c./sec. Monosynaptic reflex discharges were elicited by stimulating the lower tibial nerve at a frequency of 1/4 sec. Each point in Fig. 1 is the mean amplitude of 15 successive responses. The effect is quite pronounced and reversed by the injection of distilled water. The inset in Fig. 1 illustrates a typical monosynaptic reflex discharge. Within limits the intensity and duration of the effect depend on the amount of sodium chloride injected. It also occurs when other small nerves like the lateral and medial gastrocnemius are stimulated. The threshold is approximately 0·05 c.c. of a 3 per cent sodium chloride solution. A 0·15 c.c. of 9 per cent sodium chloride produces a facilitation which endures for 25 min. The effect occurs in adrenalectomized rats and cannot be attributed to changes in blood pressure, heart rate, or to an increase in the afferent input. It does not occur in spinalized animals. The effect occurs very rapidly, almost immediately, even with small volumes and weak concentrations, and is mediated centrally through a supraspinal mechanism. Small volumes of isosmotic concentrations of glucose and urea produce a very slight facilitation and increase the variability in amplitude of the reflex discharges. Distilled water depresses reflex excitability and at times increases the variability. Rat Ringer's solution produces a slight facilitation. Serum produces a slight facilitation and then depresses excitability. Because of the possibility of a significant difference in diencephalic temperature (the diencephalon is known to contain thermoreceptors which respond to changes in blood temperature[4]) and rectal temperature to which the injected solutions were adjusted, the effects of small volumes of serum at 5°, 10°, and 15° C above and below rectal temperature were studied. There were no significant effects of varying temperatures of the small volumes of serum injected; if anything, cold serum produced a slight facilitation. Observations confirming these results have been made in 56 different animals.

These results are significant because they demonstrate an electro-physiological change in spinal motorneurone excitability which is correlated with the facilitation of a previously learned thirst-associated simple motor act. They also provide a possible theoretical context for evaluating the recent work[5–7] on environmental induced (changes in blood composition) reactions of neurones in the supraoptic nuclei and the area postrema in terms of an animal's behaviour.

The results of a more detailed analysis of this effect and correlated changes in the electrical activity of the central pathway involved in its mediation which is in progress will be reported in the future.

PHARMACOLOGY

6β-Hydroxycortisol (4-pregnane-6β,11β,17α,21-tetrol-3-20 dione) in Liquor Amnii

6β-HYDROXYCORTISOL was originally isolated from human urine by Bernstein *et al.*[1].

The possibility that 6β-hydroxycortisol might be present in liquor amnii was suggested by the work of Ulstrom *et al.*[2], who found that the major pathway for the metabolism of cortisol in the newborn was by 6β-hydroxylation.

Liquor amnii was initially extracted with ethyl acetate using a modification of the methods described by Katz[3]. The extract was washed with N/10 sodium hydroxide in 20 per cent sodium sulphate, and then on two occasions with 20 per cent sodium sulphate. It was then dried over anhydrous sodium sulphate and filtered after the addition of two drops of glacial acetic acid. The filtrate was evaporated to dryness at 40° C using a rotary evaporator, the residue being transferred to a small wide-necked glass bottle, with five 1-ml. portions of a 1 : 1 chloroform/methanol mixture. This was taken down to dryness in a stream of nitrogen gas at 40° C, taken up in the chloroform/methanol mixture, and then transferred to a Whatman No. 3 *MM* paper. After equilibration for 3 h the spot was run for 7 h at 30° C in a *B*/50 solvent system[4]. The polar steroids remained at the base line, and were eluted with about 4 ml. of an ethyl acetate/methanol (2 : 1) mixture[5]. The extract was taken down to dryness in a stream of nitrogen gas at 40° C and the residue taken up in the chloroform/methanol solvent (1 : 1) and spotted on to Whatman No. 2 paper.

After equilibration overnight the spot was allowed to run for 12 h in a modified *BuC* system[6] at room temperature.

The paper was then dried, and examined under ultra-violet light. A clearly visible spot was seen, with an approximate R_F-value of 0·05. An elongated strip of paper from baseline to solvent front was removed and dipped into a 2 : 1 solution of 10 per cent aqueous sodium hydroxide in 50 per cent methanol and 0·02 per cent blue tetrazolium in ethyl alcohol[8]. The strip was dried in an oven at 60° C for 10 min and again viewed under ultra-violet light, using a minus blue micro 4 gelatine filter (Ilford).

Table 1. PROPERTIES OF 6β-HYDROXYCORTISOL

		Isolated	Reference*
1	Ultra-violet absorption in alcohol	238 mμ	238 mμ
2	Reaction with blue tetrazolium	+	+
3	Fluorescence with NaOH	+	+
4	Mobility in two chromatographic systems (a) Mod. *BuC* (Dixon[6]) (b) Chloroform/formamide (Zaffaroni[7])	 R_F, 0·06 R_F, 0·01	 R_F, 0·06 R_F, 0·01
5	Absorption spectrum in conc. sulphuric acid (maxima) (Bernstein[8])	— 265, 290 350, 370 — 470, 515 mμ	240, 265, 285 350, 365, 390, 475, 525 mμ
6	Mobility after acetylation with acetic anhydride chromatography using 'LT 21/80' (Bush[9]) system	R_F, 0 06	R_F, 0 06
7	Mobility after reduction using sod. bismuthate (Bush[10]) 	 R_F value in 'LB 21/80' chromatographic system (Bush[9]) = 0 01	 R_F value in 'LB 21/80' chromatographic system (Bush[9]) = 0·01
8	Mobility after further reduction using Zn/HAC (Bush[11]) 	 R_F value in 'L.T. 21/85' chromatographic system (Bush[9]) = 0 24	 R_F value in 'L.T. 21/85' chromatographic system (Bush[9]) = 0·24

* The 6β-hydroxycortisol was kindly supplied by Dr. Seymour Bernstein, Lederle Laboratories, Pearl River, New York.

Three additional spots showing a brilliant yellow fluorescence were seen, two more polar and the third slightly less polar than the ultra-violet absorbing spot. All spots were eluted with a 2 : 1 ethyl acetate/methanol solvent. The less polar of the four spots (compound 1) has been tentatively identified as 6β OH cortisol.

Identification of the isolated 6β-hydroxycortisol was based on the properties as listed in Table 1, the results being consistent with those obtained by the reference 6β-hydroxycortisol. The quantity of 6β-hydroxycortisol isolated from liquor amnii was so small that it was impossible to subject the compound to infra-red analysis.

Identification of the other polar steroids isolated from liquor amnii is being actively pursued.

This work was carried out during the tenure of a research grant from the Medical Research Council of Ireland.

HÆMATOLOGY

Staphylococcal Isocoagulases

Staphylocoagulase has been assumed to be a single enzyme elaborated by pathogenic *Staphylococci*. Investigators working with purified highly concentrated staphylocoagulase have described their product as either homogeneous[1] or non-homogeneous[2,3] when studied by free boundary electrophoresis, ultracentrifugation, or starch column chromatography.

We have now been able to show that *Staphylococci* in broth culture liberate into the medium a family of staphylocoagulases. A potent coagulase-producing strain of *Staphylococcus aureus* (*S*–58) was grown for 48 h at 37° C in tryptose broth containing 5 mg/l. of thiamine. After centrifugation, staphylocoagulase was precipitated from the supernatant by addition of 3 vol. of 95 per cent ethanol, slowly and at ice-bath temperature. The collected sediment, redissolved in distilled water, clotted oxalated 1 : 10 human plasma in 2 min and contained 50,000 clotting units/mg of protein. This preparation was subjected to electrophoresis on starch gel according to the method of Smithies[4]. Conditions of electrophoresis were: *tris* buffer *p*H 8·6, 4 V/cm, 18 h. The gel was then sliced horizontally and the cut surface placed on sterile fibrinogen agar (3 per cent bovine fibrinogen and 2 per cent rabbit serum[5]).

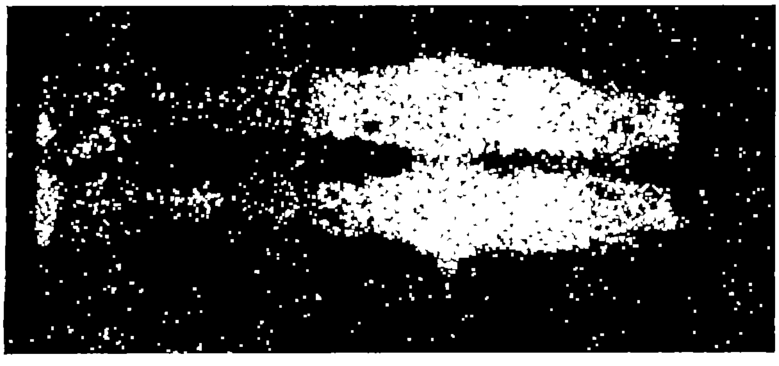

Fig. 1 Staphylococcal isocoagulases. The site of staphylocoagulase isoenzymes separated by starch-gel electrophoresis is marked by precipitation of the fibrinogen in the fibrinogen-agar. They appear as five grey opaque zones

After 24 h at 37° C, it was found that fibrinogen precipitates at several sites (Fig. 1). The reaction extending from the origin to the first band represents trailing. If a very powerful staphylocoagulase preparation is used we find trailing will obscure the individual bands. Since the reaction at the gel and agar surface is specific, it would seem that five isocoagulases are present. This experiment has been repeated with staphylocoagulase prepared from other strains and, although as many as eight distinct bands have been found at times, we have not found less than five.

Staphylocoagulase thus joins other enzyme systems, such as lactic dehydrogenase, characterized by iso-enzymes. Work is in progress to determine whether there exists differences between various coagulase-positive strains and among the several isocoagulases. Preliminary observations show that the more intensive the 'purification' procedure the fewer the isoenzymes which can be detected. Until it can be shown that the behaviour of each is like that of the others, particularly with regard to co-factor specificity and requirements, caution must be exercised in the design of studies with the staphylocoagulase system. Finally, it is not clear at this time whether the isocoagulases are entirely extracellular or whether one or more represent intracellular enzymes[4].

Bivalent Nature of Incomplete Anti-D(Rho)

Erythrocyte antibodies were first demonstrated by their ability to agglutinate erythrocytes suspended in saline; these have been termed complete antibodies. In 1944, Wiener[1] and Race[2] independently showed that certain erythrocyte antibodies were incomplete, possessing the ability to fix to the erythrocyte surface without leading to agglutination. It has been postulated[1], and generally accepted, that the complete saline agglutination antibody is bivalent, and the incomplete coating antibody univalent. Recent investigations in our laboratory using antibodies labelled with iodine-131 have led us to question this hypothesis[3,4]. Our results could best be explained by assuming a bivalent nature of incomplete erythrocyte antibodies.

The assumption of a bivalent nature of incomplete antibodies introduces the problem of explaining the inability of these substances to induce agglutination of saline suspended erythrocytes. A possible explanation would appear to be the unavailability of one or more reactive sites. It may further be postulated that the unavailability of reactive sites is due to the molecular conformation of the incomplete antibody. The experiments described here have been carried out to test this concept. The objective was to change the molecular conformation of incomplete erythrocyte antibodies. If the postulate were correct, it would be possible to make available the non-reactive site by this change, thereby converting incomplete erythrocyte antibodies into a saline acting, agglutinating type.

Incomplete anti-D(Rho) sera of high titre, without saline-agglutinating activity, were used. Titres were determined with standard bromelin and antiglobulin sera procedures. 2-Mercaptoethanol at 0·01 M, 0·1 M and 1·0 M concentrations in isotonic saline were used. Equal volumes of incomplete antibody sera and 2-mercaptoethanol were incubated for 15, 30 and 60 min at 4° C, 22° C and 37° C. The mercaptoethanol-treated incomplete antibody sera were then tested for saline agglutinating ability by adding one drop of a 4 per cent saline suspension of erythrocytes and incubating at room temperature for 5–15 min. Agglutination was determined macroscopically after centrifuging for 1 min at 1,000 r.p.m. At 4° C no saline agglutination was noted after mercaptoethanol treatment. At 37° C and 2-mercaptoethanol concentrations of 1·0 M and 0·1 M, denaturation of the sera occurred. Active mixtures were obtained with 2-mercaptoethanol concentrations of 1·0 M and 0·1 M, and an incubation time of 15–30 min at 22° C. Incomplete anti-D(Rho) sera so treated possessed the ability to agglutinate saline suspended D(Rho) positive erythrocytes. Table 1 summarizes some representative values. D(Rho) negative erythrocytes were not agglutinated by the mercaptoethanol-treated sera. In addition, antiglobulin and bromelin testing of the mercaptoethanol-treated incomplete anti-D(Rho) sera did not reveal any loss of titre of the antisera.

Table 1. Effect of 2-Mercaptoethanol on the Saline-agglutinating Ability of Incomplete Anti-D(Rho)

		Antisera titre

2-Mercaptoethanol							
1·0 M	Saline	4+	3+	2+	1+	–	–
0·1 M	Saline	3+	2+	1+	–	–	–

In order to rule out the possibility that the saline-agglutinating effect was due to mercaptoethanol action on the antigen site, experiments were performed using erythrocytes pretreated with 2-mercaptoethanol at concentrations, temperatures and incubation times similar to those used here. After washing the mercaptoethanol-treated erythrocytes, they were exposed to untreated incomplete anti-D(Rho) sera. With this procedure, 2-mercaptoethanol was inactive in converting incomplete anti-D(Rho) into a saline-agglutinating form.

There is general agreement that erythrocyte antibody sera contain a mixture of both incomplete and saline acting antibodies. Although no saline-agglutinating activity could be demonstrated in the incomplete anti-D(Rho) sera used in this study, the possibility that mercaptoethanol potentiated the action of minute quantities of saline acting anti-D(Rho) was considered. This appeared unlikely in view of prior experiments showing that the agglutinating activity of 19*S* antibodies is destroyed, rather than potentiated, with mercaptoethanol treatment[5]. To test this, various saline acting anti-D(Rho) sera were treated with 2-mercaptoethanol in a fashion similar to that used with incomplete anti-D(Rho). This study revealed the inability of 2-mercaptoethanol to potentiate the action of saline acting anti-D(Rho). Representative results are summarized in Table 2.

The ability of 2-mercaptoethanol to convert incomplete anti-D(Rho) into a saline-agglutinating antibody would appear to offer experimental confirmation of the postulate that incomplete antibody is of a bivalent nature. A working hypothesis would be to assume a molecular structure with one reactive group exposed and one or more reactive groups unavailable because of the molecular conformation of the antibody. Changing the tertiary and possibly the secondary structure of the molecule by breaking disulphide linkages with 2-mercaptoethanol would appear to make available the reactive group which had been hidden. The relatively low titre of saline-agglutinating activity obtained by 2-mercaptoethanol treatment, without loss of antiglobulin or bromelin activity, indicates that the crude techniques reported in this communication have only succeeded in exposing relatively few of the postulated hidden reactive sites.

An Uncommon Blood Group Isoantibody (Anti-M) in Neoplastic Disease

The first case in this series of anti-M sensitized patients was reported in 1958 because it presented a unique exception to the generalization that cold agglutinins are without significance in transfusion practice. The patient had received no M stimulus from either previous transfusion or pregnancy. We commented: "The possibility of a relation between the abnormal isoantibody and the patient's carcinoma of the cecum is being investigated"[1].

At that time we could find records of only 47 instances of anti-M sensitization in the entire literature. We have since encountered 9 additional patients with anti-M antibodies, and what seems remarkable is that 9 of our total of 10 cases had neoplastic disease. Six patients had carcinoma, 3 showed uterine leiomyoma. The single non-neoplastic patient had acute gastritis with bleeding duodenal ulcer. There was no particular bias in favour of neoplastic disease in the material examined; namely, cross-match specimens in 5 large general hospitals. Even if 50 per cent of all samples tested had been from patients with neoplasms, the odds against a purely chance ratio of 9 neoplasms to 1 non-neoplasm would be 102 : 1. The actual incidence of neoplasm in the surveyed population was unknown, but surely was much less than 50 per cent.

Table 1 summarizes the clinical and laboratory findings on these 10 cases. All were blood group NN and showed anti-M in the circulating plasma. We have begun screening M-negative cancer cases for anti-M and thus far have encountered 15 M-negative patients among 173 tested. These 15 were tested for anti-M with negative findings in thirteen. The two patients who were positive for anti-M (patients C. D., D. B.) are included in Table 1.

In two M-negative patients with anti-M, we tested cancer tissue obtained at the time of surgery for possible

presence of antigen M. Cancerous and non-cancerous sections of formalinized tissue (cæcum, colon, prostate, breast) were washed, ground and resuspended to 30 per cent by weight in saline and tested for ability to remove patient's anti-M from the autologous serum. The data suggested that some specific absorption of anti-M was obtained. Cancer tissue repeatedly showed complete or almost complete absorption of anti-M in case J. B., but only a 1-tube drop in titre (50 per cent reduction) was obtained in case C. D. Non-cancerous segments from the same tissue pieces showed little or no absorption of anti-M. Nevertheless, the specificity of absorption by cancer tissue remains dubious. We never succeeded in recovering anti-M in 37° and 56° C eluates[2] from these 'coated' tissues.

Detection of M-like antigen in tissues of an M-negative blood group individual would present an exciting and perhaps pathogenetically significant anomaly. Therefore, we plan to repeat these absorption experiments with fresh cancerous tissue rather than formalinized tissue, when the opportunity presents itself.

We feel it is more important at this time to seek confirmation of the association of anti-M and neoplastic disease, rather than to attempt any explanatory hypotheses. *A priori*, there seems little point in seeking anti-M among neoplasms, but it may prove worth while to seek for neoplasm in patients who present anti-M—especially in the absence of known M-antigen stimulus from transfusion or pregnancy.

We thank Dr. Elmer R. Jennings and Miss Corinne Hindmarsh, Memorial Hospital, Long Beach, for permission to include their 4 cases of anti-M (patients E. F., R. B., M. S. S. and B. M.), and Dr. Paul R. Thompson, Los Angeles County General Hospital, for his 2 cases (C. B. and E. Y.).

PATHOLOGY

Topographic Distribution of Hepatic Necrosis in Bromobenzene, Thioacetamide, Tannic Acid Poisoning, and Inhibition by Aminoacetonitrile of the Necrosis Induced by Bromobenzene

AMINOACETONITRILE inhibits necrosis induced by carbon tetrachloride in the liver of the rat[1]. Necrosis by carbon tetrachloride affects the parenchymal cells surrounding all the tributaries of hepatic veins, from the smallest (centrolobular veins) to the largest. This localization can only be explained by an increased permeability of the wall of the hepatic veins causing the onset of necrosis[2]. (Necrosis of the cells of the central zone of the lobule can be caused by increase in permeability not only of the centrolobular veins but also of the last tract of the sinusoids.) The fact that such necrosis occurs only around the efferent vessels of the liver and not around the periportal areas and the first tract of the sinusoids indicates that this increased permeability is not the result of direct action by carbon tetrachloride but is due to some substances liberated in the blood by the parenchymal cells under the action of this poison[2].

Probably other kinds of hepatic necrosis experimentally induced by toxic compounds and described as centrolobular ones, as well as the central hepatic necrosis produced by toxic substances and recorded in human pathology, are actually localized around all the tributaries of hepatic veins, including the largest ones, and are, therefore, induced by the same mechanism as that of carbon tetrachloride.

The experiments described here were aimed at examining the localization of the necrosis which appears in the liver of rat following poisoning by bromobenzene, thioacetamide and tannic acid, such compounds being known to induce centrolobular necrosis[3–5]. At the same time the action of aminoacetonitrile on these lesions has been investigated.

For the experiments with bromobenzene 40 male albino rats weighing about 200 g were used, each of them receiving an intraperitoneal injection of 0·12 ml. of this substance mixed up with 0·38 ml. olive oil. Half the animals received, both simultaneously and 24 h later, a subcutaneous injection of 20 mg aminoacetonitrile hydrosulphate dissolved in 0·2 ml. water and neutralized with sodium hydroxide. Three rats treated with bromobenzene alone died within 48 h after administration of the poison. No histological examination of their livers was made. None of the rats treated with bromobenzene and aminoacetonitrile died in the same period. 48 h after bromobenzene administration the animals were killed; liver fragments were excised from near the hilus, fixed in Davidson fluid and embedded in paraffin. The sections were stained with hæmatoxylin and eosin.

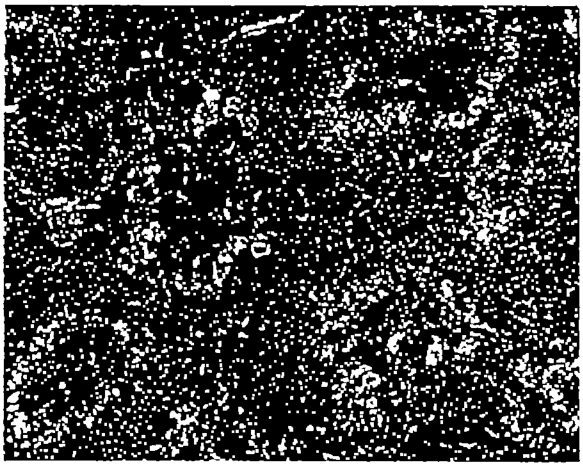

Fig. 1. Liver of rat treated with bromobenzene. (Stained with hæmatoxylin and eosin, × c. 40)

For the experiments with thioacetamide 14 male albino rats weighing about 200 g were used, each of them receiving a subcutaneous injection of 40 mg of this substance dissolved in 1·6 ml. water. Half the animals received, both simultaneously and 24 h before thioacetamide administration, a subcutaneous injection of 20 mg aminoacetonitrile. 24 h after the administration of thioacetamide the animals were killed and the experiment was completed with the same method used for bromobenzene.

Experiments with tannic acid were carried out by using 14 male albino rats weighing about 200 g. The animals were injected subcutaneously with 2 ml. of a 10 per cent aqueous solution of this acid. Half of them received, both simultaneously and 24 h before tannic acid administration, a subcutaneous injection of 20 mg aminoacetonitrile. 24 h after the administration of tannic acid the animals were killed and the experiment was completed with the same method used for bromobenzene.

Of the 17 rats treated with bromobenzene alone, 2 showed microscopically normal livers, whereas the livers of the remaining 15 rats presented a widespread necrosis and hydropic degeneration around all the tributaries, including the largest ones, of the hepatic veins (Fig. 1).

The liver of all the 20 rats treated with bromobenzene and aminoacetonitrile had a microscopically normal aspect (Fig. 2).

The liver of all the rats treated with either thioacetamide or tannic acid showed necrosis of the parenchymal cells around all the tributaries of the hepatic veins, including the largest ones.

The same result and the same severity of lesions was observed in the liver of all the animals, which together with these two substances, had received aminoacetonitrile.

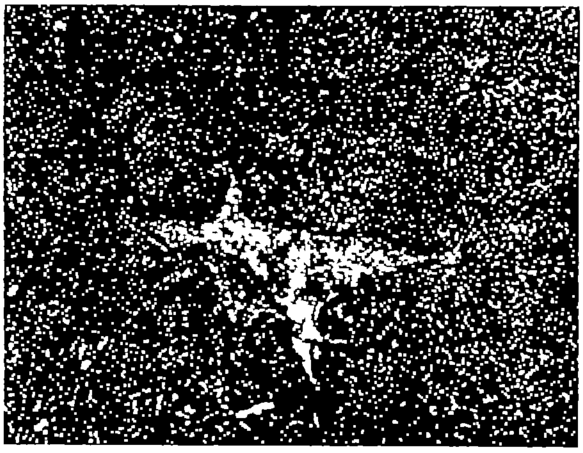

Fig. 2. Liver of rat treated with bromobenzene and aminoacetonitrile. (Hæmatoxylin and eosin, × c. 40)

In conclusion, in poisoning by bromobenzene, thioacetamide, and tannic acid, the localization of hepatic necrosis occurs not only around the centrolobular veins, but also around all the tributaries of the hepatic veins, including the largest ones. It follows that with all probability an essential condition for the appearance of these lesions, as for that promoted by carbon tetrachloride, is an increase in permeability of the wall of the hepatic veins, which is induced by products liberated in the blood by parenchymal cells under the damaging action of these poisons.

Aminoacetonitrile entirely inhibits necrosis by bromobenzene, whereas it does not exert any inhibition on the necrosis induced by either thioacetamide or tannic acid.

In vivo, Extracellular, Collagen Fibrillogenesis

In vitro collagen fibrillogenesis has been demonstrated by investigators[1–3] from solutions of collagen obtained by various means. This communication presents what we believe to be the first evidence for extracellular, *in vivo*, aggregation of collagen fibrils.

In an investigation of the utilization of tritiated proline in healing wounds in scorbutic guinea pigs, we have found the sequence of incorporation of proline to be similar to that in normal animals[4,5]. This proceeds as follows: the radioactivity appears first in fibroblasts and next appears in the extracellular material. In scorbutic wounds, the extracellular material is fibrillar but lacks the characteristic banding of collagen seen in the electron microscope as well as the characteristic staining reactions of collagen. Autoradiographically this fibrillar material was found to retain the label after the isotope had disappeared from the fibroblasts. This investigation is concerned with the fate of both proline and the extracellular material following ascorbic acid administration, as seen via electron microscopy and autoradiography.

Female guinea pigs weighing about 300 g were placed on a scorbutigenic diet for 8 days. Eight linear incisions were then made in the dorsal skin and the wounds were allowed to 'heal' by first intention for 6 days. At this time, each animal was given 1-proline-3,4,^{3}H (12 μc./g body-weight) intraperitoneally. Six days following administration of tritiated proline a wound was removed from every animal, fixed and embedded as for electron microscopy[4]. Each animal was afterwards given 100 mg ascorbic acid intraperitoneally and placed on a diet containing 20 mg ascorbic acid per 20 g diet. The remainder of the wounds were removed at 1, 4, 12, 16, 24 h, 2, 3, and 6 days following administration of ascorbic acid. All the tissues were fixed and embedded in epoxy resin as for electron microscopy. Tissue sections were cut at 1μ, coated with nuclear track emulsion, exposed for 5 weeks, and stained[7]. Five random areas of two sections from each block were photographed, as well as areas adjacent to the sections, for background determinations. Grains overlying cells, extracellular material, etc., were counted using a modified form of Chalkley's method[8], and the counts were corrected for background.

The results of the grain counts demonstrated that the intensity of label over the cells remained low at all the time periods examined, while the grain density over the extracellular fibrillar material remained at the same high level present prior to ascorbic acid administration. Electron microscopic examination of the wounds prior to giving ascorbic acid showed the presence of the characteristic non-banded extracellular fibrils previously described[8]. Within 24 h after ascorbic acid administration, this fibrillar material was entirely replaced by characteristically banded collagen fibrils, most of which were of similar diameter.

Thus the extracellular material which is labelled 24 h after ascorbic acid administration can be clearly identified as collagen, and the intensity of labelling is similar to that seen in the fibrillar material which could not previously be identified as collagen. These results are consistent, therefore, with the conversion, extracellularly, of the non-collagenous fibrillar material present in scurvy, to collagen, following ascorbic acid administration.

We are aware that these results again raise the possibility of the presence of an extracellular collagen precursor in scurvy in which *in situ* hydroxylation of proline and lysine might occur. Since this remains a controversial issue, we are attempting to extract this material and identify its amino-acid content, in the hope of increasing our understanding of this complex situation.

Prediction of Spontaneous Hereditary Diabetes Mellitus in Chinese Hamsters by Means of Elevated Alpha-2 Serum-levels

CLINICAL and pathological observations on Chinese hamsters (*Cricetulus griseus*) with spontaneous hereditary diabetes mellitus have been reported previously in several papers[1–7]. Generally speaking, the disease in Chinese hamsters is primarily pancreatogenic, with degranulation, hydropic degeneration and deficiency of β-cells. Other forms of pathological expression noted in symptomatic animals are glomerulosclerosis, arteriosclerosis, increased periodontal breakdown, and proneness toward the formation of adenocarcinomas of the pancreas.

Elevated serum α-2 levels several times greater than normal (3–8 per cent) have been reported[8] in diabetic hamsters, or in families with a high incidence of spontaneous diabetes. When symptomatic members of these high incidence families were randomly hybridized by single or double crosses involving two or four grandparents of diabetic background, normal α-2 values were re-established. At the time when this investigation was reported, many animals had high α-2 values with no clinical evidence of diabetes. In this communication we shall show that with but a few exceptions these non-symptomatic high α-2 hamsters afterwards developed chemical diabetes while the low α-animals generally remained symptom-free.

Both diabetic and non-diabetic inbred animals were obtained from the colony maintained at the Children's Cancer Research Foundation. The methods in breeding and maintaining the animals have already been described[9]. Animals were observed for a period of at least 250 days, and in some cases longer, for evidence of diabetes. Only animals showing prolonged glycosuria were considered as confirmed diabetics.

Blood was obtained by cardiac puncture and the α-2 serum-levels were determined by the Spinco model *R* system of paper electrophoresis, using their recommended procedures.

For purposes of analysis, the hamsters were divided into three groups consisting of: (1) those which were never diabetic (within 250 days); (2) those which had no initial symptoms, but later developed diabetes; and (3) those which were diabetics or showed initial glycosuria, and later were confirmed as diabetics. The condition of the animals at the time when the electrophoretic analysis was run was the point of reference for the above categories. These results are given in Table 1.

Table 1. RELATIONSHIP OF SERUM PAPER ELECTROPHORETIC α-2 LEVELS WITH THE DIABETIC STATE IN 89 CHINESE HAMSTERS*

Serum α-2 (%)	No diabetes	Confirmed diabetes No initial symptoms	 Initial symptoms and/or established diabetes
3–5	8	0	0
6–10	18	5	6
11–15	1	7	10
16–20	1	6	7
21–25	1	2	10
26–30	0	2	4
31–35	0	0	1
Total	29	22	38

* All animals observed for at least 250 days.

It will be observed that out of the 29 which did not develop diabetes, 26 animals had α-2 levels of less than 10 per cent, the majority (18 animals) giving levels between 6 and 10 per cent. Only three animals gave levels above 10 per cent. It is conceivable that if these latter animals were observed for a longer period—up to a year—diabetic symptoms might have developed.

In the 22 animals showing no initial symptoms, none was observed in the 3–5 per cent group, in contrast to the previous group where 8 animals were found to have the lowest α-2 levels. There were 13 initially non-symptomatic animals in the 11–20 per cent α-2 interval.

Similarly, the 38 animals with established diabetes or initial symptoms, such as glycosuria, and later confirmed as diabetics, showed no members in the 3–5 per cent α-2 group. There were 27 animals in the 11–25 per cent α-2 interval.

These results show a high degree of association between the active diabetic state in Chinese hamsters and the serum α-2 level. Some overlap occurred in the 6–10 per cent α-2 interval between the non-diabetics, the initially non-symptomatic, and the symptomatic groups. Most of the initially non-symptomatic high α-2 animals (above 10 per cent) were later confirmed as diabetics when observed for a period of 9 months.

The possible prognostic implications of elevated α-2 levels in selected groups of high diabetic risk, such as overweight new-borns, is being investigated by a variety of techniques.

IMMUNOLOGY

Non-specific Precipitation Patterns obtained in Double Diffusion between Serum and Extracts of Normal Organs and Tumours

It has been shown that the antigenic structure of tumours and of the corresponding normal tissues is different[1]. Specific antigens were demonstrated in spontaneous, induced and transplanted tumours of mice, rat, rabbits and chickens, as well as in various human tumours by the method of anaphylactic reaction following desensitization. By means of the gel diffusion of Ouchterlony, Zilber *et al.*[2] were able to show an antigen in extracts from a mice hepatoma lacking in normal liver. We were able to confirm this work in a tumour of the rat; we obtained a specific antigen present in the granular fraction of a transplantable hepatoma.

With this different antigenic structure in mind, we tried to elicit some immune response in rats treated with extracts of liver and hepatoma. Until now we failed to induce a response in the animals treated by tumour extracts, but in the course of this work we obtained curious lines between serum and tissue extracts, analysed by double diffusion in agar. Those lines simulate a true antigen–antibody system, and it is the aim of this communication to describe the precipitation lines and to compare them with the characteristics of true antigen–antibody systems.

We injected five groups of rats with total liver extract, with the microsomal fraction of the liver, with normal kidney, and with extracts of a transplantable hepatoma, and, finally, with the microsomal fraction of this hepatoma. The organ extracts were made in a Waring blendor, and the microsomal fractions were isolated by differential centrifugation. The animals received three injections, one of them in Freund's adjuvant. Ten days after the last injection the animals were bled.

Table 1 shows the results of this experiment analysing the serum of each animal against the five antigens studied.

Table 1. PRECIPITATION PATTERN OBTAINED BETWEEN THE SERUM OF RATS IMMUNIZED WITH NORMAL AND TUMOUR EXTRACTS AND THE EXTRACTS

Animals previously injected with	Precipitation lines present with*				
	Normal liver		Hepatoma		Kidney
	Total extract	Microsomal	Total extract	Microsomal	Total extract
Total liver extract	3/4	0/4	0/4	0/4	2/4
Microsomal liver	3/4	0/4	0/4	0/4	3/4
Kidney	1/4	0/4	0/4	0/4	4/4
Total hepatoma extract	3/4	0/4	0/4	0/4	2/4
Microsomal hepatoma	3/4	0/4	0/4	0/4	3/4
Normal serum (without previous injury)	3/4	0/4	0/4	0/4	3/4

* Results expressed as $\frac{\text{No. of animals with precipitation lines in their serum}}{\text{Total No. of animals analysed}}$

It is clear that practically all the animals present a line between their own serum and the extracts of liver and kidney, without any specificity regarding the immunization procedure. It was surprising to find analogous precipitation lines towards normal serum; it was only necessary to work with concentrated extracts to obtain the lines. We analysed also serum of rats carrying a hepatoma graft and found precipitation lines: hepatoma extracts and normal extracts provided precipitation patterns, if the reactants were sufficiently concentrated.

The using up of serum by corresponding antigens is possible. The factor present in serum is destroyed by boiling; but not the factor present in the organ extracts. On the contrary, after boiling of the organ extracts, the lines are even clearer.

The mobility of the factor present in the serum is that of an α_2-globulin; the organ factor has a β-globulin mobility.

In this experiment we did not succeed in demonstrating the presence of true anti-tumour immunity, but we discovered a factor present even in normal serum, and in serum of tumour-bearing rats, reacting with a component present not only in extracts of normal organs (liver, spleen, kidney) but also in some tumour preparations. This serum factor seems not to increase after immunization of the animals with normal organ extracts or with tumour extracts. In our case it is not a reaction between hæmoglobin present in the tumour or organ extracts and some serum protein, as described by Leonardi[4], Ambrosino *et al.*[5], Peetom *et al.*[6] or by Metzgar and Grace[7]. It is also different from the precipitation described by Tomasi[8].

This precipitation pattern looks very similar to a true antigen–antibody system, but can be differentiated in our mind by some points. Similar to an antigen–antibody system is the fact that a state of equivalence exists for this system, and that it is possible to obtain pictures similar to antigen and antibody excess. It is also possible to exhaust the serum factor by addition of small quantities of tissue extracts.

But in other aspects this system is quite different from a true antigen–antibody system. The mobility of the factor found in the serum is situated in the region of α_2-globulin, and not in the region of the antibodies, which are β- and/or γ-globulins. The tissue factor is not destroyed by boiling. The precipitation line appears only in concentrated extracts. Those three factors enabled us to distinguish between precipitation lines and a true antigen–antibody system, in which the antibody has always a β-γ-globulin mobility and is destroyed by boiling.

It is possible that the lines described here are due to electrostatic forces[3] or to chemical affinity between the components. It is necessary for everybody working with double diffusion in agar to have in mind these non-specific precipitation patterns, to avoid false interpretation of the agar plates[7]. Some controls of precipitation lines can be made very easily, as, for example, boiling of the serum and immunoelectrophoresis. In this way specific precipitation patterns can be differentiated from non-specific ones.

RADIOBIOLOGY

Isolation of a Radiation-Mortality Reducing Factor from Spleen

The radiation-mortality reducing action of cell-free extracts obtained from spleens of mice, guinea pigs and dogs has been demonstrated in a series of previous investigations[1,2]. The extraction procedure used for preparing spleen extracts has been described elsewhere[2,3]. The observation that homologous, as well as the heterologous, spleen extracts were equally effective suggests that a common chemical entity (or entities) may be the therapeutic agent[4]. This is a preliminary report of the isolation and characterization of fractions obtained from dog spleen extracts which contain this factor.

The reagents were of the highest purity available and the solutions were made with distilled water. The spleen extracts were prepared from mongrel dogs of either sex weighing 40–62 lb. The spleens were surgically exposed and the hilus vessels clamped prior to removal. The weighed organs were cut into small pieces, placed on dry

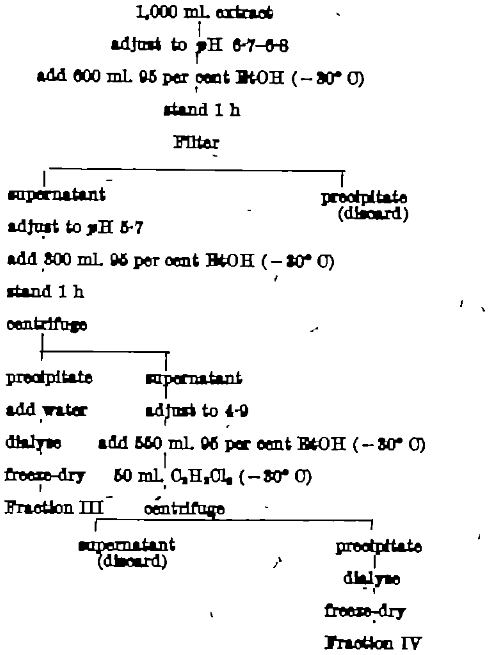

Fig. 1. A procedure for the alcohol fractionation of dog spleen extract

ice for 2 h prior to grinding in the frozen state. The powder was leached with 0·9 per cent sodium chloride for 24 h in a refrigerator. The supernatant was then centrifuged, filtered, freeze-dried, and tested for sterility in accordance with the standard procedure[1].

Evidence that this factor is associated with, or is, a macromolecule was afforded by several approaches. Sequential quantitative dialysis utilizing Visking No. 27 'Cellophane' membrane localized the bioactivity in the non-dialysable fraction. Gel chromatographic analysis utilizing 'Sephadex *G*-50' as the stationary phase and water as the eluant yielded four fractions all of which possessed substantial degrees of bioactivity.

A fraction isolated from spleen extract at 60–85 per cent relative saturation of ammonium sulphate possessed a considerable degree of protective action. However, the bio-assays were somewhat equivocal due to interference by the ammonium sulphate present in spite of dialysis for 72 h against 10 changes of distilled water. With alcohol fractionation four fractions were obtained. The first two fractions were ineffective, while Fractions III and IV exhibited considerable bio-activity. This procedure is described in the flow-sheet in Fig. 1. The fractionation was carried out in a cold room with suitable precautions to maintain the correct temperature and rate of addition of the pre-cooled reagents to minimize denaturation. The pH was adjusted with either 0·1 M dipotassium hydrogen phosphate or 0·25 N acetic acid.

The results of several fractionation experiments are summarized in Table 1. The dosage used corresponded to the relative amount of each fraction isolated from the crude extract. The procedure for the bio-assays is described in the table. A χ^2 test analysis indicates that the data are statistically significant falling within the $0·02 > P > 0·01$ level for the individual fractions and $P < 0·001$ for the extract[2,3]. Thus it may be concluded that these materials exhibit a decided radiation ameliorating action. A measure of the relative effectiveness of the fractions is gained by noting that 30 and 5 mg of Fractions III and IV are almost equivalent to 200 mg of the original spleen extract.

Table 1. Comparative Study of the Radiation-Mortality Reducing Effect of Various Fractions isolated from Spleen*

Fraction	Mean dose (mg/day†)	Survivors after 20 days‡	Survival (%)	χ^2 computed relative to control	Probability
Extract	200	40/60	66·7	14·7	< 0·001
Fraction III	30	32/60	53·3	5·91	$0·02 > P > 0·01$
Fraction IV	5	22/40	55·0	6·24	$0·02 > P > 0·01$
Saline control	—	19/60	31·6	—	—

* Male guinea pigs, mean weight 425 ± 50 g, exposed to a 2,400 c. cobalt-60 source for an exposure of 650 r. in air (refs. 2 and 3).

† Treatment consisted of five injections daily of 0·4 ml. starting 24 h after exposure to radiation. The weight of sample varied with the preparation used; however, the range was about 20 per cent.

‡ These data represent the number of survivors relative to the total number of animals tested, being the summation of several experiments over a 6-month period.

Preliminary studies indicate that a simplified procedure is achieved by pre-heating the extract, adjusted to pH 4·9 ± 0·1 at 60° C for 10 min prior to fractionation. This removes about 70 per cent of the protein, resulting in an almost quantitative precipitation of hæmoglobin. The alcohol fractionation is then performed as described. Fraction III-*H* recovery and activity is in the same order as Fraction IV; however, Fraction IV-*H* exhibits little or no protective action.

Some of the properties of the active principle may be deduced from these investigations. The boiling of spleen extract at pH 6·8 for 20 min caused a considerable loss of activity. Spectroscopic analysis revealed not only a maximum at 278 mμ but also that the ratio of absorbances at 278 mμ to 260 mμ ranged from 1·35 to 1·70. This supports the thesis that the fractions contained little or no nucleic acids or their derivatives. The presence of additional absorption maxima at 410, 545, and 575 mμ were due to the presence of hæmoglobin. Since the 410 mμ absorbance is about 10-fold greater than that of the 280 mμ absorption maximum of the other proteins in this extract this facilitates the calculation of the hæmoglobin content of the various fractions. Evidence that hæmoglobin was not the active principle was derived from the observation that the hæmoglobin content of the more active preparations was about 10 per cent and by experiments using hæmoglobin as such.

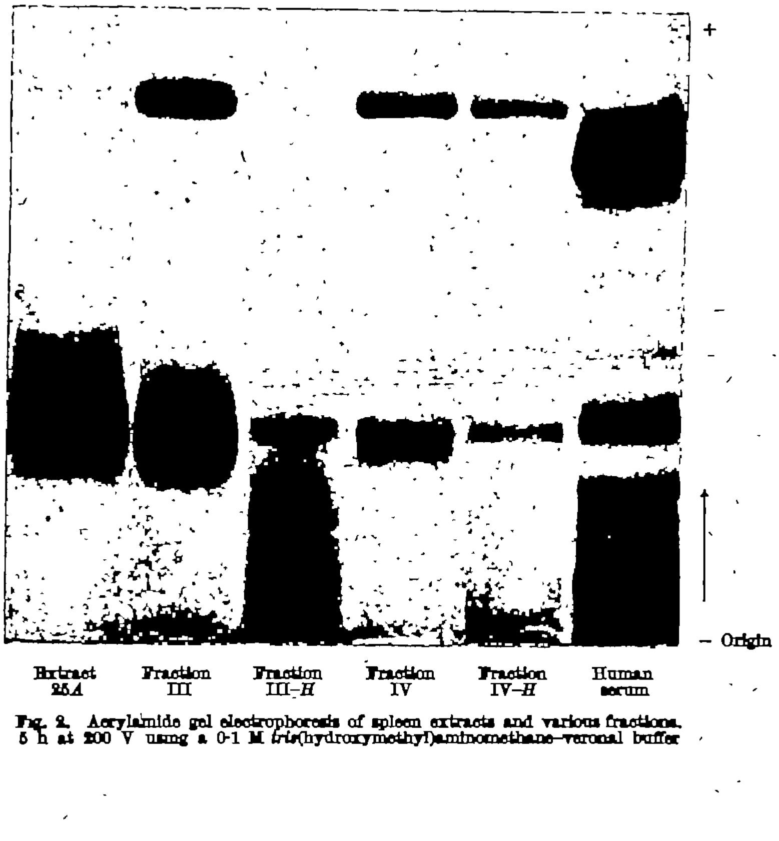

Fig. 2. Acrylamide gel electrophoresis of spleen extracts and various fractions. 5 h at 200 V using a 0·1 M *tris*(hydroxymethyl)aminomethane–veronal buffer

Electrophoretic studies were made with acrylamide gels using 0·1 M *tris*(hydroxymethyl)aminomethane: veronal buffer, *p*H 8·6 (ref. 6). Typical electrophoretic patterns are presented in Fig. 2 in which Fractions III and IV obtained by alcohol fractionation are compared with Fractions III-*H* and IV-*H* obtained by the pre-heating procedure. Human serum served as the reference. All the fractions, with the exception of III-*H*, contained a fast component the mobility of which is similar to that of albumin and another group of proteins the mobility of which falls in the globulin range. Since Fraction III-*H*, a high-potency fraction, contains little if any of the albumin-like material this suggests that the active component falls in category characterized by a lower mobility. Furthermore, Fraction IV-*H*, which possesses little or no protective action, contains a large amount of the fast component relative to the globulin-like species.

The previous data coupled with the results of semimicro Kjeldahl, biuret, and dry-weight analysis suggest that this principle is associated with or is a polypeptide or protein. More definitive conclusions about the nature of this factor must await the isolation of more active and homogeneous fractions.

We thank Lieut.-Commander Thomas Ferris and R. E. Easterling, of Rear Admiral G. W. Calver's Physical Chemical Research Laboratories, for the gel electrophoretic results. We also thank Dr. T. A. Strike for his assistance with the statistical analysis. These investigations were jointly supported by the Bureau of Medicine and Surgery of the U.S. Navy and the Defence Atomic Support Agency.

Radiation Protection by Cyanide of both Rats and Mice

MANY investigators have found[1-4] that the rat, unlike the mouse, is afforded little or no protection to irradiation damage by the prior administration of cyanide salts. In all their experiments, a limited dose-range of cyanide was tested. The frequently cited results of Dowdy *et al.*[1], for example, were obtained using a single dose (3 mg/kg) of sodium cyanide. A recent theory[5] states that compounds such as cyanide and azide owe their radiobiological action to the property of stabilization of cuprous (Cu I) ion involved in oxidative processes. The proposal suggests that the dose required to achieve protection would be sharply defined and, if not limited by chemical toxicity of cyanide, it should be possible to demonstrate protection in the rat using the proper dose. Accordingly, survival was compared in rats and mice given a wide range of doses of sodium cyanide prior to X-irradiation.

The animals used were female *CF* No. 1 mice, 70 days old and weighing 25 ± 2 g, and female Sprague–Dawley rats, 7–8 months old and weighing 270 ± 15 g. X-ray exposures were delivered with a General Electric Maximar unit operated at 250 kVp and 15 m.amp., using 0·5 mm copper and 1·0 mm aluminium filters. The mice were irradiated on a revolving wheel equipped with individual ventilated plastic capsules, at a dose rate of 38·4 r./min. Rats were placed in individual ventilated aluminium boxes, which were shifted through 180° once during the exposure; the dose rate was 21·7 r./min. Sodium cyanide solutions were freshly prepared before injection in concentrations of 0·02 and 0·03 per cent and the *p*H was adjusted to 7·0 with sodium cyanide. All treatment injections were given intraperitoneally 3–6 min before irradiation. Control animals were given no injections.

Preliminary toxicity data on sodium cyanide given intraperitoneally were obtained. For mice, the 30-day LD_{50} was 6·3 mg/kg and the maximum safe dose was 5·5 mg/kg. For rats, the 30-day LD_{50} was 4·0 mg/kg and the maximum safe dose was 3·0 mg/kg.

The irradiation experiments were carried out at two levels of X-irradiation for each species. The total whole-body doses delivered were 850 r. (LD_{90}) and 800 r. (LD_{75}) for the rats and 750 r. (LD_{90}) and 650 r. (LD_{50}) for the mice. The results of the experiments carried out at the higher irradiation levels are shown in Fig. 1. Significant protection was obtained in both rats and mice. In the case of mice given 750 r. the degree of protection increases with increasing dose of cyanide, beginning at a level of about 2 mg/kg. However, in the rat given 850 r., cyanide exerts no appreciable protection until a dose of about 3 mg/kg is reached where a sharp rise in protection ensues. This rise was checked in two separate experiments. In one, 50 per cent survival was observed and in the other 67 per cent. Considering the abrupt response these results show good agreement.

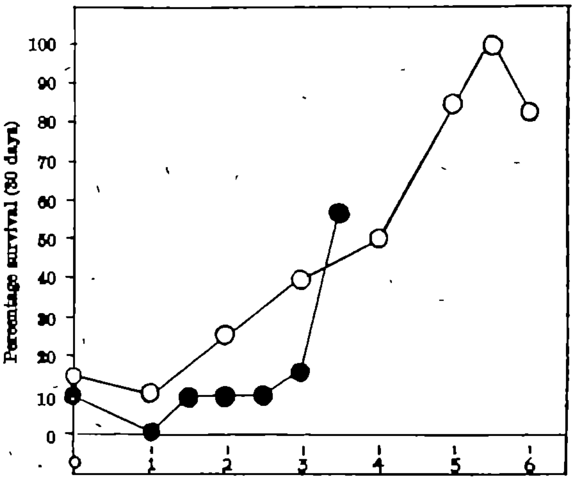

Fig. 1. Effect of treatment with sodium cyanide on the survival of X-irradiated rats and mice. Sodium cyanide was given intraperitoneally 3–6 min before irradiation. Black circles represent the results obtained on rats given 850 r.; each point is based on 20 rats except for the controls where 30 were used and the 1 0 mg/kg level where there were only 10. Open circles show the results from mice irradiated at 750 r.; each point represents 20 mice except for the 5·5 and 6 0 mg/kg levels where only 9 and 6 were used, respectively

Experiments at a lower level of irradiation indicated that for both the mouse and the rat the minimum amount of cyanide required to bring about significant protection was less than that needed for higher irradiation doses. The lower cyanide doses were about 1·0–2·0 mg/kg for mice given 650 r. (survival = 80 per cent for treated and 40 per cent for controls) and 2·0–2·5 mg/kg for rats given 800 r. (survival = 40 per cent for treated and 10 per cent for controls).

The observation that the radioprotective dose of sodium cyanide increases with larger doses of irradiation is noteworthy both from theoretical and practical points of view. Since cellular permeability generally increases with increasing irradiation dose[4] the explanation probably lies elsewhere. It is tempting to speculate that a contributing factor to the cyanide-radiation dose relations arises from the fact that cyanide ion reacts with peroxy radicals[4] and hydrogen peroxide[6]. Consequently, since the concentration of peroxy radicals produced *in vivo* presumably increases with increasing radiation dose, the dose of sodium cyanide needed to reach critical intracellular sites would necessarily increase. An elucidation of the mechanism involved would entail a study of the degree of protection as a function of the time elapsed between the administration of cyanide and onset of irradiation.

The previously mentioned theory[5] suggests that cyanide prevents a radiation-induced oxidation of the cuprous component of 4-electron transfer oxidases such as cytochrome oxidase through the selective formation of a cuprous cyanide complex which eventually dissociates. Accordingly, the cytochrome-*c* oxidase activity of the livers of mice injected with sodium cyanide was measured by the method of Hogeboom and Schneider[7]. The observed inhibitions of the enzyme were 10 per cent at a dose of 2 mg/kg of sodium cyanide and 40 per cent at 5 mg/kg. These preliminary results are suggestive inasmuch as they approximate the dosages needed for protection. We were unable, unfortunately, to demonstrate radiation-induced inhibition of cytochrome oxidase in mice or rat tissues. The difficulty is presumably associated with the sensitization of the enzyme (actually reduction of Cu^{++} to Cu^{+}) by the sulphydryl groups of the protein which are released on homogenization of the tissue[8,9].

This work was performed under the auspices of the U.S. Atomic Energy Commission. We thank Mrs. Elisabeth Moretti for assistance with the survival experiments and Mr. William Westfall for the determination of cytochrome oxidase activity.

Alterations in Skeletal Muscle after X-Irradiation and their Similarity to Changes in Muscular Dystrophy

ALTHOUGH muscle constitutes almost half the body-weight in mammals, it is generally thought to be very radioresistant and to play an insignificant part in the bodily changes which follow irradiation. In excised frog muscle, changes in the resting transmembrane potential and electrolyte composition were found only after massive doses of X-rays[1,4]. However, transient weakness and increased fatigability have been observed in man and animals after modest doses of radiation[2,4]. Caster and Armstrong[5] found a large negative potassium balance in rats after an LD_{50} of X-rays. The lost potassium appeared to originate principally in muscle. A transient post-irradiation aldolasæmia[6] also occurs as well as an amino-aciduria and creatinuria[7-9] which appears to be linearly dependent on the dose of radiation[10]. It seems likely that the creatine and other amino-acids and the aldolase were lost, in large part, by skeletal muscle and it occurred to us that subtle *in vivo* changes in muscle after irradiation might have been overlooked.

Male Sprague–Dawley rats weighing about 250 g were anæsthetized by the intraperitoneal injection of 33 mg/kg body-weight ammonium pentobarbital, placed in cylindrical lead chambers which shielded all but the hind quarters by 1-in. thickness of lead, and irradiated with 3,000 r. 250 kV X-rays filtered through 1·0 mm aluminium and 0·5 mm copper at a rate of 200 r./min. Groups of four animals were killed after 6, 12, 24, 48, 72 and 96 h; control animals were sham irradiated. The animals were bled and plasma electrolytes, aldolase and lactic dehydrogenase as well as erythrocyte electrolytes were determined by methods described previously[11]. Muscle from the irradiated limbs was analysed for electrolytes[11].

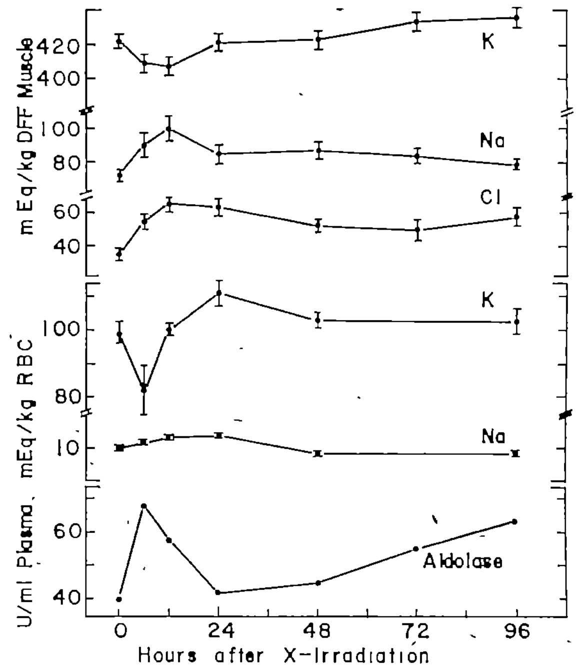

Fig. 1. Muscle and erythrocyte electrolytes and plasma aldolase after irradiation of the hindquarters of rats with 3,000 r. RBC, Red blood cells; DFF, dry, fat-free

The results are depicted in Fig. 1. Muscle potassium fell from a control value of 422 ± 4·1 m.equiv./kg dry, fat-free muscle to 407 ± 7·2 m.equiv./kg dry, fat-free muscle at 12 h but by 24 h returned to 423 ± 3·1 m.equiv./kg dry, fat-free muscle. Muscle sodium rose from a control value of 72·3 ± 2·0 m.equiv./kg dry, fat-free muscle to a peak of 98·1 ± 2·2 m.equiv./kg dry, fat-free muscle at 12 h and returned slowly to a level not significantly different from that of the controls. Muscle chloride also rose from a control value of 35·2 ± 2·2 m.equiv./kg dry, fat-free muscle to a peak of 65·7 ± 6·2 m.equiv./kg dry, fat-free muscle at 12 h. Erythrocyte potassium showed a diphasic pattern, first dropping significantly from control values at 6 h and at 24 h increasing above control values. Erythrocyte sodium rose from a control value of 9·90 ± 0·66 m.equiv./kg to a peak of 14·16 ± 0·72 m.equiv./kg at 24 h. The plasma electrolytes after irradiation were not significantly different from the values in controls.

The rise in plasma aldolase-levels from a mean in control animals of 40·2 U/ml. to 68·2 U/ml. 6 h after irradiation, followed by a rapid return to control levels, was like the aldolasæmia which has been reported previously[6]. A similar transient increase in plasma lactic dehydrogenase-levels was found. The ratio of muscle wet weight to dry, fat-free muscle in muscle from irradiated groups was not significantly different from the mean of 4·23 in controls.

The apparent lowering of muscle potassium concentration and increase in sodium and chloride concentrations may be due, in part, to a relative increase in the extracellular fluid as a result of the hyperæmia and œdema which is known to follow irradiation[12]. In view of the coincident loss of aldolase, creatine and the negative potassium balance which must be attributed largely to losses from skeletal muscle, we feel that our findings are best explained by a transient increase in cellular permeability of muscle.

In addition to weakness, a low muscle potassium, high muscle sodium and chloride concentrations as well as creatinuria and aldolasaemia are found in hereditary muscular dystrophy and have been attributed to altered cellular permeability[11]. Such changes in permeability of muscle cells may be a common reaction to certain kinds of injury and disturbances in metabolism.

This project was supported by a U.S. Public Health Service grant No. *A*–1703 and by contract No. *AF*–41 (657)–357 monitored by the School of Aerospace Medicine, U.S. Air Force.

BIOLOGY

Thermogenic Effect of Stilbœstrol on Ewes

At œstrus the cow's body temperature is elevated without detriment to subsequent fertilization[1,2]. Increased locomotory activity may partly account for the thermal response, but attention has also been directed to other metabolic changes at œstrus. Some evidence has been obtained that œstrogens may influence the cow's body temperature (Fallon, unpublished). It was decided to examine the effect of stilbœstrol on the rectal temperature of the ewe.

Eight mature Merino ewes were ovariectomized; mean live-weight was 33 kg. Eight weeks later they were divided at random within four groups and accommodated in individual metabolism cages to restrict exercise. During experimental periods the sheep were denied access to food and water.

Aqueous preparations were made to provide 2 ml. doses containing 0, 25, 50 and 100 μg stilbœstrol. The preparations were stored at room temperature 2–3 weeks before use in experiment *A*; and in experiment *B* similar solutions were prepared within 2 h before use. Intra-jugular injections were performed according to the schedule in Table 1.

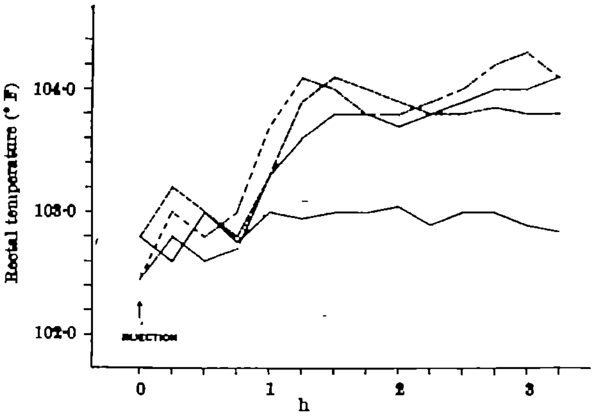

Fig. 1. Rectal temperatures in spayed ewes following intra-jugular injection of aqueous stilbœstrol solutions after 2–3 weeks' storage at room temperature. ·······, 100 μg; —·—, 50 μg, – – –, 25 μg stilbœstrol; ——, control

Table 1. PROGRAMME OF INTRA-JUGULAR INJECTIONS WITH AQUEOUS STILBŒSTROL SOLUTIONS

Table 2. RECTAL TEMPERATURES 1½–3½ H AFTER INTRA-JUGULAR ADMINISTRATION OF STILBŒSTROL IN OVARIECTOMIZED EWES

Stilbœstrol (μg)	No. of records	Mean rectal temperature (° F.)	*S.E.* (° F.)
		Exp. *A*	
0	72	102·99	0·05
25	72	103·91	0·06
50	72	104·06	0·08
100	72	103·89	0·09
		Exp. *B*	
0	72	103·34	0·11
25	72	103·20	0·12
50	72	103·38	0·10
100	72	103·24	0·11

Rectal temperatures were recorded about mid-day, immediately before injections, and thereafter at 15-min intervals. After a delay of about 45 min, the older solutions of stilbœstrol used in experiment *A* (Fig. 1) caused the spayed ewe's rectal temperature to rise by about 1° F. Records 1½ – 3½ h after injection (Table 2) indicate that each dose-level of stilbœstrol was thermogenic in relation to the control injections with water ($P < 0{\cdot}001$) and that the three dose-levels produced comparable effects ($F = 1{\cdot}78$). Fresh preparations of stilbœstrol used in experiment *B* were ineffective in eliciting a consistent thermal response within 3½ h after injection.

The role of storage in the development of thermogenic properties of aqueous stilbœstrol solutions is of interest since such preparations also lose œstrogenic potency[3,4]. However, the oxidative inactivation of the œstrogen molecule (*in vitro* or *in vivo*) has been shown to reverse its pituitary function from inhibition to stimulation[5]. Thus, the thermal response of the spayed ewe to stilbœstrol may involve profound neuro endocrine interactions.

We are indebted to Mr. J. W. James for statistical advice.

Body Temperature of Birds in Relation to Nesting Habits

The body temperature of birds has been examined by various workers[1–5,7,8]. Temperature has been shown to fluctuate in response to various internal and external influences[1,3,4,8]; there is a difference of the order of 2° C between active birds and those at rest[3,4], and a difference of 1·5° C has been demonstrated between day and night body temperatures in quails[2]. Previous work[7] has shown that the night body temperature of the masked weaver (*Ploceus velatus*) is 1·6° C lower than the day temperature.

The day body temperatures of 80 species of land birds from southern Africa have been recorded during routine collection of museum specimens. A fast-registering rectal thermometer was inserted through the cloaca to the centre of the body-cavity immediately after the bird had been shot. The temperatures of wounded birds were not taken[5,6]. Where more than one reading for a species was available, the mean was used.

Table 1 indicates the rate of decrease in body temperature after the bird is shot. The readings were taken at 30-sec intervals for 3 consecutive min.

Table 1

Species	Wt. (g)	Temperature (° C) 30	60	90	120	150	180 sec
Sacred ibis, *Threskiornis aethiopicus*	964	42·1	42·1	42·1	42·1	42·1	42·1
Laughing dove, *Stigmatopelia senegalensis*	100	43·0	43·0	43·0	43·0	42·9	42·8
Fork-tailed drongo, *Dicrurus adsimilis*	57	42·6	42·6	42·5	42·2	42·1	42·0
Golden-breasted bunting, *Emberiza flaviventris*	23	42·8	42·8	42·7	42·0	42·3	41·9
Blue waxbill, *Uraeginthus angolensis*	14	42·1	42·1	41·0	41·6	41·1	40·8

In no instance did the temperature start to drop before 1 min had elapsed after death. As all readings were taken during this 60-sec period, post-mortem decrease in body temperature can therefore be ignored.

The species under discussion are divided into two main groups, the 'nest builders' and the 'nest scrapers'. The first-mentioned use nesting material, thereby insulating their eggs to some extent, while the second group deposit their eggs on the bare ground or rock where they are not insulated from the substratum. The nesters are subdivided into tree-, hole- and ground-nesters.

Mean body temperatures of the three nesting groups are as follows:

	M	*S.D.*	*N*	$S.E._m$
Tree	41·78	0·7564	39	0·1211
Hole	41·85	0·7612	20	0·1702
Ground	41·98	0·4566	10	0·1444

The differences between these means are not statistically significant.

Mean body temperatures of nest builders compared with nest scrapers are as follows:

	M	*S.D.*	*N*	$S.E._m$
Nest builders	41·80	0·7170	69	0·0863
Nest scrapers	40·20	1·2809	11	0·3862

These mean values are significantly different at the 1 per cent level. ($t = 9{\cdot}627$, 78 d.f., $P < 0{\cdot}01$.)

No definite conclusions can as yet be drawn as to why the nest scrapers should have a lower body temperature than nest builders. However, most nest scrapers have relatively long bare legs, for example, red-crested korhaan (*Lophotis ruficrista ruficrista*), crowned plover (*Stephanibyx coronatus coronatus*), blacksmith plover (*Hoplopterus armatus*), Kittlitz's sandplover (*Charadrius pecuarius*), Cape dikkop (*Burhinus capensis*), etc., although there are exceptions such as rufous-cheeked nightjar (*Caprimulgus rufigena*) and Namaqua sandgrouse (*Pterocles namaqua*).

During the incubation of nest builders it has been shown[4,8] that there is a 'negative' temperature gradient between the upper and the lower surface of the egg, that is, the upper surface in close contact with the body of the incubating bird has a higher temperature than the lower which is in contact with the nesting material. At the Austin Roberts Bird Sanctuary, Pretoria, this gradient was found to be of the order of 4°–5° C for the Egyptian goose (*Alopochen aegyptiacus*), and 5° C for the yellowbill (*Anas undulata*).

In the rufous-cheeked nightjar in the Kalahari Desert, for 4 h (12 noon–4 p.m.) during the hottest part of the day, the temperature gradient between the upper and lower egg surfaces is 'positive' and of the order of 2° C. This reversal of the temperature gradient, where the lower surface temperature of the egg is now higher than that of the upper, is due to the fact that the heat from the substratum (reaching a temperature of 61° C) is conducted to the eggs. It has been shown[9] that certain birds keep their eggs cool during part of the day by shading them. In the nightjar and possibly in other nest scrapers, cooling appears to be achieved by incubation instead[10]. The body of the bird thus acts as a conductor removing excess heat. In this respect the lower body temperature of scrape-nesting birds may be of importance. The long bare legs of some scrapers also fit into this picture as they increase the uninsulated surface of the body, thus enabling the bird to disperse the excess heat more readily.

Urea-Levels in Blood and Tissues of Hibernating and Non-Hibernating Hedgehogs

ANALYSES were carried out during the summer from active hedgehogs (*Erinaceus europaeus*), which were fed on a 'high protein diet', after fasting for one day. Hibernating animals in winter were kept in a constant-temperature cold room (+ 4·0 ± 0·5° C) at least one week before analyses were made.

Urea analyses were performed using the manometric method developed by Krebs and Henseleit[1] as presented by Umbreit, Burris and Stauffer[2]. Besides this, the standardized method of Biochemica 'Boehringer *TC–U*' (C. F. Boehringer and Soehne G.m.b.H., Mannheim) was used. Tissue analyses were performed from tissue homogenates. Control determinations were carried out using well-fed white laboratory rats. Means from analyses of rat blood are: 31·6 mg urea/100 ml. serum and 36·0 mg urea/100 ml. whole blood. These are comparable with those previously reported[3].

Results are summarized in Table 1. Values from whole blood and blood serum are expressed in mg of urea/100 ml., those from tissues in mg urea/100 g fresh weight. In parentheses is the number of animals (sample size) from which the means presented were calculated.

It is significant that the normal urea-level in blood of awake hedgehogs is very high when compared with those of other species analysed[3]. This high urea-level has been previously[4] reported in another hibernating animal, *Citellus parryi barrowensis*.

Table 1

	Awake animals	Hibernating animals	Significance of differences
Whole blood	96·6 ± 8·2 (10)	121·0 ± 5·3 (27)	$P > 0{\cdot}02$
Blood serum	101·5 ± 3·5 (20)	118·2 ± 3·8 (11)	$P > 0{\cdot}005$
Muscle*	104·3 ± 8·6 (7)	152·0 ± 7·9 (10)	$P > 0{\cdot}001$
Small intestine	80·7 ± 5·9 (10)	133·0 ± 9·1 (10)	$P > 0{\cdot}001$

* Diaphragma was used

Hedgehogs show a marked increase in blood (and serum) urea-level in their hibernating state. Because urea is a readily diffusible compound, this increase is also found in tissues. Klar[5] has previously reported increased non-protein nitrogen-levels in hibernating hedgehogs. He claims that the non-protein nitrogen-level increases parallel with the duration of hibernation. The main cause for azotemia demonstrated by Klar is evidently the increased urea-level reported in this communication. Failure to demonstrate gradually increasing urea-levels during hibernation in this investigation probably results from periodic awakenings during hibernation[6].

The increase of urea-levels in hibernating animals depends evidently on the markedly diminished ability of kidneys to remove nitrogen-containing catabolites from the body. The main cause for this renal insufficiency is, according to Hong[7], decrease in glomerular filtration rate which follows the diminished renal blood flow during hypothermia.

In normal conditions the amount of nitrogen-containing compounds excreted in urine is qualitatively and quantitatively held as a criterion of protein metabolism. With reference to the protein metabolism during hibernation, analyses of urine have been performed[8,9], and from the results it was deduced that the protein metabolism is greatly reduced, even more than the general metabolism. These generalized deductions based on urine analyses cannot be considered as quite valid, because the retention of catabolites of protein metabolism during hibernation is evident.

Response of the Testes of Purple Sea Urchins to Variations in Temperature and Light

STUDIES on the reproductive activity of the purple sea urchin, *S. purpuratus*, made during the past eight years at Pacific Grove, California, indicate the presence of an annual breeding cycle, with maximum gonadal activity occurring during the winter months. In the course of the present investigation, designed to examine the effect of latitude on the breeding activity of the sea urchin, it was observed that the sea urchin populations distributed over a 20° latitudinal range have a uniform spawning period. These observations suggest that the reproductive activity of the purple sea urchin might be independent of temperature over a physiological range represented by this distribution. Therefore a photoperiodic response was considered as a possible explanation for the breeding cycles observed.

An experiment designed to test the role of light and temperature on gonadal activity of sea urchins was consequently prepared. The equipment was built and the experiment undertaken in the marine laboratory of the University of California, Los Angeles, where a 28,000-gallon circulating closed sea-water system is maintained. Additional experiments were performed in the laboratory of Marineland of the Pacific, Palos Verdes, California. Two tanks were constructed; one was designed to have 14 h of controlled illumination, the other, 6 h. The sea-water was maintained at 15° ± 0·5° C. Twenty-five sea urchins were placed in individual plastic containers with numerous holes for proper circulation of sea water. Each animal was removed and a 0·25-in. hole was made in the ambitus of the interadius. The sex of the animals was determined, and the gametogenic state assessed by observation of gonadal biopsies. Males were selected for this experiment. The hole in the test was then sealed with 'Plasticine' clay and treated with penicillin.

Once the spermatogenic state has been ascertained, the twenty-five selected animals were placed in the 14-h lighted tank in their plastic containers. An abundant supply of food was maintained. When examining the sea urchins for gametogenic activity the clay plug was removed and a small biopsy of the testes taken and examined under a phase-contrast microscope. Weekly checks were made on each animal over a period of 12–15 weeks. Immediately following this period, the 25 urchins were transferred to the 6-h lighted tank and were examined similarly.

The results obtained so far indicate that at 15° ± 0·5° C the 14-h period primarily stimulates the production of gonial cells. Occasionally, spermatocytes, spermatids, and spermatozoa were observed. However, when the day-length was reduced to 6 h the gonial cells, which were predominant during the long-day stimulus, were reduced in number and the spermatids, spermatocytes and spermatozoa were produced during the 6-h artificial day.

In order to assess the significance of temperature changes alone on gonadal activity, experiments are at present being made at 10° C. Eventually it is hoped to carry out experiments at 5° C, 20° C, and 30° C.

The foregoing temperatures in combination with various photoperiodic stimuli should provide an adequate means for testing gonadal activity of the sea urchin as affected by the two primary environmental variables, temperature and light.

Demonstration of Humoral and Cellular Fixed Antibodies against Homologous Tissue Antigens

THE question whether circulating antibodies appear during sensitization with homologous tissue antigens and whether they have an effect on the homograft reaction has often been discussed. Ever since the work of Mitchison[1], there is no doubt that the mononuclear cells play an important part in the homograft reaction; however, the theory that they are carriers of sessile antibodies was not unchallenged, especially since up to this date exact methods for demonstrating cellular fixed antibodies were not known.

The aim of our investigation was first to examine serological phenomena during homograft reaction and second to detect cellular fixed antibodies against homologous tissue antigens using *in vivo* and *in vitro* methods. For donors we used healthy male albino rabbits (Weisse Wiener), for recipients healthy male rabbits of the Belgian Giant strain. For sensitization we applied tissue antigens differently prepared from the spleen and kidney of the donor. To guarantee an individual specific sensitization, the antigenic material of one donor was applied to one recipient only. To one group of rabbits (group *A*) we injected a mixture of spleen and kidney cells at a concentration of 10^8 cells, to the second group (*B*) an extract prepared according to the technique described by Lejeune-Ledant[2] and to the third group (*C*) an extract prepared according to the same technique but lyophilized in a concentration corresponding to 10^8 cells. All antigens were applied intravenously. After 7 days, skin grafting according to Billingham and Medawar's method[3] was performed in order to detect transplantation immunity. 14 days after the beginning of sensitization, a series of 5 injections of lyophilized extract was applied to each recipient at intervals of 2 days at a concentration of 2×10^7 cells.

The sera for the examination of serological phenomena[4] were obtained before sensitization and afterwards at intervals of 7 days (5 blood samples altogether). Alterations in the protein content of the sera could not be demonstrated during the sensitization period. In the first two weeks the paper electrophoretic analyses of serum protein fractions showed an increase in α_1-globulins in all three groups and later on a slow increase in γ-globulins which, however, was not present in group *A*. Whereas it is suggested that the increase of the α_1-globulin fraction is a sign of an inflammatory reaction, the increase of γ-globulins could be interpreted as related to antibody formation. Experiments to detect precipitating antibodies gave negative results without exception. On the contrary, with the hæmagglutination technique of Boyden[5] individual specific antibodies could be demonstrated, but only of a low titre. It is interesting that these antibodies were present as early as 7 days after the beginning of sensitization. In our investigation the properdin content of the sera determined by an inulin adsorption method[6] rose significantly 14 days after the first sensitization and 7 days after the grafting of homologous skin, respectively. Later on, the properdin values returned to normal level.

To demonstrate transplantation immunity, a gross and microscopic examination of the homografts on the sixth day after grafting was performed. Whereas in group *A* (sensitization by cells injected intravenously) no sign of graft breakdown could be observed, the grafts in group *B* and *C* (sensitization by fresh and lyophilized tissue extracts by the intravenous route) were almost or completely destroyed at this date.

For the detection of sessile antibodies we used the regional lymph nodes of the grafting site and the spleen of rabbits of group *B* (25 specimens altogether) obtained on the fourteenth day after beginning of sensitization and on the seventh day after skin grafting, respectively. The organs were pressed through a stainless-steel sieve and, so isolated, the cells were tested for the existence of sessile antibodies following three different methods: (1) The cells were transferred to untreated animals[7]. In no case could transplantation immunity be shown. These observations are in contrast to the findings of Mitchison. An explanation might be the genetic difference of the rabbits causing the destruction of the transferred lymph cells by homograft reaction, whereas Mitchison used inbred strains of mice.

(2) Investigations of the passive cutaneous hypersensitivity reaction[7] were performed. Here the cells were injected intracutaneously into untreated rabbits and 12 h later the corresponding antigen was given. On the average 24–48 h later a positive reaction with induration, erythema in every case and sometimes even necrosis could be observed. Controls with a non-corresponding antigen or with saline showed mostly a negative result. Experiments with non-sensitized lymph cells were also negative.

(3) In order to detect sessile antibodies by an *in vitro* method we utilized the technique described by Warnatz *et al.* and Steffen[7,8]. Here lymph node and spleen cells of sensitized rabbits were incubated with the corresponding antigen *in vitro* and the washed cells mixed with a heterologous antiserum (dog, rat) of a known titre and specifically directed against that antigen. The decrease in the titre of the antiserum after incubation was determined. It is assumed that the antigen reacts with the antibodies which are fixed at the investigated cells. The decrease in titre of the heterologous antiserum after incubation with cells so prepared indicates the existence of cellular fixed antibodies. In our investigation the titre decreased 1–3 steps of an antiserum dilution row. As compared with results of the controls these findings suggest that cellular fixed antibodies exist.

β-Carotene and Sexuality in the Mucoraceae

THERE have been frequent reports of an association between β-carotene and reproduction in the Phycomycetes[1]. Recently, a stimulation of β-carotene production in mixed + and − cultures of four heteromictic[2] species of the Choanephoraceae has been reported[3,4]. It is not known whether this is a general or an isolated phenomenon in the Mucorales.

The following strains of heteromictic species were tested for β-carotene accumulation in intra- and inter-specific mixed cultures:

1 *Mucor hiemalis* +1
2 *M. hiemalis* −1
3 *Phycomyces nitens* +*H*102
4 *P. blakesleeanus* +1
5 *P. blakesleeanus* −1
6 *P. blakesleeanus* −6
7 *P. blakesleeanus* −*E*45
8 *Helicostylum pyriforme*
9 *Cunninghamella elegans* +1
10 *C. elegans* −1
11 *Absidia glauca* +1
12 *A. glauca* −1
13 *Mucor ramannianus*
14 *Circinella* sp.
15 *Rhizopus nigricans* +1
16 *Pilobolus sphaerospora*
17 *Conidiobolus villosus*
18 *Thamnidium elegans*

In addition, three homomictic species were tested:

19 *Rhizopus sexualis*
20 *Zygorhynchus moelleri*
21 *Z. vuilleminii*

All were originally obtained from the Centraalbureau voor Schimmelculture, except 13, which was isolated in this laboratory from soil. The homomictic species formed abundant zygospores on solid medium, as did the heteromictic strains in the appropriate combinations.

An inoculum of 10^7 asexual spores, which was found to be optimal, was added to 25 ml. of modified Schopfer's[5] medium in 150-ml. conical flasks plugged with gauze-covered cotton wool. The flasks were mounted on an illuminated reciprocating shaker at 25° C and the submerged shake cultures grown for up to four weeks. Cultures were triplicated at least.

The washed and partially dried mycelium was extracted with acetone and the principal pigment, β-carotene, characterized and determined spectrophotometrically[6,7].

Strains 1–8 grown singly did accumulate β-carotene to varying degrees. However, in no mixed culture was the amount of β-carotene significantly different from the expected mean of the values accumulated by the component strains grown alone (Table 1). Moreover, none of strains 9–21 accumulated β-carotene to a detectable degree, either in isolation or in mixed cultures although the homomictic cultures formed zygospores.

Table 1. β-CAROTENE ACCUMULATION BY MIXED CULTURES.
(Values are in μg β-carotene/g dry weight of mycelium)

Strains	1 × 2	3 × 5	3 × 6	3 × 7	4 × 5	4 × 6	4 × 7	5 × 6	6 × 7	6 × 7
Expected	406	148	110	147	175	137	174	112	149	111
Observed	457	137	133	152	166	128	102	120	152	123
S.D.	30	10	12	13	15	11	12	12	4	13

These results confirm and extend those of Reichel and Wallis, who found no stimulation of 'carotene' accumulation in mixed cultures of their strains of *P. blakesleeanus*[8]. Such a stimulation appears at present, therefore, to be confined to the Choanephoraceae.

Effect of Gibberellic Acid on Flowering of Apple Trees

It has been shown by Sironval *et al.*[1] that gibberellic acid (GA_3) affects growth of the main shoots in apple trees (var. Golden Delicious) and apical dominance. Apple-trees treated with 300 p.p.m. GA_3 (1–2 ml. given twice a week on the apical bud and young leaves) throughout the growing season are greater and form twice as many lateral shoots as control trees,

On the other hand, it has long been claimed by gardeners that, in apple trees, growth of the shoots and flowering are antagonist processes. Indeed, Wareing and Nasr[2], investigating the effects of gravity on growth and flower formation, have shown that apple trees (apple rootstock No. 3436) grown horizontally have a reduced growth, but initiate more flowers than apple trees grown vertically (gravimorphism). We found it interesting to investigate flower formation of apple trees treated with gibberellic acid (GA_3).

Apple trees (var. Golden Delicious) were treated with GA_3 (100 and 300 p.p.m.) in 1961 according to the method of Sironval *et al.* At the end of the growing season, the plants treated with 300 p.p.m. GA_3 were greater than the control plants (increase of about 15 cm); the plants treated with 100 p.p.m. GA_3 were also a little higher than the controls. The treated plants bore 9–11 lateral shoots, while the controls bore only 4–5 lateral shoots. In the spring of 1962 the apple trees were re-examined for flowering.

Table 1 gives the absolute number of flower buds found on the whole plant and also on the main and lateral shoots. It is seen that treated plants formed more flower buds than control plants. The increase in the absolute number of flower buds resulted chiefly from the lateral shoots, which were more numerous in treated plants; the main shoots gave a similar absolute number of flower buds in treated and control plants.

Fig. 1 gives the percentages of the different categories of buds found on main and lateral shoots, and on the whole plants: dormant buds, vegetative and flower buds.

(1) On main shoots there was nearly the same percentage of dormant buds in treated and control plants. The percentage of flower buds was, however, lower in treated than in control plants.

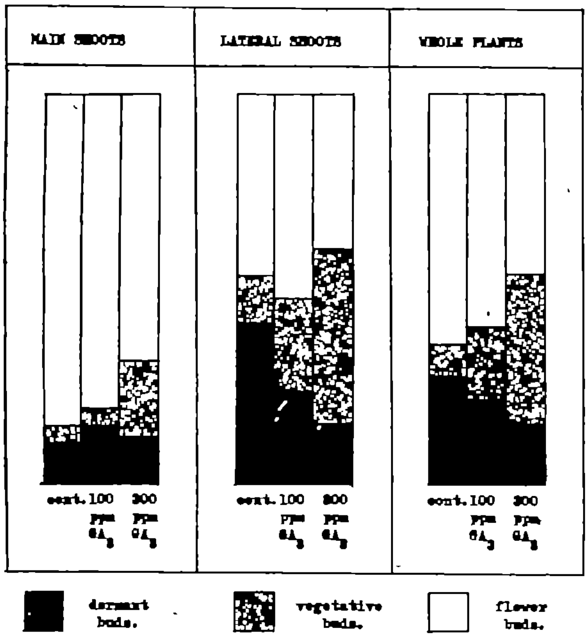

Fig. 1. Effect of gibberellic acid applied to apple trees (var. Golden Delicious) during the growing season 1961 on the proportion of dormant, vegetative and flower buds found in the spring of 1962 (relative number of the different kinds of buds expressed in percentage of the total number of buds)

Table 1. Effect of Gibberellic Acid on the Absolute Number of Flower Buds per Tree

Series	Whole plant	Main shoots	Lateral shoots
Controls	38	24	14
100 p.p.m. GA_3	58	21	37
300 p.p.m. GA_3	56	19	37

(2) On lateral shoots, the percentage of dormant buds was lower in treated plants than in control plants. The percentage of flower buds was again lower in treated than in control plants, except for the 100 p.p.m. treatment.

(3) For the whole plant, we found a decrease of the percentage of dormant buds and a decrease of the percentage of flower buds in treated trees when compared with the control ones.

This means that if, in absolute value, the number of flower buds is higher in GA_3-treated apple trees, owing to the great increase of the number of buds present on the lateral shoots, the percentage of flower buds is decreased when GA_3 is applied.

It may be concluded that the enhancement of the growth of the shoots (both main shoots and lateral shoots) by gibberellic acid treatment corresponds to a relative decrease in the capacity of the buds to form flowers. The result is similar to that obtained by Wareing and Nasr using gravimorphism; it corresponds to the relation generally claimed in practice between rate of growth of the shoots and flower formation in apple trees.

ENTOMOLOGY

Feeding Stimulants required by a Polyphagous Insect, *Schistocerca gregaria*

It has been shown by Hamamura *et al.*[1] that food selection in the silkworm larvæ (*Bombyx mori*) is controlled by three chemical factors which they have called the attractant, the biting and the swallowing factors.

The desert locust (*Schistocerca gregaria*), which is a polyphagous insect, appears to require only the attractant and the swallowing factor to evoke the normal feeding behaviour. This behaviour pattern begins with the locust approaching the food and then lowering the tips of the antennæ and palps on to the food surface and biting. Sustained feeding then continues without further testing of the food with the antennæ; the palps alone are used to test the food as the insect feeds.

The experiments described here were performed to determine whether a few widely dispersed plant compounds would stimulate feeding by *Schistocerca*, or whether a number of compounds each present in a limited range of plants would be required. A series of extracts were made from plants on which the locust normally feeds, and these extracts were then run singly on to filter paper circles. The solvent was removed from the papers, and these were then placed in cages containing locusts. It was observed that the ether extract alone stimulated a marked testing behaviour in the locusts, and this testing always terminated with a single bite after which the locust would test the surface of the filter paper elsewhere. It was therefore assumed that the ether extract contained the attractant factor, and possibly a biting factor.

To determine whether this stimulant was the same substance or substances in the plants that were tested, a series of paper chromatograms were made using the ether extract and a variety of solvents and solvent mixtures. The chromatograms were then dried and placed in cages with locusts. Certain solvents (phenol, acetic acid) were found to be retained on the chromatograms sufficiently to make the entire chromatogram repellent to the locusts. Other solvents (petrol, ether, butanol, carbon tetrachloride, acetone) did not have this effect, and in these instances the locusts responded to one zone on each chromatogram with their complete testing behaviour which included the final bite. From these experiments it seemed unlikely that *Schistocerca* required an individual biting factor that Hamamura *et al.* have found necessary for satisfactory feeding by *Bombyx*.

Table 1. CLASSIFICATION OF FEEDING STIMULANTS BASED ON THE BEHAVIOUR OF *Schistocerca* TOWARDS PLANTS

Behaviour of locust towards the plants	Olfactory stimulant	Gustatory stimulant	Classification of plant	Examples of plants in each category
Tests surface of plant and feeds	Positive attractant	Positive acceptant	Acceptable	*Dactylis* *Plantago* *Lamium*
Tests surface of plant, bites but does not feed	Positive attractant	Negative rejectant	Non-acceptable	*Zea* *Tagetes*
Locust turns away from plant	Negative repellent	Negative rejectant		*Myrica* *Lavandula* *Cupressus*

The R_F value of the active zone was not the same in each plant for equivalent solvent systems, so it was concluded that *Schistocerca* will respond to a number of attractants.

As Hamamura *et al.* have reported for *Bombyx*, the feeding stimulant is also found in the acetone extract, and filter paper circles with an acetone extract of an acceptable plant plus the ether extract of *Dactylis* induced the locust to feed (the ether extract was required to induce the locust to bite the substrate and so bring its oral receptors into contact with the surface of the filter paper). A comparison of the acetone extracts of a series of plants showed that there was more than one acceptant substance in some plants (*Dactylis* and *Trifolium* both had two), and in certain instances (*Lavendula*) a plant may have positive feeding stimulants present in its tissues although the effect of these substances is masked by negative feeding stimulants.

A classification of the feeding stimulants proposed to account for the observed feeding behaviour of *Schistocerca* towards possible food material is given in Table 1. (Note: Thorsteinson[2] adopted this classification after discussion with me.)

MICROBIOLOGY

In vitro Species (or Type) Transformation among Strains of *Brucella*

EXAMPLES reported in the literature concerning mutation in *Brucella* organisms have been received with strong criticism[1,2] arising, apart from other reasons, from the scarce number of cases involved or based on the negative results of other workers[3].

This communication presents the results of my work in this field, fundamentally related to the taxonomy of this bacterial genus, with the purpose of offering support to one of the opinions in conflict. The observations seem to prove that *Brucella* is a group of micro-organisms of particularly labile character and not infrequently affected by transformation.

Early in 1958 it was unexpectedly noticed that three *Br. melitensis* recently isolated appeared to have changed their serological behaviour only by reacting with the monospecific *abortus* serum; when tested biochemically these strains reacted like *Br. abortus*. This observation was taken at first with great reserve as it could have obviously been caused by accidental error; but a similar finding, in cultures of old storage, was soon found in the German literature as reported by Roots and Sprockhoff[4]. Decisive evidence was, however, obtained from a group of five other *Br. melitensis*. These strains, while changing antigenically to *abortus*, retained their original biochemical characteristics, in this way assuming the pattern of Renoux's *Br. intermedia*. A search for variation was therefore decided: care was taken to prevent any labelling faults to take place during the transfers of the strains in stock and the whole collection of cultures was checked at least once or twice a year by the following tests: (*a*) acriflavine test ($S \rightarrow R$ variation); (*b*) urease test; (*c*) slide agglutination test (using monospecific sera diluted to end-titre according to my technique[5]). For a final identification the inhibition dye test was also applied using basic fuchsin and thionin at concentrations of 1/25,000 and 1/50,000 and also safranin at 1/10,000. This dye was found to be a very useful tool for differentiating *Br. suis* from any other *Brucella*.

During 1959 it was found that a group of 26 strains had changed their previous classification.

When recently my collection of cultures was typed by the four known bacteriophages—10/I, 24/II, 212/XV and 371/XXIX—isolated and kindly supplied by Prof. J. Parnas (to whom I am indebted) an unexpectedly high number of discrepant results were registered. I admitted that mutation could explain them. In fact when the cultures concerned were again characterized biochemically and serologically a second group of 38 converted strains emerged from: (*a*) the whole of (27) *Br. melitensis* showing phage-sensitivity; (*b*) part of the *Br. abortus* showing phage-resistance; (*c*) other strains.

Altogether 64 stock cultures, out of a collection of 300, have suffered species or type reversion. The changes were as follows:

(*a*) 35 *Br. melitensis* changed into: 12 *Br. abortus*; 9 *Br. intermedia*; 11 *Br. suis*; 3 *Br.* 'strain AM' (*Br.* 'strain AM' is a strain with the biochemical characteristics of *Br. abortus* but reacting serologically with the *melitensis* serum).

(*b*) The variation of 12 *Br. abortus* occurred thus: 4 strains (types I and III) into *Br. suis*; 1 strain type III into *Br.* 'strain AM'; 1 strain type I became biochemically atypical and was taken as variant '*abortus-suis*'; 6 strains suffered inter-type variation: 4 strains type III changed into type I, 1 strain type II into type I and 1 type I into type III.

(*c*) All the 16 *Br. intermedia* of my collection suffered variation and they were now: 10 *Br. suis*; 5 *Br. abortus*; 1 *Br. melitensis* (atypical).

(*d*) 1 *Br.* 'strain AM' changed into *Br. abortus*.

Multiple or successive mutation was also observed in some cultures.

A Biochemical Test for Crown Gall Bacteria

Agrobacterium tumefaciens is the agent for crown gall disease of several plants, thus causing serious economic losses in many countries. Except for its phytopathogenic action, it does not display any characteristic physiological or morphological properties. Its final identification is established by experimentally induced tumours, a procedure which often demands too much time for quick intervention in an epidemic. A quick, easy and specific identification test would be very useful. We wish, therefore, to report that *Agrobacterium tumefaciens* and *A. radiobacter* produce 3-ketoglycosides from the corresponding disaccharides and bionic acids. We propose a test based on this property, which is very simple, can be carried out in any phytopathological laboratory with ordinary glassware and chemicals, gives a result after 1–2 days and is, so far as we can judge from our present experience, limited to members of the genus *Agrobacterium*.

In previous papers[1–4] we described a new type of microbiological sugar oxidation which so far is unique in its mechanism because it consists in the oxidation at carbon 3 of the glycosyl moiety of disaccharides and bionic acids. Other compounds are not attacked. The following 3-ketoglycosides have been prepared: 3-ketolactose (3-ketogalactopyranosyl-glucose), 3-ketomaltose, 3-ketosucrose, 3-ketolactobionic acid and 3-ketomaltobionic acid. These compounds can easily be detected because they quickly reduce the usual sugar reagents (Fehling, Benedict, Luff, etc.) at room temperature. It was difficult to decide the exact taxonomic position of our bacteria, which carried out the foregoing oxidation (small, motile, Gram-negative rods, tentatively classified as *Alcaligenes*) due to the lack of typical characteristics and the fact that 3-ketoglycosides had never been described before.

Therefore, a systematic search among several bacterial genera was undertaken, which showed that only *Agrobacterium tumefaciens* and *A. radiobacter* produced the same 3-ketoglycosides as our strains. The formation of the latter compounds was studied with aerated, growing cultures in the medium previously described[2] and was followed either by reduction at room temperature of the Benedict reagent or by reaction with semicarbazide[4]. Ten different strains of *A. tumefaciens* and 4 strains of *A. radiobacter* (from the American Type Culture Collection, Washington; the National Collection of Industrial Bacteria, Aberdeen; Dr. J. la Rivière, Laboratory for Microbiology, Delft, The Netherlands, and Dr. Ch. Bonnier, Institut Agronomique, Gembloux, Belgium) were positive. Lactose was a particularly good substrate and with most strains a very rapid and nearly quantitative yield of 3-ketolactose was obtained. Only *A. tumefaciens*, strain No. 11.095 (A.T.C.C.), never produced 3-ketoglycosides. We therefore doubt its correct labelling, even more so since we found no phytopathogenicity. *Agrobacterium rhizogenes* (strain 11.325 from A.T.C.C. and 8.196 from N.C.I.B.) was physiologically quite different from the other two species and did not produce 3-ketoglycosides. A total of 80 strains representing at least 33 species of the following genera did not produce 3-ketoglycosides: *Acetobacter*, *Aerobacter*, *Alcaligenes*, *Bacillus*, *Chromobacterium*, *Corynebacterium*, *Escherichia*, *Gluconobacter*, *Nocardia*, *Mycobacterium*, *Paracolobactrum*, *Pseudomonas*, *Rhizobium*, *Streptomyces* and *Xanthomonas*. It seems thus quite likely that our original strains also belong to the genus *Agrobacterium*. Electron microscopy showed them to possess 2–6 lateral flagella. They were not phytopathogenic for *Chrysanthemum frutescens*. Based on the foregoing information the following test for the quick detection of *A. tumefaciens* and *radiobacter* is proposed. A pure culture of the bacteria investigated, isolated from a plant tumour or any other source, is grown for 1–2 days at 25°–30° on slanted agar containing (in per cent w/v): 1, yeast extract (Difco); 2, glucose; 2, calcium carbonate; and 1·5–2 agar. A loopful of the bacteria is deposited on a solid medium (1 per cent lactose, 0·1 per cent yeast extract Difco and 2 per cent agar) in a Petri dish as a small heap, about 0·5 cm or less in diameter. 4–6 strains can be applied on the same plate. The latter is incubated at 28° for 1–2 days, afterwards flooded with a shallow layer of Benedict reagent and left at room temperature. If 3-ketolactose is present a yellow ring of Cu_2O becomes visible around the cell mass; after one hour it is maximal in diameter (about 2–3 cm), its yellow colour contrasting strongly with the blue reagent solution. Calcium lactobionate, when used in the test medium instead of lactose, yields the same results due to 3-ketolactobionate formation, but it is less readily available for routine analysis. Since the yield of 3-ketoglycosides from maltose, maltobionate and sucrose is much smaller, the rings are weaker and less distinct. Practical application of this test is being investigated.

We thank the Nationaal Fonds voor Wetenschappelijk Onderzoek for a grant, Dr. J. la Rivière (Delft) for strains and Dr. Ch. Bonnier (Gembloux) for strains and for carrying out the phytopathological tests.

Effect of Bromouracil-labelled Transforming Deoxyribonucleic Acid of *Bacillus subtilis* on Cell Growth

BROMOURACIL inhibits bacterial growth through its incorporation into the deoxyribonucleic acids in place of thymine[1]; however, infectivity of bacteriophage[2] and transforming activity[3] remain even though the DNA is

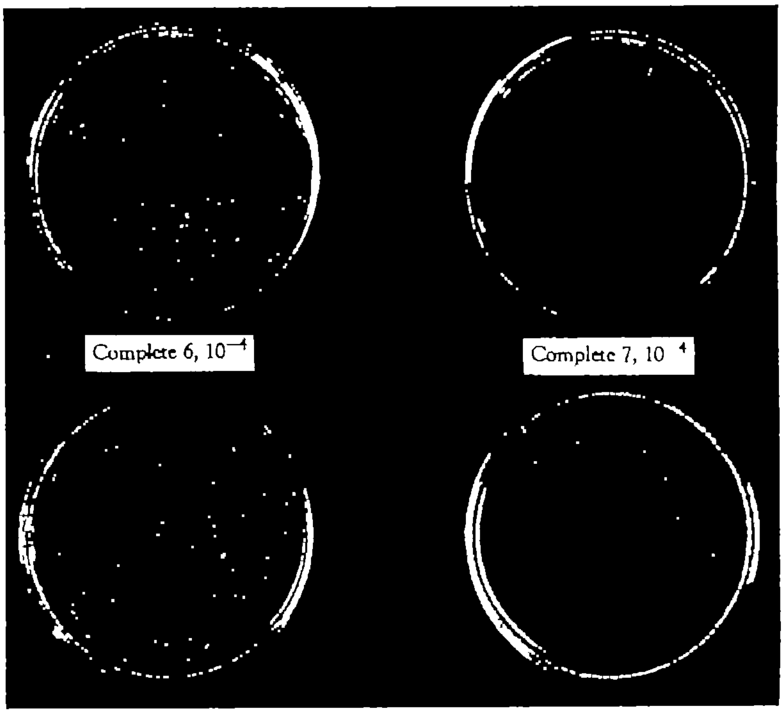

Fig. 1. Effect of incorporation of bromouracil labelled DNA on the growth of *Bacillus subtilis* strain 168 on the enumeration medium. Competent *B. subtilis* cells were exposed to wild-type DNA and to wild-type DNA labelled with bromouracil. The plates on the left are a dilution of the cells exposed to the normal DNA, while those on the right are the same dilution of cells exposed to labelled DNA. In both cases the same original concentration of cells was used

heavily labelled with bromouracil. In this communication we wish to report on the incorporation of bromouracil into *Bacillus subtilis* wild-type DNA and its effects on cell growth when the organisms are plated on the medium used for enumeration of the total cell number in transformation experience.

Ephrati-Elizur and Zamenhof[3] as well as Szybalski *et al.*[4] have reported failure to obtain measurable bromouracil incorporation into wild-type DNA. The wild-type *B. subtilis* cells were grown on the minimal medium described by Spizizen[5]; the bromouracil at a concentration of 20 μg per ml. was added 3 h prior to collecting the cells by centrifugation. DNA was isolated by the procedure of McDonald[6]. Paper chromatography of acid hydrolysed DNA by the procedure of Djordjevic and Szybalski[7] revealed the presence of bromouracil in the isolated DNA.

Transformation of strain 168 (indole- to independence) was obtained with bromouracil·labelled DNA as well as with normal DNA. The labelled DNA was slightly less effective. Transformations were done by the procedure of Young and Spizizen[8].

There was a reduction by about 10[2] of the number of cells growing on the enumeration (minimal plus tryptophan) medium of total cell number. Fig. 1 shows photographs of Petri dishes containing dilutions of the cells exposed both to normal and bromouracil containing DNA cells plated on the control medium. This effect occurred when normal and bromouracil labelled DNA's were mixed in equal proportions; however, the normal DNA antagonizes the bromouracil DNA. Acid hydrolysis of the bromouracil labelled DNA completely abolished the effect of growth inhibition. Addition of free bromouracil to the transformation medium did not inhibit growth on the control medium.

Although our results agree with those of Ephrati-Elizur and Zamenhof[3] and Szybalski *et al.*[4,9] in that the incorporation of bromouracil into DNA allowed retention of transforming activity, we find that incorporation of bromouracil into DNA causes an apparent decrease in the number of viable cells which are able to grow on control medium when these cells have been incubated under transforming conditions with bromouracil labelled DNA. The possibility that the incorporation of bromouracil is mutagenic under these conditions is being investigated.

This work was supported in part by grants from the American Cancer Society (*E*–229 and *E*–229*a*).

VIROLOGY

Potentiating Effect of 5-Fluorouracil on the *In vitro* Antipoliovirus Activity of Guanidine

PREVIOUSLY[1,2] we have shown that guanidine possesses a strong and highly specific inhibitory action against enteroviruses. This antivirus activity of guanidine seemed to us of interest due to: (1) its specificity; (2) the simplicity of guanidine molecule; (3) the ability of guanidine to stop the cytotoxic effect of poliovirus even when added to cell cultures which were infected several hours previously.

However, we were unable to determine the mechanism(s) of the *in vitro* inhibiting activity of guanidine against the poliovirus. Guanidine inhibition of poliovirus replication was not counteracted by a number of biologically active substances such as amino-acids, purine and pyrimidine bases and vitamins. In addition guanidine did not seem to act directly either on the virus or on the cell.

In order to elucidate the mechanism involved in the antiviral action of guanidine, we have investigated how this action might be influenced by chloramphenicol and 5-fluorouracil. It is known that the former inhibits protein synthesis and the latter interferes with nucleic acid synthesis.

Table 1. *In vitro* INHIBITION OF POLIOVIRUS CPE BY THE ACTION OF GUANIDINE HYDROCHLORIDE ACTING SINGLY OR IN COMBINATION WITH CHLORAMPHENICOL OR WITH 5-FLUOROURACIL

* HeLa cell tube cultures infected with different inocula of polio-1-virus (0·1 ml.). These were incubated at 20° C × 60′, washed four times with 5 ml. of Hanks's BSS which was added with maintenance medium (with or without guanidine and 5-fluorouracil). The cultures were then incubated at 36° C. Titration of CPU present in the culture media (or in whole cultures after cryolysis) was performed by the end-point method, at several time-intervals from viral inoculum.
† Titrations performed with the whole culture after its cryolysis.

Polio-1-virus (strain Brunhenders) was propagated in stationary cultures of HeLa cells, maintained in a medium containing Hanks's balanced salt solution (BSS), lactalbumin hydrolysate and calf serum. The substances to be tested were added to the culture media in the proper concentrations. The poliovirus cytopathogenic effect (CPE) inhibition was evaluated after 5 days of incubation at 36° C. The inhibition of the poliovirus replication was evaluated by counting the cytopathogenic units (CPU) present at various time-intervals in the culture media. The results are summarized in Tables 1 and 2. They show that chloramphenicol, in doses tolerated by the cells, does not inhibit the poliovirus CPE, nor does it reinforce the antipolio activity of guanidine. The antiviral activity[3] of 5-fluorouracil is confirmed by our experiments. Further, the results demonstrate that inactive or very slight active doses of 5-fluorouracil potentiate the antipolio-activity of guanidine.

We do not know the mechanism of this potentiating effect. It can be postulated that guanidine and 5-fluorouracil both interfere with the ribonucleic acid synthesis, or that 5-fluorouracil makes the cells less suitable for supporting the virus replication. However, Kovacs[4] has observed that HeLa cells treated with large doses of colchicine are able to support poliovirus replication, as do the untreated cells.

Intranuclear Inclusions produced by Bovine *para*-Influenza

Myxoviruses generally produce cytoplasmic but not nuclear inclusions in infected tissues. Reports on the cytopathology of human strains of the *para*-influenza viruses[1–4] in stained tissue culture preparations record only the finding of intracytoplasmic inclusions, although in *FL* cells specific intranuclear immunofluorescent staining has been demonstrated with *para*-influenza 3 (ref. 5). Reisinger *et al.*[7] reported both intranuclear and intracytoplasmic inclusions in calf kidney tissue culture infected with the *SF* 4 bovine strain of *para*-influenza 3.

We have passaged the *SF* 4 strain in primary monkey kidney tissue and *Hep* 2 cell cultures and have been able to demonstrate nuclear and cytoplasmic inclusions in both systems. Intranuclear inclusions have been most readily demonstrated in infected *Hep* 2 cell cultures. Cultures were grown on a medium consisting of Earle's BSS + 15 per cent horse serum + 0·1 per cent glucose + 1 per cent yeast extract + 0·2 per cent sodium bicarbonate with antibiotics. Before infection, cultures were changed on to a maintenance medium of the same composition as the growth medium, except that the horse-serum content was reduced to 1 per cent. Tube cultures inoculated with approximately 100 $TCID_{50}$ were fixed with Bouin's fluid at 2, 3, 4 and 6 days post-infection and were stained with Ehrlich's hæmatoxylin and eosin. Eosinophilic nuclear inclusions were first detected at 3 days, and at this stage were only in the nuclei, contained within syncytial areas. By four days the inclusions were demonstrable in all the nuclei within syncytial areas. Multinucleated cells containing nuclear inclusions always contained also cytoplasmic inclusions. One to nine inclusions were found scattered within the nucleus, and were sometimes of such a shape as to suggest that two or three had become fused together. Fig. 1 shows an infected *Hep* 2 cell sheet fixed and stained four days after infection. The clear halo surrounding the inclusions is probably a product of the method of fixation.

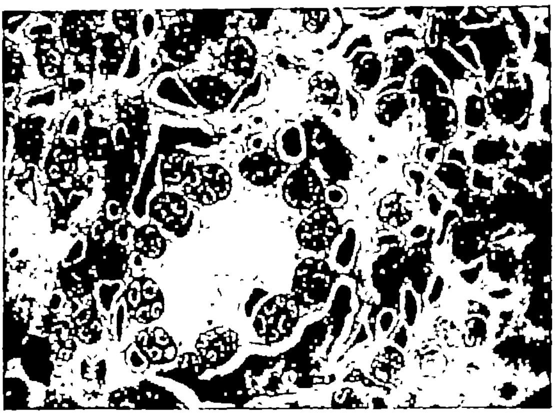

Fig. 1. *Hep* 2 cell monolayer 4 days after infection with *SF* 4 virus (stained with hæmatoxylin and eosin, × c. 233). Individual cells have lost their identity, becoming fused into a large syncytium. Nuclear and cytoplasmic inclusions are numerous and are surrounded in each case by a halo

I have been unable to demonstrate similar nuclear inclusions in *Hep* 2 cells infected with a human strain of para-influenza 3 under the same conditions. These findings suggest a biological, as well as a serological[8–10], distinction between human and bovine strains, although further work is needed to demonstrate that nuclear inclusion formation is a constant distinguishing feature. Waterson[11,12] has suggested that the measles, distemper and rinderpest viruses be placed in the Newcastle disease virus group of myxoviruses. The production of nuclear inclusions by *SF* 4 virus, an accepted myxovirus, provides another link in this association. It also means that not every virus growing in monkey kidney and *Hep* 2 cells producing syncytia and nuclear inclusions is measles as is sometimes assumed. It might be easy to confuse the two without serological or hæmagglutination tests.

I thank Dr. Robert Reisinger and Dr. Ronald G. Marshall of the U.S. Department of Agriculture for the supply of the *SF* 4 strain of virus, and Dr. M. G. Pereira, of the Central Public Health Laboratories, London, N.W.9, for the *HA* 1 virus of human origin.

Demonstration of Leptospiral and Viral Antigens in Formalin-fixed Tissues

During the past few years the fluorescent antibody procedure has been applied with increasing success in the demonstration of microbial antigens. Naturally occurring cases of leptospirosis, venereal infections, influenza, rabies, and other diseases have been diagnosed[1] and further investigations will undoubtedly extend the application of this new diagnostic tool.

The application of the fluorescent antibody procedure is nevertheless limited by the lability of some of the antigens to be demonstrated. The quick freezing of tissue specimens, which is the best method for retaining the immunological activity of the antigens, is often not practicable under field conditions. Both fixation in 10 per cent formalin and storage at room temperature progressively decrease the property of the antigens contained in the tissues to bind with the fluorescent conjugate.

Application of the fluorescent antibody procedure to the detection of leptospiral[2] and viral[3] antigens in formalin-fixed tissues has been attempted with negative results. Its feasibility was considered worth investigating, and several chemical substances were taken under consideration to determine their capacity in neutralizing the action of the formalin on the antigens.

Immune sera, globulins, fluorescent conjugates and tissue extracts were prepared according to a procedure previously reported[4]. Antileptospira sera were prepared in rabbits; anti-canine distemper and infectious hepatitis sera in dogs; anti-Newcastle disease sera in rabbits and in chickens; anti-infectious bronchitis, laryngo-tracheitis and fowl pox sera in chickens. To obtain a high antibody-level it was sometimes necessary to concentrate a conjugate by ammonium sulphate precipitation[5]. Acetone tissue extracts, for absorption of the conjugates, were prepared from fresh and formalin-fixed tissues of several animal species. Four micron sections of both fresh and formalin-fixed tissues were obtained by means of a cryostat (Harris). A Fluorex (Reichert) apparatus and the filter combination *UG*–1 (primary), *W*–2*A* (secondary) and *S–GB* 12, *GG*–9, respectively, were used for microscopical observation.

Leptospiral smears which had been kept in 10 per cent formalin for two months and were no longer stainable by means of the conventional fluorescent antibody procedure were blotted dry and fixed in acetone at room temperature for 5 min. After drying at 37° C they were placed for 5 min in one of a series of ten-fold dilutions of sodium phosphate monobasic, dibasic and tribasic, sodium bisulphite, sodium carbonate and bicarbonate, sodium hydroxide, potassium phosphate monobasic, potassium hydroxide, ammonium sulphate, ammonium chloride, ammonium oxalate and ammonium hydroxide. Afterward the slides were washed in pH 7·2 buffered saline containing 3 per cent 'Tween 80', blotted dry and reacted with the immune conjugate at 18° C (or at 37° C). After washing in buffered saline the slides were counterstained with rhodamine aspecific conjugate (Difco) diluted 1 : 10, washed in buffered saline, and mounted with buffered glycerine. Specificity of the positive results was determined in every case; immune non-labelled globulin applied to the section before the fluorescent conjugate inhibited the specific fluorescent stain. It was seen that of all the chemicals tested only the contact for 3–5 min with 1 per cent ammonium hydroxide or for 5 min with 25 per cent sodium bisulphite allowed a bright staining of the microbial bodies. A similar effect was obtained by exposing the smears to ammonium hydroxide vapours for 48 h at 37° C. Leptospira could be detected by application of ammonium hydroxide or sodium bisulphite to sections of formalin-fixed tissues of experimentally and naturally infected animals. Tissues gave identical results when submitted to fluorescent antibody diagnosis either after quick freezing or after formalin fixation for several months, and slight shrinking of the leptospira was the only morphological alteration observed. A good correlation was found between the results obtained by the fluorescent antibody procedure applied to formalin-fixed tissues and those obtained from the same cases by serological, isolation and silver impregnation techniques.

Formalin-fixed post-mortem tissues from cases of canine distemper and infectious hepatitis were submitted to the action of ammonium hydroxide and sodium bisulphite. These cases had been diagnosed by the clinical symptoms, the presence of inclusion bodies, and the demonstration of viral antigen with the fluorescent antibody procedure in sections of quickly frozen tissues. The viral antigen detected in formalin-fixed tissues by the fluorescent antibody technique was visible with equal clarity and in the same intracellular location as in the tissues which were frozen immediately after collection. The only observed difference was a marked shrinkage of the fluorescent areas.

Viral antigen was likewise clearly visible in formalin-fixed tissues of chicken embryos and chickens experimentally infected with Newcastle disease, infectious bronchitis, laryngo-tracheitis and fowl pox. The results obtained compared very favourably with those obtained from egg inoculation and from the application of fluorescent antibody procedure to quickly frozen tissues.

No cross-reaction was noticed between the different conjugates used in this study; normal non-infected tissue did not stain. 'Tween 80' applied before the fluorescent conjugate increased the brightness of the specific fluorescent areas two- to four-fold, allowing a considerable reduction in staining time. The non-specific fluorescein staining which results from the use of conjugates treated with heterologous tissue extracts can be quenched by the use of rhodamine counterstain. This finding was helpful in the diagnosis of diseases affecting different animal species because it eliminated treatment of the conjugates with species-specific tissue extracts. The striking contrast between the red background and the green antigen facilitated the detection of a considerable number of doubtful reactions.

These modifications of the fluorescent antibody procedure warrant further investigation because of the following practical implications: (*a*) elimination of the hazard of handling infection material; (*b*) simplification of collection, shipment and storage of suspected specimens; (*c*) investigation by means of the fluorescent antibody procedure of specimens submitted for routine histopathological examination; (*d*) possibility of a more extensive use of this relatively new tool.

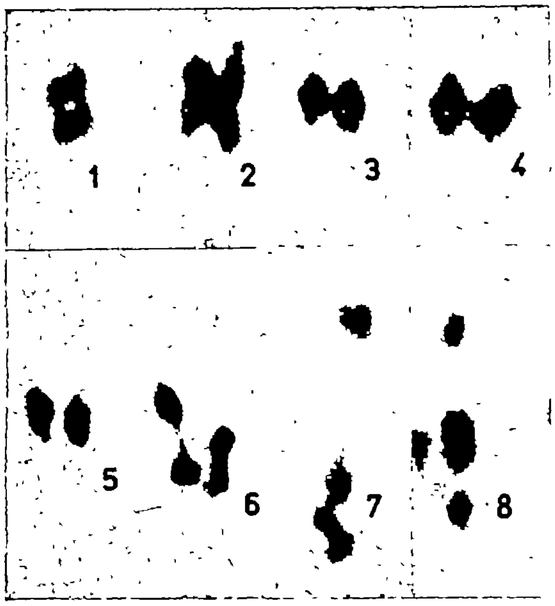
CYTOLOGY

Pseudo-Quadrivalents in Autotetraploid Rice

In the course of a statistical examination of chromosome pairing in PMC's of various induced tetraploid forms of *Oryza sativa*, I have found a regular decrease of the quadrivalent frequency from diakinesis to metaphase I. For 533 cells observed at diakinesis and 741 at metaphase, the mean numbers of quadrivalents per cell were respectively 7·61 and 6·25 : this reduction (18 per cent) is very significant. Together with the reduction of quadrivalent frequency, a complementary increase in the number of bivalents (from 8·63 to 11·01) was noticed. A few uni- and tri-valents were also present at diakinesis (on an average 0·15 and 0·05 per cell) and their number increased up to metaphase (respectively 0·47 and 0·17). These observations showed that some quadrivalents became dissociated before anaphase; they generally gave rise to two bivalents, but sometimes to one trivalent and one univalent or one bivalent and two univalents.

During diakinesis and, more frequently, during prometaphase and metaphase, some chromosomes appeared to be less closely associated than in typical quadrivalents: they were separated by a partly achromatic zone or a more or less elongated thread. Some groups of four chromosomes appearing as quadrivalents, were thus formed by a loose association between two bivalents or, less frequently between one bivalent and two univalents or one trivalent and one univalent. During metaphase, the bivalents associated in this way were both regularly oriented in the spindle, just as two independent bivalents, the achromatic zone being thus parallel to the spindle fibres. I found many intermediate figures between apparently typical quadrivalents and pairs of bivalents which seemed almost free (Figs. 1–6). I also found some stages of dissociation of quadrivalents giving one trivalent and one univalent



Figs. 1–8

(Fig. 7) or one bivalent and two univalents (Fig. 8). At metaphase, the location of some tri-, bi- and uni-valents showed that these chromosomes were proceeding from a quadrivalent.

If it is assumed that in every quadrivalent observed during prophase the four chromosomes are bound by chiasmata, it is difficult to explain their separation before anaphase. During metaphase, the chromosomes are stretched to the spindle poles, which indicates the direction of the forces operating on them; but the partition of the quadrivalent in two bivalents does not occur in that way. The chiasma frequency is not high in rice: Soriano[1] found a mean of 1·6 per bivalent for five diploid varieties. In spite of that rather low chiasma frequency, 63·4 per cent of the chromosomes of the tetraploid are associated in quadrivalents at diakinesis: this proportion is high, in comparison with the tetraploids induced in many other species. The four homologous chromosomes certainly gather at zygotene, but chiasmata are not always formed between all of them, so that a number of uni-, bi- and tri-valents may occur. It is possible that some chromosomes which are not bound by chiasmata remain nevertheless together up to diakinesis or metaphase, due to an adherence between them. Thus, some groups of four chromosomes are not true quadrivalents and may be called pseudo-quadrivalents.

These pseudo-quadrivalents are to be compared with the pseudo-bivalents observed in some haploid, asynaptic or hybrid plants, where homologous chromosomes do not form chiasmata. Several hypotheses have been proposed to explain the origin of the pseudo-bivalents, but the most frequently suggested is a fusion of the chromosome matrix[2,3]. This hypothesis may be admitted as a tentative interpretation of the nature of the adherence between some chromosomes which are not bound by chiasmata in autotetraploid rice. Thus, the decreasing number, after diakinesis, of the chromosome associations appearing as quadrivalents, and the increasing frequency of the uni- and tri-valents are interpreted as resulting from a more or less precocious slackening of some inter-chromosomal connexions in pseudo-quadrivalents.

GENETICS

Differences in Interactions between Selective Forces acting in the Wild on Certain Pleiotropic Genes of *Cepaea*

The snail *Cepaea nemoralis* is highly polymorphic for colour and banding varieties of its shell. The genetic basis of this polymorphism is fairly well known, and involves several loci, linked and unlinked, with alleles controlling clear-cut characters. The snail is also highly sedentary. It therefore offers a favourable opportunity for investigating local differences in the interaction of selective forces affecting the polymorphism. The colour and banding varieties of the shell have been shown already[1] to be subject to visual selection by predators, the more conspicuous shells being preferentially removed, so that the intercolony variation, which is considerable, of the phenotype frequencies is largely determined in relation to the visual properties of the backgrounds of the colonies. Since the polymorphism is stable, some non-visual selection, probably acting as heterozygote advantage, must maintain the balance, while visual selection sways it to different extents in different places. The majority of Cain and Sheppard's observations were made in the Oxford district; they pointed out that elsewhere a different general balance might be found because of regional differences in the overall non-visual selective values[2].

Such effects have now been found by us on a far greater scale than was anticipated, and involve both great predominances (sometimes up to saturation) of particular genes over areas large compared with that of a panmictic unit of this snail, and the abutment of such areas on others with very different frequencies, producing extremely steep morph-ratio clines. Moreover, in these areas we find a virtual annihilation of the effects of visual selection, although there is evidence that this class of selection is acting.

In the Oxford district and adjacent districts off the Chalk, intercolony variation accords well with variation in background. But on the Marlborough Downs, only 35 miles from Oxford, the situation is quite different. These are fairly typical chalk downs with large expanses of grass, and a few beech and other deciduous woods. The district investigated is roughly a rectangle of approximately 5 by 4 miles and has been searched intensively, about 7,500 snails from 148 localities having been examined. The populations are often very large and widespread here, as is usual in calcareous districts. Over almost all the district there is no correspondence of phenotype frequencies with backgrounds although habitats with sharply contrasting backgrounds are occupied by the snails, predating thrushes are almost everywhere, and in one locality at least visual selection has been demonstrated by a comparison of predated and unpredated shells.

In a compact area of about 8 square miles there is an almost complete absence of the five-banded form, the most usual of the banding forms in most colonies of *Cepaea*. This is caused by a fixation of the modifier *M*[3] converting the five-banded to the mid-banded form. In the north-east of the district investigated is an area of about one square mile which, on the contrary, has a very high percentage of five-banded snails (75–100 per cent). This heavily five-banded area approaches very close to the non-five-banded area in the extreme north of the district, and here the percentage of the five-banded form rises from 34 to 98 per cent over only 500 yards. Enclosed within the non-five-banded area there is a sub-area in which brown forms are extremely abundant, reaching 93–98 per cent on some stretches of open downland. This brown sub-area abuts on another in which yellow forms predominate, and at one place a change from 93 per cent brown forms and 0 per cent yellow forms to 12 per cent brown forms and 80 per cent yellow forms occurs over a distance of at most 180 yards. (Pink forms remain at about 8 per cent.) Finally, a long narrow sub-area, cutting right across the colour sub-areas, has a remarkably high proportion of the spread-banded form, very rare elsewhere.

Subsequent investigations in other districts of downland have shown similar areas, characterized by high frequencies, often approaching saturation, of yellow, pink, mid-banded, spread-banded, and five-banded forms; the frequencies do not vary in relation to the available types of background, and the common morphs are often visually inappropriate. In all these areas, including those of the Marlborough Downs, the sizes of the areas and of the populations enclosed are so great that the possibility of genetic drift being an important factor can be neglected. Selective forces, certainly not visual, must be acting to produce these *area effects*, and calculation suggests that quite slight changes of selective value of the homozygotes relative to the heterozygotes, from those present in the Oxford district, would suffice to produce a very marked area effect. The nature of the non-visual selective forces needs investigation.

Several workers have shown a variation in gene-frequency from place to place because of the variation in action of one selective force or in interaction of two[3-6]. The results are analogous with ours for the Oxford district, in which, although non-visual selection maintains the polymorphism, the variance between colonies is caused by variation in direction and pressure of visual selection. But we find in other districts that, with the same classes of selection acting, the variance between colonies is as great as or greater than in the Oxford district, yet is determined scarcely at all by visual selection but almost entirely by non-visual, in such a way that large areas are characterized by rather constant and often extreme gene-frequencies which may change abruptly at the edges of the areas. With suitable material, such differences in action and interaction of different selective forces will no doubt be shown to occur widely.

A full statement of this investigation will be published elsewhere[7].

Transpositions of Modulator in Maize into Divided and Undivided Chromosome Segments

Variegated pericarp ($\overline{P^{rr}Mp}$), a highly unstable allele in maize, comprises two distinct and separable components, symbolized as P^{rr} and *Mp*. The P^{rr} gene which, when unaccompanied locally by *Mp*, conditions uniformly pigmented (self-coloured) pericarp and cob is fixed in position at the *P* locus in the short arm of chromosome 1. In contrast, modulator (*Mp*) is an element which is transposable independently in somatic cells from this position to a wide variety of other chromosome sites, and preferentially to those nearby. *Mp*, when immediately associated at the *P* locus with P^{rr}, suppresses pigment-producing action of the latter, giving colourless pericarp and cob. The composite, variegated pericarp phenotype is the outcome of numerous *Mp* transpositions during ear development, resulting in P^{rr} expression in the form of irregularly distributed coloured pericarp sectors of various sizes on a colourless background[1,2].

The results summarized here show that during a mitosis in which a transposition from the *P* locus occurs a state of division at the recipient locus is not a necessary condition of re-incorporation of *Mp* into a chromosome. Critical evidence on this point was afforded by the genetic analysis of twinned mutations of medium variegated to self-coloured and light variegated pericarp.

Twinned self-coloured and light variegated mutants evidently originate in a somatic mitosis which results in daughter cells of two kinds with respect to *Mp*. These cells then become progenitors of a pair of adjacent, but unlike, cell lineages. *Tr–Mp* composition of the light variegated component can be inferred directly from the resulting pericarp phenotype. Medium variegated plants are heterozygous for variegated and a stable colourless allele ($\overline{P^{rr}Mp}/P^{wr}$). Light variegateds carry a transposed modulator (*tr–Mp*) in addition. Self-coloured mutants are P^{rr}/P^{wr} at the *P* locus, and may or may not carry a transposed modulator. The presence or absence of *tr–Mp* in the self-coloured co-twin can be determined in crosses of this mutant with a suitably constituted strain possessing the dissociation (*Ds*) factor described by McClintock[3].

Assay by the *Ds* technique of 80 independently occurring twinned mutations showed that in 52, or about two-thirds of them, the self-coloured mutant was *tr–Mp* positive and was *tr–Mp* negative in the remaining 28. Thus the twinned mutations, although phenotypically alike, proved to be of two genotypes.

It may be assumed in the case of the minority class of twins that when division of the chromosome carrying the variegated allele ($\overline{P^{rr}Mp}$) occurs at the *P* locus *Mp* is lost from one, but not the other, of the two resulting chromatids, and that one daughter cell (light variegated) acquires directly, but in a different location, the *Mp* unit which the other daughter cell (self-coloured) loses.

Two *tr–Mp* units, one in each co-twin, are to be accounted for in the majority class of twinned mutations even though, as in the other category, there is a single donor variegated allele in the parent medium variegated cell ($\overline{P^{rr}Mp}/P^{wr}$). Evidently *Mp* is reduplicated twice during a single mitotic cycle in these cases, once at the *P* locus and again elsewhere after transposition.

It was postulated that *tr–Mp* in the majority class of twinned mutations is incorporated at a new site during a differential mitosis before the chromosome at that level has split into chromatids. Reduplication of *tr–Mp* then ensues in phase with division of the chromosome segment in question. A prediction that follows from this hypothesis is that *tr–Mp* will be located in the same position in both members of such a twin.

Three-point linkage tests between *tr–Mp* and markers on the short arm of chromosome 1 were made with 13 twinned mutations of the majority class. The observed amounts of recombination for the seven twinned mutations in which *tr–Mp* was found to reside on chromosome 1 are given in Table 1. Estimates of recombination in this material are affected by secondary transposition of *tr–Mp*, as well as by sampling. In 11 of the 14 paired entries in Table 1 the recombination value is less in the self-coloured than in the light variegated class. This bias is attributable to the fact, established in a previous investigation, that when more than one *Mp* unit is present, as in light variegated

Table 1. Recombination Frequencies between Transposed Modulator and Chromosome 1 Markers in Co-twin Mutants

Twin mutant	Member	No. of plants scored	Percentage recombination of *tr–Mp* with			
			P	*T*1–5*b* (1S.17)	*T*1–2*b* (1S.43)	*T*1–7*c* (1S.79)
1	Self-coloured	764	3·7		5·6	
	Light variegated	542	2·2		4·6	
4	Self-coloured	633	3·2		9·0	
	Light variegated	402	6·4		9·4	
6	Self-coloured	137	13·0		19·7	
	Light variegated	581	9·3		13·1	
9	Self-coloured	466	7·1		10 7	
	Light variegated	121	4·1		4·1	
11	Self-coloured	323	12·4		11 2	
	Light variegated	228	4·4		4·4	
12	Self-coloured	967	10·3			3·4
	Light variegated	473	21·1			5·1
13	Self-coloured	136	20·4	19·1		
	Light variegated	480	32·3	19 0		

plants the frequency of transposition of each *Mp* is sharply reduced[4].

When allowance is made for secondary transposition of *tr–Mp* and sampling effects, two conclusions become apparent from the results in Table 1. First, the amounts of recombination observed between *tr–Mp* and the markers within co-twins correspond closely enough to suggest that the sites of *tr–Mp* in the two respective mutants are identical. Each of the seven twinned mutations affords an independent test of this relation, and conformity to the rule is apparent in six of them. Twin 11 is possibly an exception. The second conclusion is that the position to which *Mp* is transposed differs from twin to twin.

The coincidence in chromosome position of *tr–Mp* in the members of a twin pair is in agreement with the hypothesis that *Mp* may be transferred from the *P* locus to a new site, and then re-established there, in advance of division of the chromosome into chromatids at that level.

A fuller account of these experiments has been published in *Genetics*[5].

This work was aided by grants from the research committee of the Graduate School of funds supplied by the Wisconsin Alumni Research Foundation and by grants from the National Science Foundation.

Mutation and Recombination of Flagellar Antigen *i* of *Salmonella typhimurium*

CHANGES in the flagellar antigenic constitution of many *Salmonella* species have been reported[1]; but their genetical basis is unknown. As the flagellar antigen is a protein, flagellin, the commonest kind of mutational change in it is presumably alteration of a single amino-acid, which would perhaps cause only a minor change in its serological character. We now report a serological and genetical investigation of mutants of *S. typhimurium* with slightly altered forms of the phase 1 flagellar antigen *i*.

S. typhimurium strain *LT2 adeC*-7 *proA*-46[2] was inoculated into plates of semi-solid medium containing a just immobilizing concentration of rabbit anti-*i* serum and an excess of serum against the alternative, phase 2, flagellar antigen. Swarms spreading faster than the parent strain yielded eight mutants, each with a phase 1 antigen slightly different from the wild-type antigen *i*. A further mutant antigen was obtained in a strain of *S. typhi* previously given antigen *i* by transduction from *S. typhimurium*. Serological analysis of the nine mutant forms of *i* (*iM*5 to *iM*13) showed that two of them were antigenically indistinguishable; these two mutants arose in different clones, presumably from identical mutations. No reversion to wild-type *i* was detectable, even by the sensitive test of selection in semi-solid medium with mutant-specific serum. All the mutants were normally motile in phase 1 (cf. 'curly' mutants[3]) and their phase 2 antigens were unchanged. All, like the parent, had ε-*N*-methyl lysine in their flagellins[4]. However, antigens *iM*6 and *iM*9 differed from wild-type *i* and the other mutant forms by their reaction with non-specific reagents; bacteria with these flagellar antigens were agglutinated, to titres of 2–100, by sera from non-immunized rabbits and rabbits immunized with serologically unrelated *Salmonella*, and even by several anti-*i* sera completely absorbed with the antigen used for immunization. Suspensions of *iM*6 and *iM*9 flagella, but of no others, caused flocculation of Indian ink particles in 0·5 per cent sodium chloride. The method used for isolation of mutants would detect only those which lacked some serological specificity of wild-type *i*. As was to be expected the anti-*i* serum used to select mutants agglutinated the mutants to lower titres than it did wild-type *i*. Several other rabbit anti-*i* sera agglutinated all the mutants and the wild-type to about the same titre; but these sera after complete absorption with any one mutant still agglutinated wild-type *i*, in most cases to a substantial titre. This shows that, as expected, each mutant form of *i* fails to combine with one or more kinds of antibody molecule which combine with, and agglutinate, wild-type *i*; that is, that each mutant has lost some of the antigenic specificity of wild-type *i*. Anti-*i* (wild-type) sera fully adsorbed with any one mutant agglutinated some other mutants, as well as wild-type; sera from three different rabbits gave the same complex pattern of residual activity. These results, and those with one serum absorbed with all possible pairs of mutants, indicate the existence of at least thirteen sub-factors in antigen *i*, each mutant lacking a different sub-factor or combination of sub-factors.

Unabsorbed rabbit anti-mutant sera had equal titres (1,000–20,000) with the homologous mutant antigen, wild-type *i* and the rest of the mutant forms of *i*; after complete absorption with wild-type *i* each serum still agglutinated its homologous mutant antigen, to titres of 200–6,000. Thus all the mutants (except perhaps the non-specifically agglutinable *iM*6 and *iM*9) possess antigenic specificities or sub-factors absent in wild-type *i*. Antisera against *iM*7, *iM*10 and *iM*12, fully absorbed with wild-type *i*, agglutinated all three mutant antigens; their relationship as analysed by cross-absorption is:

*iM*7	a, b, c
*iM*10	a, b, d, e
*iM*12	a, d, f

the letters representing antigenic sub-factors absent from wild-type *i*.

To test for recombination between pairs of mutant *i* antigens we first obtained from each serological mutant one or more non-motile (because non-flagellated) variants resulting from mutation at *fla* sites closely linked to *H*1, the locus determining the phase 1 flagellar antigen[5,6]. A fla^- variant of one *i* mutant (recipient) treated with phage *P*22 grown on the fla^+ form of some other *i* mutant (donor) was inoculated on to semi-solid medium containing sera against the donor and against the recipient mutant *i* antigens, each fully absorbed with wild-type *i* antigen, and anti-1,2 serum, to immobilize bacteria expressing the phase 2 antigen; motile (fla^+) transductants with wild-type (that is, recombinant) *i* antigen, but no others, can spread in this medium. Antigen *iM*8 could not be tested because it was available only in *S. typhi*. No wild-type recombinants were found in crosses of *iM*9 with other mutants; it may be a double mutant. Wild-type *i* recombinants formed 1–30 per cent of the total of fla^+ transductants in crosses of *iM*6 with *iM*5, *iM*7, *iM*10, *iM*11 and *iM*12; and a very small proportion in crosses of *iM*10 with *iM*5, *iM*11 and *iM*12 and of *iM*5 with *iM*11. Thus the sites of the *iM*6, *iM*10, *iM*5 and *iM*11 mutations at least do not overlap. The order of the sites of mutation within the $H1^i$ gene and the linked fla^- sites was inferred from experiments of this sort, and others involving fla^- donors, on the premise that fla^+ transductants with *H*1 antigens requiring four cross-overs would be much less common than those requiring only two cross-overs. For example, with a $fla^-{}_D$ donor and a $fla^-{}_R$ recipient a high proportion of fla^+ transductants with the mutant *i* antigen of the donor excluded the order fla_R–fla_D–$H1$, which would necessitate four cross-overs; and with a fla^+ donor and fla^- recipient an abundance of fla^+ transductants with wild-type (that is, recombinant) *i* excluded the order *fla*—*D*–*R*–, where *D* and *R* are the sites of mutation within $H1^i$ of the donor and the recipient, respectively. The inferred order of the mapped sites is *fla* 50–*fla* 58–*fla* 57—*M*10–(*M*5, *M*12)–*M*11–*M*6—*fla* 52–*fla* 55. Iino[3] attributed the locomotor deficiency and short wave-length of the 'curly' phase 1 flagella of *S. typhimurium* strain *SW* 577 to mutation within the *H*1 locus; crosses of strain *SW* 577 with *fla*- forms of our serological mutants confirmed this, and indicated that the 'curly' site is probably between the *M*11 and the (*M*5, *M*12) sites.

Thus mutation within $H1^i$, the gene determining the structure of flagellin *i*, may cause a change in the serological character of antigen *i* (and in some mutants a non-specific agglutinability also) without impairment of locomotor function; or a loss of locomotor function without antigenic change[4]; and the sites of mutation can be mapped linearly within the gene. Some of our mutant *i* flagellins have now been shown to give tryptic-digest peptide maps different from that given by wild-type flagellin[7]; the amino-acid sequence in flagellin being unknown, it is not possible to compare the genetic map with the order of the corresponding amino-acid changes along the polypeptide chain.

MISCELLANEOUS

Tsetse in the Environment of Ancient Man in Southern Rhodesia

SUMMERS[1] in Southern Rhodesia has examined the distribution of prehistoric sites (that is, containing traces of ancient man), and the historic routes followed by invaders and pioneers since 1823, and concluded that there was throughout the whole prehistoric and historic periods "a marked aversion to Mopane woodland" (that is, deciduous woodland dominated by *Colophormum mopane* and now occurring especially in the Zambezi and Limpopo valleys). He suggests that this aversion was because of the presence of the tsetse *Glossina morsitans* in *mopane* areas.

It is generally agreed (for example, Hornby[2]) that tsetse, before modern drugs came into use, kept out all kinds of domestic stock except poultry from their areas, and that consequently they excluded any men who could not or would not live without their stock. Historical examples of this exclusion embrace the alignment of the roads used by the ox-drawn wagons of European pioneers, as noted by Summers[1]. However, Summers's hypothesis requires that tsetse should exclude also Stone Age men who had not yet acquired any domestic animals. If tsetse had any effect on the distribution of such primitive men, it must have been wrought through the human disease, sleeping sickness, and of course Rhodesia is the type-locality of the organism, *Trypanosoma rhodesiense*, which causes the acute form of sleeping sickness. It should be noted, however, that sleeping sickness as we know it to-day does not exclude hunters and food gatherers. In the first place, although sleeping sickness cannot occur in the absence of tsetse, tsetse can occur in the absence of sleeping sickness; in fact sleeping sickness is very localized, and the areas in which it is found are but a small fraction of the areas occupied by its vectors. Secondly, even in places where sleeping sickness occurs, hunting and food gathering go on. A well-known instance is the Malagarasi River system in the Western Province of Tanganyika, which is almost uninhabited during the wet season, but is visited by hunters, fishermen and collectors of honey during the dry season. During 1953, 1954 and 1955 this area produced more than half the cases of *T. rhodesiense* sleeping sickness diagnosed in all Africa (Ashcroft[3]). It is, of course, possible that in the past *T. rhodesiense* sleeping sickness was a more widespread and more easily contracted disease than it is to-day, and that it totally excluded man in the same way that animal trypanosomiasis (nagana) totally excluded cattle from all tsetse areas in the recent past. But it is also possible that *T. rhodesiense* sleeping sickness is a modern disease which did not exist at all in prehistoric times. In the absence of any evidence either way it does not seen legitimate to postulate alterations in the properties of a trypanosome to explain archæological observations.

It is suggested that, while the alignment of the European pioneers' roads to avoid tsetse areas is a historical fact, an alternative explanation must be sought for the aversion to *mopane* areas of peoples not known to have domesticated animals.

A Radioactive Marking Ink

WHEN autoradiography is used to detect labelled compounds on paper chromatograms, a radioactive ink is a useful adjunct. With this ink, a visible mark can be made on both the paper and the X-ray film in order to assist their re-alignment after the film has been developed. For radioactive components of such ink, non-volatile compounds of carbon-14 or sulphur-35 have been suggested, but suitable materials are expensive so that a cheaper alternative was sought.

A satisfactory ink has now been made incorporating promethium-147, which emits β-particles (0·27 MeV) and has a half-life of 2·6 years. I thank Dr. J. C. Charlton of the Radiochemical Centre, Amersham, for the suggestion that this inexpensive isotope might be useful.

The promethium-147 was supplied as the chloride 1 mc. in 0·25 ml. N hydrochloric acid. This solution was diluted with 1·5 ml. water and N ammonia solution was added to make it neutral to phenol red; it was then added dropwise to 56 ml. 'Mandarin' indian ink (Winsor and Newton) with thorough mixing after each addition. If the isotope is supplied in a larger volume of acid, or for other varieties of ink, it would be advisable to check first that the ink will tolerate the addition of the calculated amount of ammonium chloride.

Marks made with the ink mixture gave intense images on Ilford 'Ilfex' film after overnight contact. For use on chromatograms which required some weeks' contact to detect compounds of low activity, the mixture was further diluted 1 : 20 with indian ink.

The radioactivity in the ink marks on ordinary filter paper or on filter paper impregnated with silicic acid was not removed by repeated washing with water; it was, however, leached out by N hydrochloric acid.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, January 28

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, .C.2), at 2.30 p.m.—Discussion on "Electricity as a Measure of the Rising andard of Material Prosperity", opened by the President.

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burl-gton House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. Ju Chin Chu olytechnic Institute, Brooklyn): "The Role of the Chemical Engineer the Space Age".

INSTITUTION OF MECHANICAL ENGINEERS, EDUCATION AND TRAINING ROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—iscussion on the Government White Paper: "Industrial Training: Govern-ent Proposals".

UNIVERSITY OF LONDON (in the Chemistry Lecture Theatre, Birkbeck llege, Malet Street, London, W.C.1), at 6 p.m.—Prof. D. J. G. Ives: ome Reflections on Water"* (Inaugural Lecture).

Tuesday, January 29

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, ower Street, London, W.C.1), at 1.15 p.m.—Dr. H. Kalmus: "Axioms d Theorems in Biology".*

PLASTICS INSTITUTE, REINFORCED PLASTICS GROUP (at the Wellcome uilding, Euston Road, London, N.W.1), at 4 p.m.—Symposium on "Cost-g".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in mmittee Room 9, House of Commons, London, S.W.1), at 5.30 p.m.—r Frederick Brundrett, K.C.B., K.B.E., M.A., and Sir Owen Wansbrough-nes, K.B.E., C.B.: "Science and Government".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, ndon, S.W.7), at 5.30 p.m.—Sir Patrick Linstead, F.R.S.: "Ten Years fter—The Growth of the Imperial College 1953–63"* (Decennial Address).

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical edicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—r. R. L. Turner: "Molecular Aspects of Clot Lysis".* (Sixth of twelve ctures on "The Scientific Basis of Medicine" organized by the British stgraduate Medical Federation.)

INSTITUTION OF ELECTRICAL ENGINEERS AND ROYAL AERONAUTICAL CIETY, LONDON JOINT GROUP (at the Royal Aeronautical Society, 4 amilton Place, London, W.1), at 6 p.m.—Discussion on "Connectors in rcraft".

SOCIETY OF INSTRUMENT TECHNOLOGY, SYSTEMS ENGINEERING AND UTOMATION SECTIONS (at Manson House, 26 Portland Place, London, .1), at 7 p.m.—Mr. D. A. Mackintosh: "The Application of Automation the Pulp and Paper Industry".

Wednesday, January 30

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, ndon, W.1), at 5 p.m.—"The Eruption of Kilauea 1959–60" (colour und film); Dr. P. E. Kent and Dr. R. Casey: "A Kimmeridge Sandstone North Lincolnshire".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy ace, London, W.C.2), at 5.30 p.m.—Mr. J. F. Eastham and Dr. E. R. ithwaite: "Pole-Change Motors using Phase-Mixing Techniques".

CHALLENGER SOCIETY (in the Rooms of the Linnean Society, Burlington ouse, Piccadilly, London, W.1), at 5.45 p.m.—Mr. B. D. Loncarevic: The First Results from the International Indian Ocean Expedition".

BRITISH INSTITUTION OF RADIO ENGINEERS, TELEVISION GROUP (at the ondon School of Hygiene and Tropical Medicine, Keppel Street, Gower reet, London, W.C.1), at 6 p.m.—Mr. F. J. D. Taylor: "Propagation of levision Signals by Satellite".

ROYAL SOCIETY OF ARTS (at John Adam Street, London, W.C.2), at p.m.—The Right Hon. Lord Robens, P.C.: "Coal and its Future" (Cad-an Memorial Lecture).

INSTITUTE OF INFORMATION SCIENTISTS (at the Swedenborg Society Hall, Bloomsbury Way, London, W.C.1), at 6.15 p.m.—Mr. J. Farradane: bstracting and Information Retrieval".*

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with e SOUTH-WEST ESSEX COLLEGE OF TECHNOLOGY CHEMICAL SOCIETY, the South-West Essex College of Technology, Forest Road, London, .17), at 7 p.m.—Film Show.

Thursday, January 31

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, ower Street, London, W.C.1), at 1.15 p.m.—Mr. P. J. Syrett: "Photo-nthesis: the Basis of Life".*

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 0 p.m.—Sir Lindor Brown, F.R.S., Mr. H. M. Powell, F.R.S., Sir Gordon therland, F.R.S., Dr. H. W. Thompson, F.R.S., and Prof. C. H. Wadd-gton, F.R.S.: "Some Aspects of Science in China To-day".

UNIVERSITY COLLEGE, LONDON (in the Physiology Theatre, Gower Street, ndon, W.C.1), at 5 p.m.—Dr. J. D. Judah (Wistar Institute, Philadelphia): The Biochemistry of Ion Transport".*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at voy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Resistance twork Analogues as Aids to Solving the Laplace Equation".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION G.88 (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on 'sychological Tests—Are They Any Use ?" opened by Mr. A. G. P. Elliott.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical dicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—. R. D. Keynes, F.R.S.: "The Nerve Impulse".* (Seventh of twelve tures on "The Scientific Basis of Medicine" organized by the British stgraduate Medical Federation.)

Thursday, January 31—Friday, February 1

CHALLENGER SOCIETY and REPRESENTATIVES FROM THE MARINE LABORATORIES (Development Commissioners' Scheme) (at the Zoological Society of London, Regent's Park, London, N.W.1), at 10 a.m. daily—Meetings on "Productivity" and "The Effects of Warm Water Effluents"; Dr. L. H. N. Cooper: "An Approach to Historical Oceanography"; Dr. J. Wickstead: "Food and Feeding in Pelagic Copepods".

Friday, February 1

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the SOCIETY OF DYERS AND COLOURISTS, at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. W. H. Cliffe: "An Historic Approach to Colour".

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), from 6.30 p.m. to 10 p.m.—Conversazione.

Saturday, February 2

LONDON COUNTY COUNCIL (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. A. Robinson: "The Recreations of a Naturalist".*

Monday, February 4

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. Donald W. Tull: Presidential Address.

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. L. F. Boyd: "Celestial Laboratories".*

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. M. Stacey, F.R.S.: "Recent Investigations on Immuno-Polysaccharides".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned;

ASSISTANT EXPERIMENTAL OFFICER (male, with a pass degree, or its equivalent, in agriculture, botany or biology) AT THE WELSH PLANT BREEDING STATION, to assist in the classification, recording and maintenance of the Station's collection of plants introduced to this country—The Secretary, Welsh Plant Breeding Station (University College of Wales), Plas Gogerddan, near Aberystwyth (January 31).

SENIOR BIOCHEMIST (with a science degree, preferably with honours, or the A.R.I.C. and experience in clinical biochemistry or a closely related field) IN THE DEPARTMENT OF PATHOLOGICAL BIOCHEMISTRY, Glasgow Royal Infirmary—The Secretary, Board of Management for Glasgow Royal Infirmary, 84 Castle Street, Glasgow, C.4 (January 31).

HEAD (with a higher degree and substantial teaching and industrial experience) OF THE DEPARTMENT OF ELECTRICAL ENGINEERING (Grade IV), Enfield College of Technology, Enfield, Middlesex—Chief Education Officer (F.3), Middlesex County Council, 10 Great George Street, Westminster, London, S.W.1 (February 1).

PROFESSOR AND HEAD OF THE DEPARTMENT OF BIOCHEMISTRY, NUTRITION AND FOOD SCIENCE, University of Ghana—The Registrar, University of Ghana, P.O. Box 25, Legon, Accra; or The Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1 (February 4).

LECTURER IN THE HISTORY OF SCIENCE—The Registrar, The University, Leicester (February 7).

LECTURER (with competence in physiological psychology and/or experimental psychology) IN PSYCHOLOGY—The Registrar, The University, Leicester (February 7).

LECTURER and ASSISTANT LECTURER IN PURE or APPLIED MATHEMATICS; LECTURERS and ASSISTANT LECTURERS (with a special interest in teaching microbial cytology, microbial metabolism, or general biology of micro-organisms) IN THE MICROBIOLOGY DEPARTMENT; an ASSISTANT LECTURER IN PHYSICS; and an ASSISTANT LECTURER IN THE PHYSIOLOGY DEPARTMENT—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (February 8).

LECTURER (with a special interest in geochemistry) IN GEOLOGY—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (February 8).

PROFESSOR AND HEAD OF THE DEPARTMENT OF PHYSICS—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (February 8).

PROFESSOR OF PSYCHOLOGY (to be Head of the new Department of Psychology)—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (February 8).

LECTURER or ASSISTANT LECTURER IN SOCIOLOGY (Social Anthropology)—The Secretary, The University, Northcote House, The Queen's Drive, Exeter (February 9).

ASSISTANT LECTURER (with special qualifications in applied mathematics) IN THE DEPARTMENT OF MATHEMATICS—The Assistant Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (February 11).

LECTURER or ASSISTANT LECTURER (with qualifications in either pure or applied mathematics) IN MATHEMATICS—The Registrar (Room 22, O.R.B.), The University, Reading (February 11).

BIOCHEMIST (with an M.Sc. or Ph.D. in biochemistry or physiological chemistry, or equivalent, and at least three years satisfactory experience of biochemistry or chemical pathology) with the Cork Health Authority—The Secretary, Local Appointments Commission, 43 Upper O'Connell Street, Dublin 1, Republic of Ireland (February 15).

CHAIR OF ZOOLOGY in the University of Malaya—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, February 15).

LECTURER (preferably with qualifications in statistics or numerical analysis) IN THE DEPARTMENT OF MATHEMATICS, University of Ghana—The Registrar, The University of Ghana, P.O. Box 25, Legon, Accra; or The Assistant Registrar (Overseas), University of Ghana, 15 Gordon Square, London, W.C.1 (February 15).

ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, The University, Sheffield (February 16).

OFFICIAL FELLOWS (2), one as TUTOR IN INORGANIC CHEMISTRY and the other as TUTOR IN BIOCHEMISTRY or PHYSIOLOGY—The College Secretary, Balliol College, Oxford (February 18).

LECTURER or ASSISTANT LECTURER (preferably with research interests in solid-state physics, particularly the Mossbauer effect, low temperatures and N.M.R.) IN PHYSICS—The Registrar, The University, Manchester 13 (February 20).

HEAD (with good academic qualifications and preferably industrial or research and teaching experience) OF THE DEPARTMENT OF PURE AND APPLIED PHYSICS—The Secretary, Royal College of Advanced Technology, Salford 5, Lancashire (February 22).

CHAIR OF ELECTRONICS—The Secretary and Registrar, The University, Southampton (February 23).

LECTURERS or ASSISTANT LECTURERS (2) IN PHYSICS—The Registrar, The University, Hull (February 25).

CHAIR OF VETERINARY MEDICINE tenable at the Royal Veterinary College —The Academic Registrar (University of London), Senate House, London, W.C.1 (February 28).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN CHEMISTRY (including Agricultural Chemistry), PHYSICS, PHARMACY, ENGINEERING, METALLURGY, and related subjects—The Registrar, The University, Nottingham (February 28).

CHAIR OF CHEMICAL PATHOLOGY at the Postgraduate Medical School of London—The Academic Registrar, University of London, Senate House, London, W.C.1 (March 1).

LECTURER/ASSISTANT LECTURER (preferably with experience in teaching and research) IN THE DEPARTMENT OF BIOCHEMISTRY in the newly established Faculty of Medicine, University of Malaya—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, University of Malaya, Pantai Valley, Kuala Lumpur, Federation of Malaya (London and Malaya, March 15).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN BIOCHEMISTRY, CHEMISTRY, CHEMOTHERAPY, ENGINEERING, METALLURGY, PHARMACOLOGY or PHYSICS—The Academic Registrar, University of London, Senate House, London. W.C.1 (April 1).

TURNER AND NEWALL RESEARCH FELLOWS IN ENGINEERING, INORGANIC CHEMISTRY or PHYSICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 1).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN PHYSICS, CHEMISTRY, COLLOID SCIENCE, BIOCHEMISTRY, ENGINEERING, METALLURGY, PHARMACOLOGY, CHEMOTHERAPY, or related subjects—The Secretary-General of the Faculties, The Old Schools, The University, Cambridge (April 30).

ASTROPHYSICIST (with a Ph.D. degree and some observatory experience), to take charge of a new 15-in. reflector with photoelectric and spectrographic attachments, to teach, and to undertake a research programme in close relation with an active radio astronomy group based in the Departments of Physics, Electrical Engineering, and Mathematics—Head of the Department of Physics, Queen's University, Kingston, Ontario, Canada.

BIOLOGIST, for cancer research involving tissue culture and electron microscopy—Prof. K. R. Hill, Pathology Department, Royal Free Hospital, Gray's Inn Road, London, W.C.1.

LECTURER (with a good honours degree in mathematics and experience of teaching in schools) IN THE DEPARTMENT OF EDUCATION—The Registrar, The University, Liverpool, quoting Ref. No. CV/219.

NATIONAL RESEARCH COUNCIL and other POSTDOCTORAL FELLOWSHIPS IN THE DEPARTMENT OF PHYSICS—Prof. M. W. Johns, Chairman, Department of Physics, McMaster University, Hamilton, Ontario, Canada.

POSTDOCTORAL RESEARCH ASSISTANT, for work on nuclear magnetic double resonance techniques—Dr. D. W. Turner, Chemistry Department, Imperial College of Science and Technology, London, S.W.7.

PRINCIPAL LECTURER (well qualified with sound teaching and research experience) IN CHEMISTRY—The Academic Registrar, Hatfield College of Technology, Hatfield, Herts.

RESEARCH ASSISTANTS and GRADUATE TEACHING ASSISTANTS (students studying for degrees or Ph.D. and M.Sc. in Chemistry) at the Edmonton or Calgary Campus—Dr. H. B. Gunning, Head, Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada.

RESEARCH PHYSICIST, to carry out a programme of absorption cross-section measurements in the vacuum ultra-violet—Prof. R. W. Ditchburn, F.R.S., J. J. Thomson Physical Laboratory, The University, Whiteknights Park, Reading.

SCIENTIFIC INFORMATION OFFICER (Abstractor) (with a degree in agriculture or natural science and able to translate from German and/or Russian) —The Director, Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire.

TECHNICIAN or JUNIOR TECHNICIAN (preferably experienced in bacteriological, immunological and serological techniques) IN THE DEPARTMENT OF ANIMAL HUSBANDRY AND VETERINARY HYGIENE—The Assistant Secretary, Royal Veterinary College (University of London), Boltons Park, Hawkshead Lane, Potters Bar, Middx.

THE BRITISH MUSEUM

THE British Museum Bill, which received its second reading in the House of Commons on December 20, is an important first step towards the projected National Reference Library for Science and Invention—that essential and overdue counterpart of the new National Lending Library for Science and Technology. It provides, in particular, means by which the transfer can be effected, in due course, of books and other objects to this projected Reference Library as well as to the new library building to be erected at Bloomsbury. As the chief secretary to the Treasury and Paymaster-General, Mr. J. Boyd-Carpenter, explained in moving the second reading, the British Museum is the oldest of Britain's major national cultural institutions, and its age alone has meant that its legal foundations are tied up in a great mass of largely archaic legislation. The Bill proposes to repeal *in toto* some sixteen statutes, two of which go back to the eighteenth century.

While this is one of the great libraries in the world, the capacity of which is vastly overtaxed, under the present law it is possible, apart from the newspaper repository at Colindale, to store this material only in the Bloomsbury building. Although erection of a new library building on a site adjoining the Museum has been proposed for some years, the present law would not permit the use of such a building for the books of the library. Fresh legal powers would first be necessary, as they are required to permit lending the contents of the Museum for exhibition or disposing of its property. Mr Boyd-Carpenter also referred to the need to revise the constitution of the trustee body and the desirability of giving a separate legal entity to the present British Museum (Natural History) at South Kensington with its out-station at Tring, which had, in effect, for many years been a separate institution.

Taking these four major matters in succession, Mr. Boyd-Carpenter said that, under the present law, the collections could only be housed for exhibition in "authorized repositories" as defined by statute. Under Clauses 3 and 9 of the Bill, it would be possible to designate further places, such as the proposed library building at Bloomsbury, and the National Reference Library for Science and Invention, to be built, as a part of the Museum, on the South Bank in buildings to be shared with the new Patent Office and including the existing Patent Office library. It is hoped that work on this will start in 1963 and that the Reference Library will function not later than 1966.

This is the aspect of the whole project with which scientists and technologists are probably most familiar. However, it received little attention in the debate, although Mr. W. R. Rees-Davies stressed the importance of completing as soon as possible the building of the National Reference Library, and Mr. Austin Albu dealt with this in greater detail. Mr. Albu thought that there now seemed to be general agreement that the plans produced for the new Reference Library under Sir Frank Francis were developing satisfactorily, but that there was some concern as to whether what was proposed would prove a satisfactory permanent arrangement. There was reason for strengthening the scientific and technological side of the trustees, and Mr. Albu thought that the Research Councils had an interest in this matter. He was not convinced that such a specialized library as the new Reference Library had its place in the British Museum, and there was still some anxiety over the separation of the current books and periodicals, to be situated on the South Bank, and the non-current books, which would be located at Bloomsbury. Quick reference to these was also frequently important, and, while Mr. Albu gave a qualified welcome to the Bill, it was not unreasonable that he should look for some assurance that the constitution of the Trustees was such as to ensure that the special interests of science and technology and the contribution which an efficient reference library of this character could make to industry were fully safeguarded.

That alone puts into perspective the importance of the proposals of the Bill with regard to Trustees. Mr. Boyd-Carpenter did not suggest that the present system was not functioning reasonably well, though he pointed out that this was due largely to the development of the non-statutory system of the Standing Committees which carried out most of the day-to-day control of the Museum. Nevertheless, the present body of fifty-one people, twenty-three *ex-officio*, was by modern standards too large, and it seemed highly desirable to put this body on a similar basis to the trustees of other major national institutions.

The British Museum Act, 1753, specified the Archbishop of Canterbury, the Lord Chancellor and the Speaker of the House of Commons as Principal Trustees. Others specified at the time included the Secretaries of State, of whom there were then only a few, the Lord Chief Justice and the Bishop of London. It has been inevitable that all these could not be present at all meetings concerning the Museums. In fact, the running of the two Museums has been in the hands of the Standing Committee of twenty, mostly Trustees elected with the view of such service, but including one previous *ex-officio* trustee, in Mr. Chuter Ede, in view of the interest he had taken as Home Secretary. It has been useful to have had on call in the Principal Trustees men whose wisdom and experience have been a great source of strength in difficulty, but one of the main disadvantages has derived from the fact that the Standing Committee has had to serve the two Museums.

This disadvantage will be removed by the formal separation of the two Museums, and a proposed new trustee body of twenty-five for the British Museum, Bloomsbury, fifteen appointed by the Prime Minister on the same basis as for other national institutions, will remove the basis for some superficial criticism. Four of the new Trustees will be appointed on the nominations of the Presidents of the Royal Society, the Royal Academy, the British Academy and the Society of Antiquaries of London, respectively, and five by the Trustees of the British Museum. Professional expertise is not sought in the Trustees but rather sympathy with the work, a wide knowledge of affairs and of Government administration, and the capacity to encourage the staff. The new Trustees will appoint their own chairman.

On the third point, Mr. Boyd-Carpenter said that the Bill would give the Trustees the power to lend abroad on the same basis as at home, and would regularize the lending power at home distributed over a number of statutes—subject to the interests of students visiting the Museum. He assured the House that the words of the proviso gave the Trustees sufficient protection against any pressure which the Government might exercise to make loans for purposes of broad Government policy which the Trustees might not wish to make. Related to this was the question of disposal covered by the following Clause 5 of the Bill. These powers were at present scattered in a number of statutes which it was proposed to repeal. Mr. Boyd-Carpenter thought that the powers now proposed represented a fair balance between reasonable restraint of reckless disposal of articles which subsequent Trustees might consider should be retained, and compelling a responsible body to retain objects which no sane person would wish to retain. Special provision was made in respect of unwanted books and periodicals so as to permit the advantages of microfilming being obtained, and tentatively the year 1850 had been taken as the line of demarcation.

The fourth point was the establishment, under Clause 7, of a separate body of Trustees for the present British Museum (Natural History). As already noted, this gives formal expression to a separation which has long existed in actual practice. Of the twelve Trustees for this Museum, eight will be appointed by the Prime Minister, one by the Treasury, on the nomination of the President of the Royal Society, and three by the Trustees of the British Museum (Natural History). Mr. Boyd-Carpenter thought that the Prime Minister would probably consult the Minister for Science in making his nominations.

Although from what Mr. Chuter Ede and Dr. Barnett Stross said in the debate it appears that the separation of the two Museums is regarded with anxiety in some quarters, from a practical point of view it is long overdue, and in spite of the surprising smoothness with which the previous arrangements have worked it should be possible to improve the effectiveness of the administration of both bodies without encouraging the division between the arts and the sciences to which Mr. Ede referred. It is clearly of advantage to remove the basis of some carping criticism, for the new arrangements for Trustees will permit the removal of some who were not even aware of their trusteeship and provide the opportunity for seeing that scientific interests, for example, are adequately represented on both bodies. It should be correspondingly easier to secure the services of men of the experience and judgment desired when it is known that the trusteeship is no sinecure but offers opportunities of genuine public service.

This is the more important, not only in respect of the new National Reference Library, if it is to render its full contribution to the service of science and technology, but also in respect of the service which the two Museums are to render to research. As Mr. J. Dugdale pointed out in the debate, the British Museum is both an international collection and a centre of learning and research. If the same institution is to serve both the scholar and the layman, wise judgment as well as skilful administration will be imperative, and this is equally true of the British Museum (Natural History). Dr. Barnett Stross was obviously somewhat concerned on this point and commented on the bearing which the hours of opening had on this question of the use of the Museum for research. Mr. Albu suggested that the British Museum (Natural History) now functioned to the extent of 90 per cent as a research institute for natural history and biology, in which fields it had an international reputation, and its staff included leaders in their special subjects.

On the question of staff, Clause 6 provides that the salaries and conditions of service of the director and other staff shall be determined by the Treasury, and in the debate Sir Cyril Black urged that the staff should be on a parity with the Scientific Civil Service in this respect. It was essential that the conditions of service should be adequate to retain the services of men who were leading authorities in their line of work. Mr. Ede also thought that no doubt should be left regarding the status of the Museum staff as Civil Servants.

The wide and enlightened interest taken in the functions of the two Museums was a most encouraging feature of the debate, and if those functions are to be satisfactorily discharged and the potentialities of the new National Reference Library realized the quality of the staff is of paramount importance. On this, the economic secretary to the Treasury, Mr. E. du Cann, who replied on the debate, said no more than that the staff had increased by 50 per cent in the past ten years, and it is to be hoped that all these points will be carefully watched as the Bill proceeds through the House of Commons and then through the House of Lords. If this first debate is any guide, there seems little reason to fear that the scrutiny in Parliament will be one-sided. There was no excessive preoccupation with the modernization of the display functions of the two Museums, and if their research functions received rather more attention than the contribution which a national reference library can make to technological research and industrial progress, the presence of the Minister for Science should ensure that the balance is redressed when the Bill reaches the House of Lords. The Advisory Council on Scientific Policy should make sure that he is adequately briefed on all the vital points.

It is indeed essential that the question of comprehensiveness should not be overlooked in this connexion, particularly in view of the location of the National Lending Library for Science and Technology outside London. That is a factor which needs to be weighed the more carefully in view of the proposed division of the contents of the Reference Library between the South Bank and Bloomsbury. It is only too easy under such conditions for careless or unenlightened administration, not to mention parsimony in finance, to put endless frustration in the way of the genuine scholar and investigator. There is no need to look beyond the Post Office to find endless examples of advances in technique and ease of communication repeatedly offset by human perversity.

How far, in fact, it is desirable to separate the library activities generally from those of the Museum proper may be for inquiry and consideration. In this connexion, however, it should be remembered that the present director of the British Museum, Bloomsbury, has shown himself well aware of the dynamic potentialities of the new Reference Library and imaginatively alive to what is required to realize such possibilities, as well as assuring that his staff would play a full part in the co-ordination of national library activities generally. He recognizes that no library can hope to be self-sufficient to-day and that effective co-operation is an essential condition of real economy of national resources. Equally, he recognizes that sufficient financial and material resources must be available to secure the buildings, equipment and staff of the quality required, and it is important that this factor should be impressed on the Government as cogently as possible in the forthcoming debates.

These and other requirements have been clearly set forth by Dr. R. S. Hutton in a paper contributed to a symposium in the *Journal of Documentation* for March 1961, and they will bear re-examination in the discussions on the new Bill. Useful as it may be to remove obsolete procedures and to free the British Museum, Bloomsbury, from restrictions of the past, including its close linking with the British Museum (Natural History), all this is only the first stage. It clears the way and gives the opportunity. Whether the opportunities are fully used depends on the vision and determination which are brought to bear, on the resources which the Government make available, and on the extent of the support and co-operation which is forthcoming from other libraries and institutions and from a wide range of scientists, technologists and scholars and their professional institutions.

ALFRED NOBEL

Nobel: The Man and His Prizes.

By H. Schuck, R. Sohlman, A. Osterling, G. Liljestrand, A. Westgren, M. Siegbahn, A. Schou and N. K. Stahle. Edited by the Nobel Foundation. Pp. x + 690. (Amsterdam and London: Elsevier Publishing Company, 1962.) 60*s*.

THIS huge volume, published under the auspices of the Nobel Foundation, gives an account of the life of Alfred Nobel and a full list of the prizewinners with comments on the achievements for which they received the award.

It is intended to issue within the next two years nine other volumes giving in full the Nobel Lectures in English up to 1961 with the address on the presentation of the awards and a biographical account of the prizewinner. Beginning with 1962, this full account of the awards will be given in annual year-books.

The story of the life of Alfred Nobel, based on all available documents, letters and information and impressions gained from his associates, is the most authentic account which has so far been written. It depicts a rather sensitive, lonely man of quite extraordinary ability and a high appreciation of the spiritual values in life. Though he had only a fragmentary education which ended when he was sixteen, he spoke and wrote fluently in English, French and German in addition to Russian and Swedish. His researches and inventions entitled him to the highest rank of scientists. He had also great financial ability. After losing his fortune through the fraudulence of his partners he built up another fortune which enabled him to establish the Nobel Foundation.

Probably the most interesting aspect of his life was his high idealism. Though he repudiated the Christian religion, which he thought had brought persecution and suffering to so many, and could not believe in a God who would inflict punishment for all eternity on suffering mortals, he was filled with awe and reverence for the mystery of life and a love for his fellow men, with an infinite compassion for unnecessary poverty and suffering.

He predicted that the science in which he was engaged would produce weapons of such destructive power that war would become impossible. He wrote: "When two army corps can annihilate each other in a second, all civilized nations, it is to be hoped, will recoil from war and discharge their troops". Modern nuclear and biological weapons have proved the truth of his prediction so far as the results in war are now concerned, but unfortunately civilized nations have not yet recoiled and agreed to settle their differences by peaceful means.

The rest of the book consists of the list of all the awards given since the Foundation was established in 1901 with an account of the achievements for which the awards were given. This interesting account affords a review of the great advance in science made since the beginning of the present century.

The Peace Prizes given for efforts made to realize Nobel's ideal of the end of war give interesting glimpses of international politics in the present century.

Such is the account of the life and achievements of a great idealist who devoted his life and his fortune to the promotion of human welfare. BOYD ORR

THE STUDY OF MAN

They Studied Man

By Abram Kardiner and Edward Preble. Pp. 287. (London: Secker and Warburg, Ltd., 1962.) 25*s*. net.

ONE of the authors of this book is a psychoanalyst who worked with Freud and has taught both anthropology and sociology; the other is an anthropologist in a school of psychology. The result is that this set of biographical essays comprises studies not only of the founder of psychoanalysis but also of six anthropologists: Tylor, Frazer, Boas, Malinowski, Kroeber and Ruth Benedict; a biologist, Charles Darwin; and two sociologists, Herbert Spencer and Durkheim. The essays combine useful biographical details with a certain amount of gossip and some shrewd observations on the scientific achievements of each of the subjects. Despite the rather arch titles of the chapters, for example, "Boas: Icy Enthusiasm"; "Freud: Chimney Sweeping", and the triviality of some of the material, each essay does help to throw some new light on the way in which the man concerned did his work.

The idea of the book is not to give a history of anthropology but to relate the "seminal hypotheses" of the "few great innovators" in the development of the science of man to the events of their lives and the spirit of the times. The main theme throughout the book is human adaptation, and the birth and growth of the scientific tradition of the study of human culture is presented within this framework. The hypotheses, theories and techniques of the scientists examined are represented as being essentially responses to the collective interests and needs of their time. Idiosyncracy and genius are not denied, but are treated as being on the individual level, not on the cultural level.

The book is an interesting argument for the importance of the study of the impact of institutions and cultural change on the human mind in modern times, and for the need for the development of techniques for measuring the effect of these changes on man. From this point of view it is an attempt to bring psychology and anthropology more closely together. But the final chapters on the significance of psycho-dynamics for the investigation of culture are not very convincing. The attempt to illustrate the usefulness of psycho-dynamics by explaining how scientific interest in man and culture "happened to develop in the nineteenth century" is not much more than a rather weak piece of social history.

R. FIRTH

HUSSERL'S PSYCHOLOGY

Phänomenologische Psychologie

Vorlesungen Sommersemester 1925. Von Edmund Husserl. Herausgegeben von Walter Biemel. (Husserliana, Band 9.) Pp. xxviii + 650. (The Hague: Martinus Nijhoff, 1962.) 31 guilders, paper; 37 guilders, cloth.

THE appearance of Volume 9 of *Husserliana* under the editorship of Dr. Walter Biemel is an occasion of special significance. He is now laying down his task after some fifteen years of close association with the

Archiv at Louvain. Besides the present assemblage of papers, he has been responsible for Volumes 2, 3 and 6. Therefore, now may be the appropriate moment to offer him an expression of gratitude on behalf of those who are scholars of Husserl, both for shouldering a heavy burden, and no less for achieving such a high level of meticulous accuracy and comprehensiveness in the treatment of his most difficult material.

The collection now before us comprises Husserl's lectures during the summer of 1925 on phenomenological psychology, together with some very important supplementary material, namely, his article in the *Encyclopædia Britannica*, (fourteenth edition, 1929, and subsequent issues), and the course he gave in Amsterdam on the same subject. In addition, there are a number of appendixes and comments on the text. It is characteristic of the editor's care that whenever it has been desirable to modify Husserl's original titles, the fact is noted in special < > brackets.

In general, these pages can be taken to cover what is essentially the whole of the master's thought up to that period on psychological and transcendental themes within the general conspectus of phenomenology.

Much of Husserl's labour consisted in an attempt (and in his view a triumphant one) to overcome the evils of psychologism, that is, the intrusion of psychological elements into what should be purely logical processes. He sees the methods of natural science and of psychology as quite distinct, except that both stand in need of some rationalization of the essential, if they are to become exact. Furthermore, it is clear that, on such a basis, phenomenological psychology and transcendental phenomenology together should improve the prospect that some day the ideal of Leibniz for an all-embracing science may materialize. In recent years, the rapid development of symbolic logic points to its possible conquest eventually of ethics and æsthetics. Even if this should prove to be the case, it would not invalidate Husserl's inclusion of metaphysics within his circle, nor yet of at least an element of teleology which seems to be inherent in some aspects of contemporary biological theory.

The importance of all this for present-day science lies perhaps in Husserl's profound grasp of the subjective. It may be that natural philosophy, in the widest sense, is moving outwards a little from its purely impersonal position into one in which mankind becomes more closely interwoven with the object of contemplation.

Husserl does not claim that adequate, apodeictic, fundamental knowledge follows of necessity from the use of the phenomenological method, but only that it can do so if the 'bracketing' or reduction—that is, suspension of judgment—and observation have been made with sufficient care. The divergent streams—historically speaking, transcendental for Descartes, psychological for Locke, Berkeley and Hume—are brought together again in phenomenology as the true successor of Platonic concepts and of all that is of the *esse* of Greek philosophy.

F. I. G. RAWLINS

THE SCIENCE OF PREHISTORY

The Idea of Prehistory

(The New Thinker's Library.) By Dr. Glyn Daniel. Pp. viii + 171 + 8 plates. (London: C. A. Watts and Co., Ltd., 1962.) 15*s*.

THE eight lectures here published were delivered in 1956 as the second Josiah Mason Lectures in Archæology in the University of Birmingham. The material of prehistory is defined by the author as "the unwritten remains of the early past of man". It thus covers all those ages of human history which precede the literate cultures of the ancient world, as well as the non-literate cultures which continued to subsist alongside the peoples which possessed written records. The predominant role of archæology in producing the material of prehistory is well brought out, though archæology itself is correctly defined as covering a wider field extending right down to the recent past.

Prehistory is a newcomer in the learned world. The term itself was first used in 1851. Dr. Daniel records its gradual development, showing how the study drew on the older activities of the collectors and the dilettante, how it profited from the triumph of stratigraphical geology and how it was influenced by the evolutionary concepts of the nineteenth century. Finally, he sets out the most recent stage that lies within our own memory, when the study became firmly based on the scientific method, on the abundant material provided by archæology and on contacts with the natural sciences. Much of the material in the four lectures devoted to this development is well known; but the lucid and logical presentation gives it a new force and vigour.

The next three chapters discuss the relations, not always happy, of prehistory with other branches of study. Here the author is often treading on delicate ground. His account of the diffusionist theory and his unequivocal condemnation of the extravagances of the hyper-diffusionist heresy of the recent past is a model of balanced analysis and judgment. His condemnation of the racist uses of prehistory will find general assent. The discussion of the relations between prehistory and ethnographic and sociological studies is perhaps unduly pessimistic. The summary of the Russian approach (p. 120) was written before the availability in English of Mongait's survey, and does not represent the present position. On the other hand, his desire to see a closer integration of prehistory into the general historical perspective is most welcome. History in the narrower sense (that is, written history) has much to gain from a wider use of archæology; prehistory, which depends so largely on archæological material, should provide the methodological basis for the association.

The final chapter, "Prehistory and the Public", sits rather loosely on what has gone before. It shows clearly that public interest in early history and prehistory is no modern development and offers certain explanations of the popular interest in the subject. Dr. Daniel concludes that the "real justification of prehistory is not in origins or techniques or in perspective, but in pleasure; the pleasure of prehistory is in the recovery of the treasures of man's prehistoric past that have been dropped on the way and lost".

C. A. RALEGH RADFORD

PROGRESS AND PROPHECY IN SPACE

Advances in Space Science and Technology

Vol. 4. Edited by Frederick I. Ordway III. Pp. xiv + 431. (New York and London: Academic Press, Inc., Publishers, 1962.) 100*s*.

THIS fourth volume follows the same pattern as its predecessors: six separate topics are reviewed in articles which average seventy pages each in length. In the first contribution, J. Mass and E. Vassy deal with the Doppler effect of artificial satellites. Starting from first principles, they show the manner in which the frequency of the received signal changes as a transmitting satellite passes by, and how this variation can be analysed for the purposes of orbital determination, navigation and scientific studies of the ionosphere. R. A. MacGowan is the author of the second contribution, a brilliant though inevitably somewhat speculative one on the possibilities of extra-terrestrial intelligence: he reviews the many theories of the origin of planetary systems (concluding that such systems are numerous) and discusses the origin of life; he tries to define the process of thinking, describes how 'thinking automata' might come to dominate the Earth and points out that such forms of 'life' would be the most likely emissaries from superior communities.

The third contribution, on multiple staging in carrier rockets, by H. E. Nylander and F. W. Hopper, is a competent and yet somewhat unsatisfactory survey, not because of any fault on the part of the authors but rather because of the subject, which although omnipresent in space technology is difficult to treat as a separate abstract topic. In the fourth article M. Tucker presents a thorough review of spacecraft entry and landing in planetary atmospheres. He lays most emphasis on re-entry into the Earth's atmosphere, but also discusses landings on Mars, Venus and Jupiter. Next, S. J. Gerathewohl gives an excellent account, running to more than a hundred pages, of the development of manned artificial satellites and space stations. But he evades the brutal truth that, if the space stations he describes so fully are outside the Earth's atmosphere, their crews are likely to be killed when bursts of high-energy protons are emitted from the Sun at times of major solar disturbances: he merely remarks that adequate radiation protection must be provided, without saying how. Finally, J. J. Barré provides a very detailed account of the possible role of radioactive elements as sources of energy for spacecraft propulsion, with copious data on the properties of the elements in question.

These admirable individual contributions have been well edited and printed; together, this volume and its three predecessors serve as a valuable, though as yet incomplete, encyclopædia of space science and technology.

D. G. KING-HELE

RADIOACTIVITY AND MAN'S ENVIRONMENT

Living with the Atom

By Prof. Ritchie Calder. Pp. ix + 275 + 16 plates. (Chicago and London: University of Chicago Press, 1962.) 5.95 dollars; 42*s*.

THIS book reports on two colloquia organized by the Section of Nuclear Medicine of the Pharmacology Department of the University of Chicago in 1960. They dealt with radioisotopes in man's environment, and with public health and the problem of disposal of radioactive waste. Both discussed the present state of knowledge and uncertainty about the hazards and benefits attending the use of radioactive materials, and also how this knowledge can be translated into public information.

The author gives his own and other people's contributions to a discussion on responsible reporting in Chapter 2. It is difficult for the reporter to steer a course between the attractive liveliness that approaches the sensational, and the dry factual report that few will read; and it seems that the value of good science articles is slowly breaking in on proprietors. He feels that there is a fear and distrust of scientists, as people who ought to be above human fallibility but unforgivably err like everyone else; and he points out the dangers also of the responsibility for major decisions resting in the hands of men who do not know sufficient about science to be able to challenge with any confidence the advice that comes to them from their experts. There is something in this, although one would feel that a knowledge of men and a flair for consulting the right experts is what brings men to high office. (What keeps them there, however, is often a shrewd calculation of the limitations of the populace; and, in an ideal democracy, every voter would as a duty be reasonably knowledgeable on every issue.) It is true, certainly, that there is less understanding of scientific matters than there is of really difficult subjects like economics or bringing up children; and that this is largely due to communications.

The book itself, a really excellent piece of reporting, illustrates the problems that the journalist has to face. It describes the uses of radioisotopes, and also their effect in changing the whole of man's environment. The accounts of the ways of disposing of radioactive wastes—burying, running out to sea, hopefully incorporating them in glasses, faithfully moving mountains by extruding acres of cement into underground faults, and ruefully counting the cost of using outer space as a dustbin—between them offer so much information that I found them quite exacting reading. A layman could be pardoned for wondering whether already there are curies at the bottom of his garden. Which method is the safest as regards long-term interference with the environment? What is the most practicable now? Which is the most economical? These are the questions that everyone ought to know enough at least to ask. The book includes accounts of the hazards of uranium mining, and of life in a nuclear submarine. It should serve to spread the author's sound common-sense attitude towards the problems of nuclear radiation, as well as the facts brought out in the colloquia.

G. R. NOAKES

PROGRESS IN OCEANOGRAPHY

The Sea

Ideas and Observations on Progress in the Study of the Seas. General Editor: M. N. Hill. Vol. 1: Physical Oceanography. Pp. xv + 864. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1962.) 188*s*.

THIS is the first of three volumes reviewing the achievements of the past twenty years in understanding the physical, chemical and geological processes in and below the oceans. The first volume, covering the major fields of physical oceanography, illustrates the vast expansion which has taken place in these subjects since the publication of *The Oceans* by Sverdrup, Johnson and Fleming in 1942.

Articles by thirty-three contributors cover the physical properties and equations of motion of sea-water, small-scale and large-scale interactions between the sea and the atmosphere, dynamics of currents, transmission of sound, light and other electromagnetic radiation, various types of wave motion, and turbulence. Wave motions are reviewed in articles on ripples, statistics and dynamics of wind waves, microseisms, internal waves, long waves, tides, surges and long-term variations in sea-level.

The editors are to be commended on achieving a satisfactory balance between the many rival claims on the space available. In spite of this wide coverage there remain some topics that could usefully have been expanded such as recent work on current systems, wind-wave generation, coastal processes and ship-wave interactions. It must be remembered that significant progress has been made in some of these fields, such as non-linear interactions, since the time of writing (December 1959–October 1960).

Some contributors succeed in providing particularly timely and valuable reviews of their subjects. Among these must be mentioned Groen and Groves on "Surges", Hansen on "Tides", including recent storm surge computations for the North Sea, Lafond and Cox on "Internal Waves", reviewing the latest measuring techniques such as the isotherm follower and providing much new information on internal waves and their correlation with surface slicks.

The most notable contribution (and longest, 214 pages) is the review of large-scale air–sea interactions by Joanne

Malkus which provides a detailed and coherent picture of the present position in this field. Interaction problems are classified into: (1) formally tractable dynamical problems such as wind-driven ocean currents: (2) conservation studies of sources and transport of energy and solutes, for particular ocean basins, for example; (3) statistical analysis of observational data; (4) descriptive studies relying largely on physical analogues. Many recent investigations of the heat and water exchange between the atmosphere and oceans are discussed and related to climatological and general circulation studies.

Of particular interest to all workers in geophysical subjects will be the stimulating and critical concluding remarks by Dr. Malkus concerning the direction which our future effort must take. In particular, attention is directed to the necessity for "growth in the fundamental physics of turbulent, heat-driven fluids" and the need to pose questions which "... isolate tractable features of the complexity which can be treated under relatively controlled conditions". The scientific and economic background to all geophysical investigations, including oceanography, depends on the answer to her final question "... concerning *what* do we need more and better data the most?". It would have been most refreshing if more contributors had taken advantage of the sub-title of the book to take such a critical look at their branches of the subject.

The reader is certain to be impressed by the growing stature of physical oceanography as a scientific discipline. Although basically an observational science, the growing numbers of theoreticians and experimenters which it has attracted are responsible for many new and valuable fields of investigation. The editors and publishers must be congratulated on this worthwhile enterprise; the remaining volumes will be eagerly awaited. J. N. HUNT

MATHEMATICAL ANALYSIS OF TRANSIENT CIRCUITS

Transient Circuit Analysis

By Prof. Y. H. Ku. (The Van Nostrand Series in Electronics and Communications.) Pp. xiv+441. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1961.) 79s.

THE importance of circuit analysis is reflected in the great number of books on this subject, especially those emanating from the United States. It is of some interest to compare the present book with another book on the same subject, also by an American professor, written about a decade ago.

Both books cover roughly the same ground, including Maxwell's and Kirchhoff's rules, Fourier series, integral and transform, Laplace and Heaviside transforms, complex variable and inverse transform, Bessel, gamma and error functions. There is also in both books a fairly full treatment of the transmission line.

The great difference between the two books lies in the authors' approach to the subject. In the earlier book the author is concerned to demonstrate to electrical engineers the importance of mastering advanced mathematical techniques in order to solve engineering problems. The book is well supplied with practical problems, the initial approach is more elementary and some of the more difficult mathematical proofs are omitted, the reader being given references to mathematical works. In the present book the author's approach is frankly mathematical, and he clearly has supreme confidence in the mathematical outlook and training of the modern electrical engineer. In an introductory chapter the author appears concerned to show that engineering problems do exist to which the mathematical techniques may be applied. Thereafter the work is mainly mathematical and one almost expects an asterisk to the first chapter with a footnote saying that this chapter may be omitted on a first reading. References are given throughout the book to other works, but the author has aimed at making his book as self-contained as possible and has included in appendixes reprints from original papers.

The symbols used are generally well chosen, but the British Standards Institution might be somewhat distressed at the apparent dimensional error in the equation:

$$L\frac{di}{dt} + R_0 i^2 + S\int i\,dt = e$$

The author states not very far away that $(R_0 i)$ is a resistance, but his demonstration of a non-linear equation could have been made without this unsatisfactory symbolism by writing the equation as:

$$L\frac{di}{dt} + \left(\frac{R_0}{I}\right) i^2 + S\int i\,dt = e$$

where I is a constant, having the dimensions of a current.

The author's treatment of the solution of differential equations is satisfying both in its adequacy and freedom from unnecessary complications. The inclusion of methods of solving cubic, quartic and quintic equations is an attractive feature.

The square wave is in the forefront of the Fourier analysis of periodic waves, but although the author gives the Dirichlet conditions for satisfactory analysis, he makes no reference to Gibbs's spike and presumably considers that since the spike does not affect the standard deviation it can safely be ignored. This possibly illustrates a difference between the mathematical engineer of to-day and the more practical-minded engineer of yesterday, but it seems regrettable that a defect in Fourier analysis, exposed more than sixty years ago, should be in danger of being forgotten by our present-day mathematicians. Gibbs's spike can, of course, be eliminated quite easily by changing the shape of the periodic wave from a square wave, which cannot be realized in practice, to any approximation to a square wave which has no discontinuity.

This minor criticism apart, the book is an excellent text-book on a difficult subject. It is intended for graduates and would be too advanced for most undergraduates.

A. H. M. ARNOLD

SCIENCE FOR THE MODERN WORLD

Chemistry, Physics and Biology for the Modern World

Chemistry. By Prof. George Porter. Pp. ix+116. Physics for the Modern World. By Prof. E. N. da C. Andrade. Pp. viii+100. Biology for the Modern World. By Prof. C. H. Waddington. Pp. ix+120. (Science for the Modern World Series, Vols. 1, 2 and 3.) (London: George G. Harrap and Co., Ltd., 1962.) 4s. 6d. each volume.

THERE are severe problems in writing a chemistry, physics or biology book which in the span of some hundred pages must cover the basic theories, techniques and technologies of the subject. Accepting the necessity to solve the problem, these three books are regarded as a fine attempt.

Their presentation is attractive, their English is direct, their diagrams clear and useful, and they are served by a very full index.

The chemistry book deals with atomic theory, the characteristics of common elements, their atomic structure and the shape of the molecules they form. The kinetic theory is introduced and used for explaining the states of matter. A number of important chemicals are then interpreted according to this theoretical background.

The physics book includes information on Newton's laws of motion, the absolute zero, the basic ideas of wave motion and the passage of electricity through matter. It also includes an interesting chapter on atomic structure which reviews the progress made and indicates the possibilities and the danger arising from the use of atomic energy.

The biology book progresses from the structure of cells and the functions of their parts to their association to form tissues and organs. It considers the integration of organs in an organism and then of organisms in societies and communities; finally, binding the whole sweep of living activity in the chains of time to arrive at the theory of evolution.

A reader coming to the subject for the first time will probably find the degree of compression in these books far too much for him. Ideas flow too quickly, one after another, and there is not sufficient space given to descriptions or diagrams which might illustrate them. They might well stimulate many towards further reading in the subjects, but the short book lists for physics and chemistry do not seem to be appropriate. Some of the recommendations are formal text-books and demand of their readers some mathematical ability and some laboratory experience.

The Series presents good reading for those with some experience of the subjects. They are not 'bread and butter' books, but should be regarded as readers and have a place in the library. A potential sixth-former might read them to real advantage, whatever his intended specialization, for he will gain from them not only a welter of information but also an overall picture of the subjects. Each member of the Series is complete in itself, and may be read without reference to the others.

PROTEIN CHEMISTRY

Advances in Protein Chemistry

Vol. 15. Edited by C. B. Anfinsen, Jr., M. L. Anson, Kenneth Bailey and John T. Edsall. Pp. x + 447. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.) 13 dollars; 93s.

FOR many biologists and chemists, *Advances in Protein Chemistry* is an institution rather than a phenomenon, but this volume may interest a wider audience. That the authority, originality and editing of the reviews are first-class goes without saying; but the subject-matter represents, I suspect, a conscious effort by the editors to look away from the present busy centre of protein research back to the origins and outward to the periphery where protein chemists are illuminating many ancient biological problems.

Thus the late Kurt Felix, who himself has spanned almost the whole history of protein chemistry, opens this volume with his final survey of protamines. This recalls the empirical cookery which began the science (and from which we can still learn so much), but jumps to the frontiers of fashion when discussing combination of protamines with nuclear deoxyribonucleic acid.

The same approach is reflected in two other chapters in this book. Czok and Bucher, in their review of crystalline enzymes from rabbit muscle myogen, take us back to the original source of many of the purified enzymes which are at present providing useful employment for enzymologists and protein chemists. Even biophysics has its neglected corners: D. W. Kupke quotes Linderstrøm-Lang as saying, "Osmotic pressure has simply become unfashionable", but manages to persuade us that a little digging into these particular archives would be very profitable.

Two other articles indicate that the editors are determined to expand the horizons of protein chemistry. How do metabolites go in and out of cells? Halvor Christensen asks all the right questions, refuses to supply any glib answers, but suggests that protein chemists could provide some useful facts.

Finally, one chapter threatens to bring us out of our laboratories altogether. A scholarly article by Waterlow, Cravioto and Stephens dispassionately discusses human protein malnutrition; but we are left feeling that this is one field of research which ought rapidly to be abolished for lack of starting material.

BRIAN S. HARTLEY

ENERGY METABOLISM IN THE RUMINANT

The Energy Metabolism of Ruminants

By K. L. Blaxter. Pp. 329 (4 plates). (London: Hutchinson and Co., Ltd., 1962.) 63s. net.

THE revival of interest in calorimetric investigations with farm ruminants owes much to the work done by Dr. K. L. Blaxter at the Hannah Dairy Research Institute. Since 1950, he and his colleagues—notably Dr. D. G. Armstrong and Dr. N. McC. Graham—have designed respiration chambers for calves, sheep and goats, and more recently mature cattle, and used them for investigations of energy metabolism with notable success. Outstanding have been the measurements of the efficiencies with which the lower fatty acids, produced in quantity in the fore-stomach of the ruminant, are used in maintaining body processes and producing body fat.

In the winter of 1960, Dr. Blaxter gave the Clive Behrens lectures in the University of Leeds in which he discussed the energy metabolism of ruminants in the light of recent knowledge, particularly in relation to the formulation of rations to meet the energy needs of domestic ruminants. The lectures have now been expanded to make a book which is undoubtedly a classic in its own sphere, as in that of animal nutrition in general.

The book is in four sections: the theory and technique of direct and indirect measurements of heat production; the expenditure of energy by ruminants, as affected by level of feeding, activity, environment and function; the utilization of the energy of the end-products of the digestion of food; and the application of experimental findings in the development of feeding systems. The treatment of subjects is comprehensive and in general of a high standard. One might mention in particular the description of the apparatus and technique of animal calorimetry; or the account of the utilization of the energy of the end-products of digestion of food for maintenance and in the processes of growth and fattening. The short account of energy metabolism in relation to lactation, however, is by comparison superficial, and in part misleading. On occasion, especially in the chapters on the effect of environment on heat loss, unnecessary and often tedious detail has been included: this could well discourage the reading of the book in its entirety, an unfortunate consequence since the author's logical development of his subject gives an excellent perspective.

The last section of the book, however, can be recommended without reservation. It includes a brilliant appraisal of present-day systems of evaluating foods and feed requirements, and of their historical development, written in a most stimulating manner. In the final chapter the framework of a new feeding system is described. It is based on the metabolizable energy of foods determined at the maintenance-level of nutrition, and in the calculation of feed requirements adjustments are made according to the type of ration and the function of the animal. This represents an important departure from existing systems which attribute to individual foods specific values for a particular function and assume that such values are additive and that the same relative values apply to all functions. The new scheme has many merits and is worthy of careful consideration.

The book is well produced, with very clear, but occasionally slightly imperfect, figures. It will provide useful reading for a wide audience, from the progressive farmer who wishes to be well informed to the research worker in animal physiology. It is, of course, also an excellent book for students.

J. A. F. ROOK

SELECTIVELY INDUCED CALCIFICATION

Calciphylaxis

By Dr. Hans Selye. Pp. xxxi + 552 + 13 plates. (Chicago and London: University of Chicago Press, 1962.) 25 dollars; 189*s*.

It is the opinion of Dr. Selye that the mammalian body contains a defensive or phylactic system which enables the body to produce calcareous deposits at localized sites. By this means the effects of a pathogen can be reduced and local inflammatory responses initiated. This idea forms the basis for the title of this book and for the long chapter (120 pages) devoted to a catalogue of the abnormal mineralizations known to medical science. The implication is that as with other defence systems calciphylaxis may become pathogenic in certain circumstances. It is important to realize, however, that there is no proof that any disease in man depends on calciphylaxis. Dr. Selye has reached his conclusions on the basis of some very exciting experiments and the phenomenon of calciphylaxis is best described by considering one of these.

A 100-g rat was given an oral dose of 1 mg of dihydrotachysterol. The following day 25 μg of ferric chloride were injected beneath the skin. A local deposit of calcium salts occurred during the next 2–3 days at the site of the injection. A different type of effect could be produced if ferric oxide saccharate was injected instead of ferric chloride. In this case it was found that after 2–3 days the heart, bile duct, duodenum and renal cortex were mineralized. Similarly, injecting egg albumen intravenously led to the calcification of the pancreas, while egg yolk produced a mineralization of the spleen and part of the liver.

Dr. Selye rationalizes these phenomena by talking first about the sensitizing agent. This is usually dihydrotachysterol although other substances that act like vitamin D or parathyroid hormones have the same effect. These substances normally mobilize calcium in the body, but there is no information as to what effects these very large doses have in these experiments except the idea that they sensitize the body. The second feature in these experiments is the critical time of 24–48 h between the two injections. Without this critical time-lapse the calciphylactic response is not usually obtained. This critical time is much greater than is necessary for the substances administered to produce their usual responses. Finally, there is the injection of the second substance, called the challenger or vital mordant. This is thought to act by increasing the ability of the target organ to calcify, although it does not appear to be responsible for the direct precipitation of calcium salts.

By developing these concepts Dr. Selye provides himself with a systematic basis for the discussion of the phenomenon of calciphylaxis. What is needed most in this investigation, however, is a background of biochemical data for at the moment the phenomenon is completely mysterious. This absence of analytical data also extends to other parts of the investigation. In a book of this length one is surely entitled to know which calcium salts are being deposited, but again this information is virtually absent. This complete absence of chemical data suggests that this book may be slightly premature, but this will be justified if it fulfils the wish of Dr. Selye that it attracts many more scientists to investigate this most interesting phenomenon and to use this powerful experimental tool.

K. SIMKISS

GEMSTONES

Gems

Their Sources, Descriptions and Identification. By Robert Webster. Vol. 1: Pp. xii + 1–464 + plates 1–17. Vol. 2: Pp. vii + 465–792 + plates 18–20. (London: Butterworth and Co. (Publishers), Ltd., 1962.) 190*s*. the complete set of two volumes.

The two volumes of this work form a comprehensive account covering the history, descriptive mineralogy and technology of gemstones (both natural and synthetic), and the special techniques which have been developed, especially since the Second World War, to test them.

The first volume begins with a short chapter on the geological origins of gemstones and the methods used for their mining and recovery. The main descriptive chapters follow, with diamond, ruby and sapphire, and emerald treated first, and other well-known gemstones next. A long chapter of nearly sixty pages, arranged alphabetically, then follows in which almost every mineral ever fashioned as a gemstone is described. Synthetic and various types of imitation gems are then discussed, and a section on the cutting and polishing of gemstones is inserted before a concluding chapter on organic gem materials. In this first volume the emphasis is largely on the history, distribution and mode of occurrence of gemstones; but adequate space is devoted to crystal form and chemical composition, and inclusions are given generous treatment. Very full descriptions are given of the absorption spectra and luminescent characters of the various species under X-rays and ultra-violet light. A most useful feature in this volume, of considerable assistance to the practising gemmologist, is the gathering together of all the descriptive and diagnostic characters for the individual species in the one chapter; in this respect the book differs from many other texts on the subject, which describe the various physical properties of gemstones in separate chapters.

The second volume deals with crystallography of gemstones and the determination of their physical properties. In describing the instruments and techniques used the approach is essentially practical, and there is a wealth of experimental detail. The theoretical background is by no means neglected, however, and explanations are usually developed along historical lines and from first principles. A number of useful identification tables (showing refractive indices/specific gravities, hardness, dispersion, luminescent characters/absorption spectra and other properties) and a glossary of alternative gem names, misnomers and trade names conclude the second volume.

A few minor errors were noticed in the text, and should be eliminated in any future edition. On p. 716 the heading of Table 2 should read "Colour Dispersions of Gemstones" and not "dispensions". Initial capitals are omitted from the names of the geological systems on several occasions and also from the generic names of fossils.

These volumes will form a most useful work of reference for practising gemmologists and for others seeking information on gemstones and gem testing. They are well produced on good quality paper, and a notable feature is the abundance of up-to-date black-and-white photographs, although some of the colour plates are of indifferent quality for modern colour printing—a disappointing feature in such an expensive work.

E. A. JOBBINS

John Anderson, Viscount Waverley

By Sir John W. Wheeler-Bennett. Pp. xv+430+16 plates. (London: Macmillan & Co., Ltd.; New York: St. Martin's Press, Inc., 1962.) 45s. net.

FOR most scientists Viscount Waverley's achievements, and more especially his contributions to science, have been so admirably summarized by Lord Bridges in his biographical memoir for the Royal Society and its addendum by Sir Henry Dale that there is little for Sir John Wheeler-Bennett's volume to add. Nevertheless, it is of real interest, particularly at the present time, for its demonstration of the importance of the scientist being sometimes 'on top' and not merely 'on tap' and as illustrating the value of a scientific training and outlook in the higher levels of the Civil Service and in the Cabinet itself. Sir John Wheeler-Bennett gives full weight to this aspect of Lord Waverley's career as well as to his outstanding gifts as an administrator. This is particularly notable in respect of Lord Waverley's part in the Anglo-American relations in the field of nuclear fission, of which Lord Bridges has commented that it is very difficult to say how this all-important development could have been carried out so successfully under the stress of war had there not been a Minister of the Crown with his very special qualifications for the work. If the Americans were impressed by the fact that a British Minister and member of the War Cabinet knew enough about science to understand what the scientists were discussing, scientists in Britain were equally impressed, as Sir Henry Dale has testified, by the value of having in a position of authority such as the Lord President of the Council, a man with so natural an understanding of the meaning of science, and so instinctive a knowledge of, and sympathy for, the possibilities and the difficulties of research. Apart altogether from the general interest of the book it has on these two counts an assured place in the literature on the relations of Government and science, if not of administration generally.

R. BRIGHTMAN

Nuclear Reactor Fuel Elements

Metallurgy and Fabrication. Edited by Albert R. Kaufmann. (Prepared under the auspices of the Division of Technical Information, United States Atomic Energy Commission.) Pp. xii+739. (New York and London: Interscience Publishers, a division of John Wiley and Sons, Inc., 1962.) 203s.

CONTRIBUTIONS from twenty-five authors make up the present book, which covers a wide range of topics from reactor physics to the processing of irradiated fuel elements. The book provides much which should be of general interest to reactor designers and to metallurgists engaged in the field of nuclear energy. The original intention to describe something of the art of making fuel elements is fulfilled in only three of the 18 chapters of the book, namely 11–13, followed by a useful catalogue of testing and inspection methods. These chapters describe in detail the manufacture of uranium bar and strip and the fabrication of clad fuel elements and bundles. The treatment is necessarily empirical but authoritative, and should appeal to the fabrication specialist. The fabrication of ceramic fuels is only briefly described. Seven chapters of the book are in the form of excellent short introductory essays on subjects including reactor physics, fuel element problems, cladding materials, heat transfer, processing of irradiated fuel elements, fluid fuel systems and fuel element economics. The remaining chapters are probably too long and detailed to appeal to the beginner and too superficial to appeal to the specialist for general reading; nevertheless, they contain very useful tabulated data on the alloy systems of uranium, plutonium and thorium, and a survey of operational types of fuel element with the performance statistics and main types of failure experienced. Unfortunately throughout the book there is very little reference to data published after 1958.

S. F. PUGH

Design and Function at the Threshold of Life

The Viruses. By Prof. Heinz Fraenkel-Conrat. Pp. vii+117. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1962.) 1.95 dollars; 14s.

THE chemical study of viruses is now recognized as important by even the most reactionary virologists, and is now contributing to our knowledge of biological systems of all kinds, largely because the fundamental mechanisms utilized by the viruses are essentially much the same as those found in the higher organisms, but the viruses are simpler and often easier to manage because of this simplicity.

Heinz Fraenkel-Conrat has contributed much to the advances which have been made in this field over the past few years, and a book from his pen is very welcome at this moment. Naturally, in dealing with the viruses, the author has concentrated very largely on the chemical aspects of the smaller members of this group, and in particular with the tobacco mosaic virus, which is certainly the most completely studied, if scarcely the most representative, of the small viruses.

A large part of the text is concerned with a detailed discussion of the chemistry of the proteins and of the nucleic acids, and the parts which they play, and therefore much of the book is of interest to biologists in general. The reader will also gain an interesting, if unintended, insight into the author himself.

Naturally, in a short book of this type it is not possible to do more than skim over the general subject of virology, although as the author himself states: "This little book contains a fair amount of information". Some excellent illustrations are included, but undue space has been given to pictures of models of tobacco mosaic virus "reconstituting", which, although fun, are not very informative.

It is surprising to note that, although the major theme of the text concerns the nucleic acid of the tobacco mosaic virus, the names of its discoverers are not mentioned anywhere.

ROY MARKHAM

The Nature of Biochemistry

By Prof. Ernest Baldwin. Pp. xiii+111. (Cambridge: At the University Press, 1962.) 13s. 6d. net; 2.75 dollars.

AN author who has previously written two highly successful and widely read books about biochemistry might perhaps be excused for feeling apprehensive about the merit and timeliness of his third effort. Prof. Baldwin need have no doubts on either score. Biochemistry is still very much of an unknown subject to the staff and sixth-form students of our schools, and there can be little doubt that many potentially good scientists are lost to biochemistry because of lack of adequate information at school-level. This book should be of considerable help in correcting this situation, for its purpose is to explain to those leaving school what biochemistry is about.

It is perhaps not surprising that the thread of Baldwin's own interest, comparative biochemistry, should run through the book, and this thread is particularly strong in the opening sections. However, this aspect usually has its own special attractions for sixth-form students, and the author uses it to good effect in illustrating the essential simplicity and unity underlying the complexity of biochemical processes.

Through being essentially readable, there is sufficient depth in the book to test the inquiring mind and indeed some passages will require considerable concentration on the part of the young reader. However, for the most part, the book flows in characteristic Baldwin style. Extremely well produced to the high standards usually associated with the publishers, this book can be strongly recommended to all who wish to learn something of the life-process.

K. S. DODGSON

LEARNED SOCIETIES AS PUBLISHERS

THE Scientific Publications Council met at the Ciba Foundation, London, on December 13, to discuss the "Publication of Journals by Scientific Societies" with Prof. A. S. Parkes (Physiological Laboratory, Cambridge) in the chair. Dr. P. N. Campbell (Courtauld Institute of Biochemistry, London) introduced the subject with which he had been much concerned in so far as it affects the Biochemical Society. Societies exist to advance their respective sciences; since publication is one of the chief means to this end, the production of a journal may be regarded as a most important activity for a scientific society, which must adopt a strict editorial policy to set a standard in the field.

Old-established journals produced by commercial publishers generally adopt the same high standards, but as publication in science grows more profitable, the proliferation of specialized journals leads not only to the fragmentation of science, but also to higher costs to subscribers and, in some instances, to lowering of editorial standards.

Societies can be associated with journals in one of three ways.

In the first arrangement the society owns and publishes the journal itself. This ensures it complete control, the greatest financial benefit and, provided the society is large enough (for example, the Chemical Society), it seems the most desirable scheme.

Secondly, the society may own the journal, but employ a publisher. This arrangement is adopted by many smaller societies with no permanent editorial staff, often to secure financial backing when starting a new journal. The publisher prints, promotes, sells and distributes the journal for a commission. The Cambridge University Press does this for a number of societies, treating all exactly alike on a *pro rata* basis. It does an excellent and reliable job of printing at low cost; but the commission charged for its publishing activities, Dr. Campbell considered, is high. However, if a society has no professional staff, such liaison with a publisher may be a reasonable compromise.

Thirdly, the journal may be owned by a publisher though the society appoints the editors. The society runs no financial risk, but it also stands to gain least if the journal succeeds, so that this arrangement is rather unsatisfactory. However, a society wishing to operate in this way might do well to consider the Company of Biologists, a non-profit-making organization which owns and publishes several journals on this basis.

What can be done to help scientific societies regain the initiative ?

Dr. Campbell thought that responsible scientists should be urged to consider carefully before accepting requests to serve as honorary editors of a new commercial journal. The time had come, he proposed, for societies to collaborate, taking advantage of the best commercial methods, in the production, promotion and distribution of their journals. A source of funds is required to tide societies over the early stages of publication; also advice is needed on printing and distribution costs, and accommodation must be found for editorial offices. A joint distributing organization should be created to enable societies to collaborate over subscriptions and the storage and despatch of their journals; the same organization might undertake promotion of sales.

In reply to a question, Dr. Campbell said that he advocated increasing the size of existing journals rather than a multiplicity of small journals published on science, although, as Dr. T. R. E. Southwood (Imperial College of Science and Technology, London) suggested, societies start new journals not only to cover new fields but also because the editors of existing publications have neither time nor space for expansion. The question of sales promotion restrains many societies from severing their connexion with publishers, since large institutional sales are needed to subsidize the free distribution of journals to societies' members.

Mr. A. L. Bacharach (*British Journal of Nutrition*) perceived the horns of a dilemma: one could support small specialist journals, intelligible and interesting throughout, which, because of their small circulations, are expensive; or one could support large unspecialized journals, which are to a considerable extent unintelligible and costly in time to read selectively.

Dr. D. Richter (Medical Research Council Neuropsychiatric Unit, Carshalton) thought national journals are tending to give way to international periodicals with world-wide circulations such as can best be provided by the great publishing houses.

Mr. Donn Casey (Reproduction Research Information Service) described his experiences in starting the *Bibliography of Reproduction*, a new title-list with fourteen issues annually of eighty pages each. He is compiling, promoting and distributing this with the aid of one full-time assistant with some part-time help. It is printed by lithography, the plates for which are prepared in the office with an I.B.M. typewriter, no photographic process being used. The quality is quite good, while the process is fast and costs a fraction of normal type-setting.

Mr. R. W. David (Cambridge University Press) said that he hoped he could speak with uncommercial impartiality, although this did not mean that the Cambridge University Press was not as competitive and efficient as any commercial publisher. A society should first satisfy itself that its publisher is really necessary. The publisher provides (*a*) finance and (*b*) a distribution service. The former is much easier than many societies believe; it is financial assistance at the early stages that is so valuable. Once a journal is established the subscriptions come in before the bills have to be paid. Through his distribution facilities, a publisher can promote sales to a marginal public; but a specialist journal for a well-defined clientele might need no publisher at all. The publisher's commission normally covers promotion, warehousing and distributing costs. However, as Dr. H. J. Rogers (National Institute for Medical Research, Mill Hill) pointed out, a society undertaking these tasks for itself would not necessarily realize the whole of the publisher's commission, for it would not only lose the benefit of the university press, whose printing costs are low, but it might also have to employ extra staff.

Dr. A. C. Stickland (Institute of Physics and the Physical Society) said that many printers and binders will distribute journals directly. Mr. J. C. Graddon (Royal Society) agreed, adding that the Royal Society now publishes by itself and employs a firm of packers and distributors. Many Fellows have waived their right to copies of all the Society's publications in favour of receiving, on request, free reprints of particular papers that interest them. Dr. Campbell's scheme was reminiscent of the science centre proposals for collaboration between the societies in shared premises, with their own publishing house and printer in the basement.

Dr. W. R. S. Garton (Imperial College of Science and Technology, London) emphasized the distinction between reputable publishers and a less-scrupulous minority that act as *entrepreneurs*—it is the latter that start most of the new journals in order to 'sell' science as a commodity. It is wishful thinking to suppose that in the absence of a genuine need such journals would fail for lack of support: librarians dare not ignore them. A puzzling feature is the list of illustrious names on the titulary boards of these journals—names that not even death can always delete from the roll, as Dr. R. K. Callow (National Institute for Medical Research, Mill Hill) interjected. New journals should in general only be supported if they bear the imprint of a society. Mr. A. V. S. de Reuck (Ciba Foundation, London) remarked that if economic selection did not eliminate poor journals, perhaps some way should be found whereby journals could be reviewed like books and some machinery for explicit selection set up for the benefit of librarians. Mr. J. A. Rivers (J. and A. Churchill, Ltd., London) replied that reviews may sell good books but they do not necessarily condemn bad ones, and he doubted whether they would be effective with periodicals. While they are profitable, new journals will continue to arise, Dr. Rogers believed, and it would be a tragic mistake for scientific societies to lower their standards in order to compete with the less-desirable of these. The societies must set the standards for all, including the commercial publishers.

A. V. S. de Reuck

THE TEACHING OF BIOLOGY

By Prof. D. G. CATCHESIDE, F.R.S.
Department of Microbiology, University of Birmingham

There is at present much discussion concerning the reform of biological teaching. The reasons are varied. There are impressions that university entrants in biology are poorer than formerly and worse prepared for the study of their subject, so biology must be made more attractive for brighter pupils. There are all the newer studies for which space must somehow be made, giving rise to questions as to which of the older material, if any, is fundamental and what relative adjustments could be made. There is the recognition that very much in the living world is common to plants and animals and micro-organisms, and that therefore the cleavage into botany and zoology, as well as the separation from medicine and agriculture, goes deeper, far deeper, than it should. This is especially true of the structure and function of cells, studied by the methods of physiology, biochemistry and genetics. However, the common ground extends well beyond cell biology, and it is possible to write truly biological curricula which, with quite minor changes, may be studied with reference to either plants or animals, or to a combination of the two or, even, to a very considerable extent, with micro-organisms only. As well as the immense growth of biochemistry, there is an important new field of biophysics to take into account. The less important, though more obvious, aspect of this concerns the specialized machines with which modern physics has supplemented the microscope; the more important aspect is the way in which individual physicists, shying from the anonymity of teams grouped around huge machines, are bringing physical ways of thought to bear on biological problems.

There are therefore several adjustments required in biological education, without further delay, partly to prevent continued fragmentation of biology, partly so that biologists may understand the newer biochemical and biophysical knowledge which is sweeping their subject, and partly so that biochemists and biophysicists may be given a broad and fundamental view of biology. Only in this way is there a chance of making the spectrum of biological knowledge continuous. No one person can hope to encompass the whole in any detail. Most will be specialists in some fairly narrow range, though a few may absorb to differing extents in several regions.

The solution to teaching at university-level lies in the devising of new curricula which are not mere chimeras of existing courses, for biology is not merely a mixture or synthesis of zoology and botany. The courses should permit a biology student to specialize to a greater or lesser extent and attain an honours standard in three years from entry into a university. The specialisms possible may be expected to be more varied than at present, recognizing that none can properly cover the whole of botany or of zoology. Indeed, what university course really does so even at the present time? The first year of a biology student should include a general course in biology and a general course in physical sciences; between them these should provide the whole of the specialist or vocational study.

Most authorities seem to agree that more understanding of the principles of physical sciences is needed by most biologists. It is fairly easy to see what these should be, and there is a reasonable prospect that physicists and chemists will be sufficiently interested to plan educative courses which will achieve the main objectives. These should be to fit the developing biologist with an understanding of the principles of the physical sciences, especially in the context of their relevance to biological systems. The significant topics, several of which are not exclusively chemical or physical, ought to include:

(1) Elementary particles and atomic structure, isotopes and their application to biology.

(2) Dynamics, mass and gravity; the biological effects and applications of high and low gravity.

(3) Chemistry of inorganic and organic substances, with special reference to those of biological importance.

(4) Macromolecules.

(5) Rates of reaction, catalysis and the properties of membranes.

(6) Electricity, light and other radiations; biological applications, for example, X-ray crystallography.

(7) Thermodynamics; work in biological systems; high-energy bonds.

(8) Stellar and planetary evolution.

(9) Earth sciences, climatology and meteorology.

The general course in biology, which should be suitable also for biochemists and biophysicists, must be planned to give a perspective of the subject, both as regards the different levels of integration which it has and which cut right across the division into plants and animals and, indeed, micro-organisms, and the relationship of these levels to one another. Broadly, the topics may be arranged in the following way:

(1) The cell as the basic unit of organisms, its constituent materials and their acquisition and its metabolism. Emphasis needs to be placed on the general similarity in constituent compounds and processes, on the means of energy transport and utilization, and the control of metabolic processes.

(2) The organization of cells to form tissues and more-or-less complexly differentiated organisms, with the consequent problems of procurement and processing of materials and the organization and integration of functions.

(3) Reproduction, ranging from the cellular and subcellular levels to the organismic and dealing with chromosome theory, the structure and function of genes and the problems of development and differentiation.

(4) Evolution, including the elementary processes of change in heredity, the evolution of adaptation, the nature of genetic systems and the consequences of these for variation and the supposed nature of species and speciation.

(5) Diversity and the problems of classification, with special reference to the principles and purposes, both as regards the classification of plants and animals as a whole and also at the finest levels of distinction. Suitable illustrative material should be drawn from plants, animals and micro-organisms, though not exhaustively.

(6) The behaviour of populations, as regards the interdependence of the individuals for energy and materials, their interactions and consequent change. The relation of organisms to environment, noting the relation of ecology to evolution.

(7) Behaviour, as a special aspect of relationship between individuals or of individuals with environment.

It is on this basis that one may take issue with Prof. R. D. Preston[1] that above the level of "cell biology", defined by him as "the physics and chemistry of individual cells", botany and zoology are too different to teach together in one department and that they are "at least as different as physics and chemistry". The reality of biology as a subject lies in the unity inherent in the apparently universal similarity in the constitution of cells, of their mode of reproduction and of their integration, differentiation and evolution to more complex levels of organization.

One may agree, in principle, with Preston that no one can be expected to have the capacity to contain the whole of botany or of zoology and at the same time have the mathematical and physical knowledge and skill needed to cope with certain of the work commonly referred to as 'molecular biology'. Nevertheless, every biologist, in the full sense of the term, should have a general understanding of the principles behind such work and of the results and their significance. This is essential if the co-operation of biologists with physicists, specialized in various ways, is to be achieved. Likewise, it is essential to design courses in biology suitable for the biological education of those physicists and chemists who aspire to be biophysicists and biochemists.

I would probably agree, also, that 'classical' biologists, presumably anatomists, morphologists and taxonomists, generally dealing with material that is not alive, are supremely necessary and probably have no need for an extensive knowledge of the physical sciences. In the realm of anatomy, as revealed by the electron microscope, we are surely back to the position of lack of serious distinction between plant and animal material. No one can fail to be impressed by the similarity of structure shown by sperm tail and the cilia of fern spermatozoa. In electron microscopy, no botanist can afford to ignore work on animals, or to abandon the field to the biophysicist.

In the case of taxonomy, also, I would like to be sufficiently revolutionary, or perhaps atavistic, to suggest that training in this 'specialism' should fit the taxonomist to turn to plants or animals. The principles and methods are the same, only the details are different; a competent taxonomist could surely acquire a good working knowledge of a new group in a year or two, if he put his mind to it, in the presence of proper collections and library and laboratory facilities. The more modern aspects, the new systematics, embraces experimental methods and concepts in cytology, genetics and evolution which are, common to plants and animals. These have been studied over many years by geneticists, sometimes with plants and sometimes with animals, but always with a broad knowledge of the field. Here the 'gap' is illusory.

I do dispute that the work of taxonomists, anatomists and morphologists is the foundation on which all the rest stands. A modest knowledge of genetics, for example of the bacteria or of certain viruses, would dispose of this notion. The whole deductive and inferential structure of biology as a science, largely derived by the methods of genetics, physics and chemistry, is independent of descriptive biology in its development. Of the methods, only the first is characteristically biological and biological alone.

After the first year at the university, during which one may hope for a common course for biologists, we may expect that many students will wish to specialize. It should be possible to do this to different extents and into fields which are not co-extensive with those of the historical divisions of botany and zoology. In neither of these has teaching ever been truly comprehensive, simply owing to the exigencies of time and the limitations of staffing. It would be realistic to recognize this and to plan second- and third-year courses leading to suitable specialization in, for example, taxonomy and ecology, genetics, plant or animal physiology and biochemistry and microbiology, as well as more general courses or combinations of courses for those who may need them. Clearly, the possible range, as now, would be determined by the staffing at any particular university.

In common with Prof. R. A. Morton[2], in commenting on the 'training' of biochemists, I believe it is essential that any course of biology should be educational, intellectually stimulating and contain aspects hard enough to stretch the mind of the student. The quality of education is to be judged mainly by the extent to which it kindles a true spirit of continued inquiry and study. The precise content of the course matters little; the spirit and the manner of its study do. These should constantly lead to inquiry and discovery by the student. It is unnecessary to make believe that a course in any way covers the whole of a subject. A student, well educated as a student, will be able to go on and learn more of his subject and even to branch out into new fields after graduation.

My purpose has been to indicate how the teaching of biology at a university can be unified and what most biologists' education in the physical sciences should encompass. Likewise, I have desired to indicate what minimum view of biology as a whole the biochemist and biophysicist should have.

COLOUR AND LIFE

> I sometimes think that never blows so red
> The Rose, as where some buried Cæsar bled . . .
>
> *Omar Khayyám.*

IT is a far cry from bleeding bread and medieval massacres of Jews to interior decoration and eye-shadow; from photosynthesis to photography, respiration to Rembrandt, ultra-violet honeylines to tattooing and television. All these and other topics, more chaste perhaps, were compassed in and between the sessions (during September 20–21, at Birkbeck College, London) of the thirteenth annual symposium of the Institute of Biology, the title of which epitomizes the dual link, the unsaturated bond, between them all: "Colour and Life".

The first morning's session, under the chairmanship of Prof. O. V. S. Heath, dealt with structural colours (Prof. W. D. Wright, Imperial College, London) and chemical colours (Dr. J. B. Harborne, John Innes Institution, for plants; Prof. T. W. Goodwin, Aberystwyth, for animals). The effects of surface, of transparency and of background on specular and diffuse reflexion include structural colour when there is differential reflexion due to scattering, interference or diffraction, though the last is of doubtful significance in living systems. Tyndall scattering (macaw) and interference (peacock, beetles, *Morpho* butterflies) were illustrated and analysed, using spectral reflexion factor methods (for a first general idea) and spectral luminance factor methods (which take account of direction and therefore discriminate specular and diffuse components and do justice to iridescent hues). Though coloured transparent non-metals, unlike metals, have not a coloured specular reflexion, the metallic effect can be produced from a multilayer of such material.

The first requirement for a pigment is a conjugated system of alternating double and single carbon–carbon bonds. Carotenoids, all based on a tetraterpenoid skeleton (8 five-carbon isoprene units), are widely distributed in most plant organs. Animals can only synthesize to the sterol (triterpenoid) level; their carotenoids are direct diet derivatives. Incidence and colour function (flowers, fruit, skin, feathers) in both kingdoms was reviewed.

Flavonoids (anthocyanins and allies) are mainly of higher plants. Progressive colour changes occur as phenolic hydroxyls are multiplied (for example, scarlet to mauve) or for other simple changes. Many are indicators and perhaps stimulated the Rubáiyát couplet felicitously quoted by Harborne. Odd cults like blue roses will vainly seek delphinidin in Rosaceae; blues must here be engineered—if engineered they must be—otherwise.

Quinonoids (*p*-benzoquinone nucleus) are again mainly plant pigments, often mysteriously hidden in roots or under bark. They colour fungi and occur in echinoids and scale insects—ancient and modern providers of dyestuffs.

Nitrogenous pigments are the most diverse. Allied to chlorophylls and blood pigments (*vide infra*) based on the four-pyrrol porphyrin molecule is prodigiosin of bleeding bread. The polymeric-indole-group melanins mainly belong to animals (possibly fungi, too), but their distribution is confused by looseness of definition (formerly, anything black was a melanin), and the difficulty of detaching their proteins. Other nitrogenous pigments were reviewed.

In the general discussion, there was substantial agreement on the need to measure colour of whole organisms; ripening of tomatoes, lures in ethology and ultra-violet honey guides being quoted.

The afternoon session (under Prof. Helen Porter) included colour and classification in lower plants (Prof. G. E. Fogg, Westfield College, London), photosynthetic pigments (Prof. C. P. Whittingham, Queen Mary College, London), respiratory pigments (Prof. H. Munro Fox, Queen Mary College) and colour change in animals (Dr. D. B. Carlisle, Anti-Locust Research Organization).

Clandestine consultation of coloured Floras apart, pigment specificity and a largely biochemical taxonomy make thallophytes amenable to colour diagnosis; 'misfits' (*Prototheca*, photosynthetic bacteria) are few. The by-product type of pigment in fungi and lichens is, not surprisingly, too variable to use above genus-level, and its use may be frankly artificial (for example, spore colour); but photosynthetic pigments are fundamental and conservative, and validly diagnose major groups in bacteria and algae (conditioned masking, as in red *Hæmatococcus*, apart)—though broader-based evidence could be desired. Difficult cases were reviewed and the legitimacy of phylogenetic speculation assessed.

Photosynthetic efficiency is measured by comparing action spectra (oxygen yield against wave-length) with absorption spectra. In brown algae, fucoxanthin contributes as efficiently as chlorophyll; phycocyanin and phycoerythrin are similar, carotenoids less efficient. The energy is transferred to chlorophyll with low loss by inductive resonance. Derivative-spectrum studies, comparison with the adenosine triphosphate and electron sequences in animal respiration, and Witt's short-flash experiments correlating types of absorption-change with the electron-transport sequence, lead to the now generally accepted concept of two photosynthetic processes using different pigments and linked by a thermal dark reaction (Whittingham and Bishop) which involves loss of free energy probably coupled with phosphorylation.

From the succinct review of the structure and occurrence of respiratory pigments, cytochrome was omitted as having little colouring effect on tissues and none on whole animals. Hæmoglobin, hæmerythrin and chlorocruorin contribute little direct, hæmocyanin nothing; but non-respiratory hæmoglobin derivatives (porphyrins in the earthworm, certain shells, touraco birds) do. In a few marine worms, green is due to dietary chlorophyll; but the green of insects and *Actinia*, like the greens and blues of birds' eggs, blue wrasse and blue coral, is due to bilins (based on a pyrrol chain instead of a ring)—much commoner contributors than porphyrins to animal colour.

Changes in animal colour are morphogenetic (gradual metabolic substitution through heat (*Carausius*, *Schistocerca* hoppers), light, diet (*Flamingo*, *Carcinus*), background (isolated *Locusta* hoppers), crowding (gregarious *Locusta* hoppers), courtship (mallards, prawns), etc.)—or kinetic (chromatophoral darkening of prawns in unwelcome light; breeding-dress of some fish; aposematic-cryptic transformation of *Sepia*, etc.). The simplest responses, of either type, are directly stimulated, but more often the effector is under central control, either nervous (beak in cephalopods, with their special brainlobe) or endocrine (Crustacea, sexual colour-change of fish); or both.

In a lively but unresolved discussion, the 'aposematic' function of striping in the (highly palatable) *gregaria* hoppers was challenged in favour of disruptive crypsis (still) combined with episematic signal function (moving).

The general discussion which followed brought out the dangers of the effects of colour contrast on description. Relevant charts produced by the Technical Optics Section, Imperial College of Science and Technology, were demonstrated.

The theme of the second morning, at which Dr. K. Mellanby took the chair, was colour perception and behaviour. Dr. J. D. Carthy (Queen Mary College) (invertebrate perception) opened with the caveat: sense-organ discrimination need not imply colour vision, which can only be tested by whole behaviour. *Pieris brassicae*, neutral to green while feeding but highly attracted when egg-laying (Ilse), shows the need for the comprehensive approach, as does the history of bee-training to colour. An extensive review followed of visual pigments, evidence of all types for spectral discrimination and sites thereof, and double receptor systems, in such groups as have been investigated.

Dr. U. Weidmann (Birkbeck College), speaking on colour and animal behaviour, reviewed the whole vast field of releasers, their interaction with one another and the background, and the conflicting selection between camouflage and signalling: to trace the mode of evolution of the colour patterns that play such a prominent part in this behaviour. The special case of symbiont signalling was illustrated from Manning's experiments with honey-guides for bumble-bees and Daumer's demonstration of ultra-violet honey-guides in (to us) plain red flowers (bees seeing the ultra-violet pattern). Finally, evidence of some rudimentary æsthetic appreciation in certain groups was presented.

Dr. Katharine Tansley (Institute of Ophthalmology), speaking on human colour perception, briefly reviewed the accepted facts about rods and cones, and the evidence for and against the two principal theories of colour vision (the trichromatic and Hering's). In the face of the complex interconnexions of retinal ganglion cells, it is not reasonable to expect clear-cut sensitivity curves. Simultaneous contrast may arise, on the other hand, not through adjacent pigmentary synthesis and breakdown (Hering) but through adjacent nervous excitation and inhibition, for which these interconnexions are relevant. If such opponent mechanisms are present in each of three pigment systems, both theories stand to some degree confirmed. Discussion on all three papers in the morning session continued vigorously into the lunch-hour.

The final session, at which Sir Gerard Thornton, president of the Institute, took the chair, was centred around the psychology of colour. Dr. R. W. G. Hunt

(Kodak Research Laboratories), dealing with the acceptability of colour reproduction, started with the faults of even a purely optical image (flare, contrasting background, in telescope and camera obscura), and showed how they were added to in transparency-viewing and television by reduced luminance (and therefore colour-saturation) and subtense, before we even start to match colours. This again results in further loss of colour-saturation because the process-colour mixture stimulates more than one of the retinal receptor types. In general, acceptability depends on a scene's looking as it might have looked.

Miss Kathleen A. Battersby (studio director, British Colour Council) discussed, as an artist, colour in everyday life. She traced the evolution of the new technology and the parallel growth of dictionaries of colour standards it has exacted, covering hue (subjective counterpart of wave-length), tone (depth of colour), intensity (degree of brilliance), and texture (a range appropriate to different materials). Gay and beautiful colours are now available to the humblest; background and lighting studies show that it pays to beautify workplaces, a doctrine illustrated by a striking series of 'before-and-after' lantern slides.

Finally, Dr. H. Gwynne Vevers (Zoological Society of London) reviewed adornment in man and other animals. Among invertebrates camouflaged by debris, there is some evidence of systematic choice. Active adornment by transfer of coloured secretions is known in birds, though in mammals, living in an olfactory world, it is rare until man. The speaker discussed tattooing and analogous practices, body paints of plant (woad, henna) and mineral origin (ochres) and the evolution of cosmetics from ancient Egyptian 'kohl' through medieval lip-rouges to the phantasmagoria of current, mainly synthetic, products.

W. B. BROUGHTON

RIBOSOMAL AGGREGATE ENGAGED IN PROTEIN SYNTHESIS: CHARACTERIZATION OF THE ERGOSOME

By DR. F. O. WETTSTEIN, DR. T. STAEHELIN and DR. H. NOLL

Department of Microbiology, School of Medicine, University of Pittsburgh

RIBONUCLEOPROTEIN particles (ribosomes) are essential components in protein synthesis. In all cells so far examined, the basic ribosomal units are particles of uniform size characterized by a sedimentation constant of 70–85 *S* and composed of two relatively stable sub-units of unequal size corresponding to about 50 *S* and 30 *S*. Dimers of 100 *S* have been isolated from *E. coli*[1], higher aggregates with sedimentation constants of up to 155 *S* have been observed in preparations from mammalian cells[2-4]. Less is known about the functional unit that is fully active in protein synthesis. From studies with *E. coli* ribosomes, Tissières *et al.* have concluded that both 70 *S* and 100 *S* particles are active when combined with a messenger RNA containing the genetic information[5,6]. Similar conclusions were drawn from experiments with mammalian reticulocytes believed to be endowed with a more stable RNA template[7]. However, in all these experiments only a small fraction (approximately 5 per cent) of the ribosomes were shown to be active *in vitro* and hence the proposed relations between the physical state and biological activity are subject to considerable uncertainty. Further difficulties arise from spatial considerations: it is not easy to imagine how a messenger RNA molecule, large enough to direct the synthesis of a protein sub-unit, may be accommodated on the surface of a 100 *S* (70 *S*) particle in a configuration that remains accessible to a sequential line-up of aminoacyl transfer-RNA molecules. Some of these difficulties would seem to disappear if it were postulated that in the native state a small number of 70 *S* particles are combined with the messenger RNA (*m*RNA) to form a larger structural unit. We postulate that about five 70 *S* ribosomal particles, engaged in protein synthesis, form a precise geometric structure providing a unique spatial arrangement for the messenger RNA to display its active functional surface. The results of experiments with rat liver ribosomes reported here give support to this hypothesis.

In an attempt to correlate particle structure and amino-acid incorporation activity, ribosomes were prepared by different methods and the sedimentation pattern in a sucrose gradient compared with the results of incorporation studies. Homogenization was carried out in Hoagland's[8] medium *A* (0·05 M *tris*, 0·025 M potassium chloride, 0·005 M magnesium chloride, 0·25 M sucrose). Standard ribosomes ('*A* ribosomes') were prepared according to Korner[9] by addition of deoxycholate (DOC) to the post-mitochondrial supernatant and subsequent centrifugation at 105,000*g* for 120 min. Zone centrifugation analysis in a sucrose gradient containing Med. *A* salt buffer (0·05 M *tris* buffer, 0·025 M potassium chloride, 0·005 M magnesium chloride) showed that in such preparations most of the ribosomes were present in the 73 *S* and 113 *S* state, the relative proportions contained in these two peak positions being subject to considerable variations (Fig. 1*a*, *b*). Similar variations are found in published data obtained both with bacterial and mammalian ribosomes[2,4-6,10,11]. We found that these variations are mainly determined by the temperature at which the manipulations were carried out. In particular, lowering of the temperature settings of the ultracentrifuge during the preparative runs produced a pronounced shift of the distribution toward the heavier particles. When temperature conditions close to 0° C were maintained throughout the isolation procedures, more than 50 per cent of the ribosomes sedimented at a rate corresponding to more than 100 *S* (Fig. 1*c*).

In order to determine the biological significance of the heavier aggregates, the isolation procedure was modified. The post-mitochondrial supernatant fraction containing 1·3 per cent DOC was added as a 5-ml. top zone to 13-ml. centrifuge tubes. The tubes had been previously filled with 4 ml. of 0·5 M sucrose layered over 3 ml. of a more concentrated sucrose solution. In three sets of tubes the sucrose concentration of this bottom layer was adjusted to 1·0, 1·5 and 1·8 M respectively. All tubes were then centrifuged at 105,000*g* for 4 h. The transparent pellets were rinsed, dissolved in medium *A* salt buffer and the solutions clarified by low-speed centrifugation.

The results of analytical tests, summarized in Table 1, show that increasing the density of the bottom sucrose layer resulted in an efficient purification of the dense nucleoprotein particles by eliminating most of the protein impurities and other contaminants of lower density or molecular weight. Thus, in the tubes containing 1·5 and 1·8 M sucrose, the metallo-proteins remained as an intensely yellow band just below the interface of the bottom layer; the pellets were nearly colourless and dissolved quickly to give perfectly clear solutions. In contrast, the pellets formed in 1·0 M sucrose were yellow and, when re-suspended, always gave turbid solutions. Table 1 also shows the amino-acid incorporation activity of the three preparations, both with respect to original input and the RNA content of the recovered ribosomes. It may be seen that in all three preparations, the ribosomes

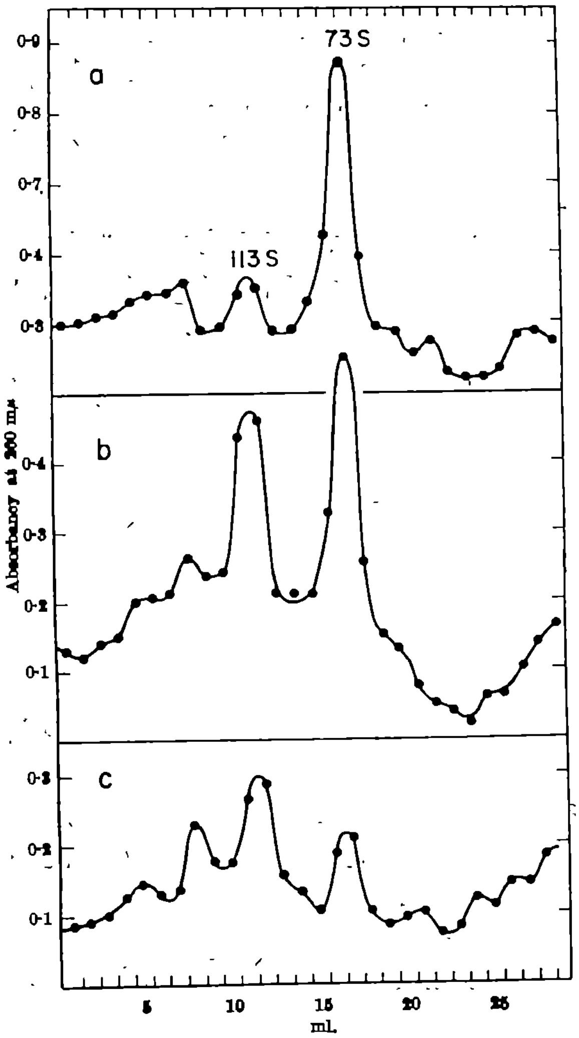

Fig. 1. Zone centrifugation analysis of different preparations of *A* ribosomes. 1-ml. samples were layered in form of an inverted gradient (12) over 27·5 ml. of a sucrose gradient (exponential 0·3–1·0 M) containing medium *A* salt-buffer (0·005 M Mg^{++}) and centrifuged in a Spinco *SW* 25 rotor for 4 h at 25,000 r.p.m. The bottom of the plastic tube was punctured with a hypodermic needle and 1·0 ml. fractions collected with a specially designed fraction collector

recovered from 1 g rat liver incorporated practically the same amount of ^{14}C-leucine into protein, whereas the recovery of RNA decreased from 1·85 to 1·16 mg/g liver as the density of the sucrose was raised. This suggested that the observed increase in specific activity resulted from the selective sedimentation of a heavy particle fraction responsible for biological activity. This conclusion is supported by the results of the sedimentation analysis shown in Fig. 2. From the observed change in particle size distribution it may be estimated that ribosomes with a sedimentation constant of less than about 200 *S* are considerably less active in protein synthesis than the heavier aggregates of the ribosome solutions. After incubation for 15 min at 37° C, most of the heavy aggregates had broken down into 113 *S* and 73 *S* particles, so that the sedimentation patterns of the three preparations became almost identical.

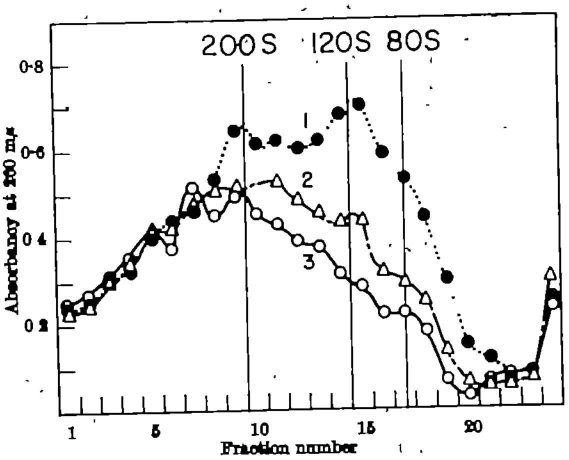

Fig. 2. Sedimentation patterns in a sucrose gradient of ribosomes purified by centrifugation through sucrose layers of different densities. Preparations 1, 2 and 3 were isolated as described in the text and 0·3 ml. samples, containing the ribosomes in form of an inverted gradient, layered over 4·4 ml. of a sucrose gradient (exponential 0·26–0·75 M). The tubes were centrifuged in a Spinco *SW* 39 rotor for 20 min at 39,000 r.p.m. and 4° C, and 24 × 0·20 ml. fractions collected as described in legend to Fig. 1

The physical nature of the active particles and the mechanism of dissociation during incubation were investigated in subsequent experiments. Ribosome preparations ('*C* ribosomes') containing more than 90 per cent of heavy particles ($S > 120$) were used. They were prepared by the procedure described here in which the sucrose concentration in the bottom layer of the preparative centrifuge tube was raised to 2·0 M. The purity of these preparations is reflected in their low protein content (weight ratio of protein/RNA $\leqslant$ 1) and their dependence on an external amino-acid supply for optimal protein synthesis (Fig. 3).

The structure of the heavy aggregates was studied by examining the size distribution of *C*-ribosomes after centrifugation in a 30-ml. sucrose gradient. For optimal resolution in the analysis of the sedimentation pattern, the fluid was collected by passage through a continuous-flow ultra-violet absorption cell attached to a strip chart

Table 1. CHEMICAL COMPOSITION AND AMINO-ACID INCORPORATION ACTIVITY OF RIBOSOMES ISOLATED BY ZONE CENTRIFUGATION THROUGH SUCROSE SOLUTIONS OF DIFFERENT DENSITIES

	Sucrose concentration in 3-ml. bottom layer (M)	Rat liver input, wet weight (g)*	Protein content of ribosomes recovered per 1·0 g liver (mg)†	RNA content of ribosomes recovered per 1·0 g liver (mg)‡	Approximate weight RNA/protein	^{14}C-leucine incorporated by ribosomes recovered per 1·0 g liver (c.p.m.)§	^{14}C-leucine incorporated per mg RNA (c.p.m.)
Preparation 1	1·0	12	3·04	1·85	0·6	7,600	4,150
2	1·5	12	1·10	1·42	1·3	7,400	5,150
3	1·8	12	0·77	1·16	1·5	7,200	6,200

*Homogenization was carried out after addition of 28 ml. medium *A* to 12 g rat liver. After sedimentation of the heavy cell elements, 20 ml. of the post-mitochondrial supernatant (ref. 8) were carefully removed with a syringe, avoiding contamination with sediment or lipid layer on top. In calculating the values shown in the table, only the recovered portion of the postmitochondrial supernatant per g liver was considered; this corresponds to 60–70 per cent of the actual yield.

†Assayed according to Lowry *et al.* (ref. 13) using crystalline bovine albumin as standard.

‡Estimated from the absorbancy at 260 mμ using the relation 20 absorbancy units = 1·0 mg RNA.

§Incorporation assays were carried out under standard conditions as described in the legend to Fig. 3. The ribosomes were prepared as described in the text and assayed after storage at −60° C. The incorporation tubes (total volume 1·0 ml.) contained the standard mixture described in the legend to Fig. 3 with the following additions: 0·2 ml. ribosomes equivalent to 0·6 g liver, appr. 4 mg. *p*H 5 enzyme protein (ref. 8), 0·1 μmoles each of 19 L-amino-acids excluding leucine and 0·04 μmole DL-leucine-1-^{14}C with a specific activity of 10·2 mc./mmole. The incubation time was 30 min.

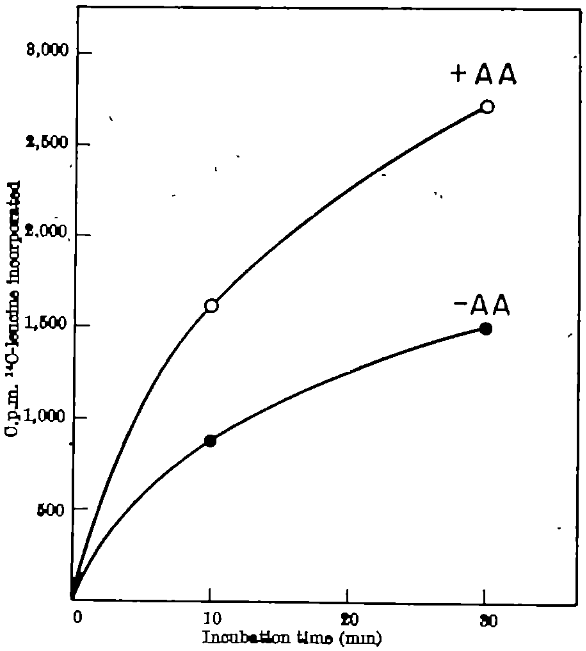

Fig. 3. Stimulation of amino-acid incorporation activity of *C* ribosomes by addition of amino-acid mixture. The standard incorporation mixture, adjusted to a final volume of 1·0 ml., contains the following reagents in μmoles: $MgCl_2$ (3·2), HCl–*tris* buffer *p*H 7·6 (30), β-mercaptoethanol (2·0), ATP (1·0), GTP (0·4), K-phosphoenolpyruvate (10), crystalline pyruvate kinase (0·01 mg). Ribosomes, soluble enzymes, radioactive leucine and non-radioactive amino-acid mixture are added as specified below. After incubation at 37°, the reaction mixture is stopped with 1 ml. 1 M sodium hydroxide. After standing at room temperature for 1 h, protein was precipitated by addition of 1 ml. 2·5 M perchloric acid containing 20 mg 'Hyflo Super-Cel'. (In the 0-time controls samples kept at 0° C are immediately subjected to this treatment.) The precipitate, collected on a filter disk, was washed successively with 0·5 M perchloric acid, propanol–ether (1 : 2) and propanol–ether–$CHCl_3$ (2 : 2 : 1) and dissolved in a hyamine (1 ml.)–toluene (15 ml.) scintillation mixture (ref. 14) for radioassay in a Packard 'Tri-Carb' liquid scintillation spectrometer, model 314 X. Maximal deviation between duplicate samples above 100 c.p.m. is < 10 per cent above 1,000 c.p.m. < 5 per cent of the mean. Counting efficiency is approximately 50 per cent. Zero time controls usually give about 50 c.p.m.
The assays represented in the graph contained the following additions. 0·04 μmoles DL-leucine-1-^{14}C (10·2 mc./mmoles), ribosomes equivalent to 0·6 g liver (corresponding to about 0·5 mg RNA) and postmicrosomal supernatant equivalent to 0·06 g liver. The postmicrosomal supernatant was prepared by centrifugation of the postmitochondrial supernatant at 105,000*g* for 2 h. and subsequent dialysis at 0° C for 24 h against a 60-fold volume of medium *A* salt buffer containing β-mercaptoethanol (0·005 M). A mixture of 19 L-amino-acids (0·1 μmoles each) excluding leucine was added only to the series represented by the upper curve

recorder. A constant flow rate was maintained with a precision pump. A typical recording, reproduced in Fig. 4*a*, shows a sequence of 7 peaks, spaced at decreasing intervals, ranging in position from about 70 to 240 *S*. The seventh peak is barely resolved from a large proportion of heavier material that appears polydisperse, presumably because the close spacings of the bands in this region prevents further resolution under these conditions.

Incubation of *C*-ribosomes at 37° C in medium *A* salt buffer solution causes some breakdown of the heavy aggregates resulting in a corresponding increase of the absorbancy in the satellite peaks (Fig. 4*b*). No optically detectable quantities of low molecular weight material absorbing in this region were released under these conditions. Addition of minute quantities of crystalline pancreatic ribonuclease, corresponding to a final concentration of 1·2 × 10^{-8} g/ml., greatly accelerates this breakdown process with the result that most of the particles are now obtained in the 73 *S* and 113 *S* state (Fig. 4*c*). Under these conditions, an increase of the absorbancy at 255 mμ, equivalent to about 3 per cent of the total input, was sometimes observed in the top layer of the gradient. The nature of this material and the mechanism of its release are now under investigation.

The regular spacing of the satellite peaks and the RNase-induced breakdown into 70–113 *S* particles indicates that the higher aggregates represent oligomers of the 73 *S* particles.

For molecules of similar shape and density, the sedimentation constant *S* is related to the particle weight *m* by the equation:

$$S^{3/2} = km$$

in which *k* is a constant. When the experimentally determined $S^{3/2}$ values corresponding to the satellite peaks were plotted against the relative particle weights, taken to be multiples of the 73 *S* mass, a straight line was obtained (Fig. 5). This suggests that the 73 *S* particles are assembled into larger aggregates of compact structure and similar shape so that transitions from one aggregate form to another will not result in drastic shape changes.

More precise information concerning the size of the active particle was gained from incorporation studies with isolated fractions taken directly from sucrose gradient tubes. *C* ribosomes were centrifuged in the 30-ml. swinging bucket rotor and 1·0-ml. fractions collected.

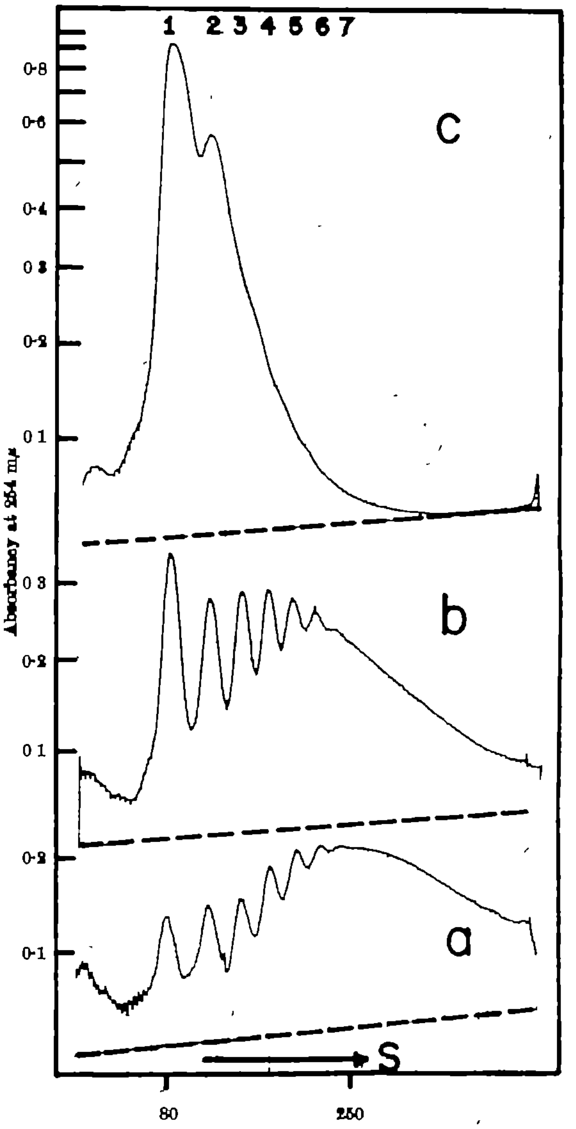

Fig. 4. Effect of RNase on particle size of *C* ribosomes. (*a*) *C* ribosomes (0·5 mg RNA) were suspended in medium *A* salt buffer and centrifuged in a sucrose gradient for 2 h at 25,000 r.p.m. as described under Fig. 1. The absorbancy of the effluent was scanned in a flow cell and recorded automatically. The pellet at the bottom of the tube contained 20 per cent of the input absorbancy. (*b*) *C* ribosomes (0·5 mg RNA) were incubated in 1·0 ml. of medium *A* salt buffer at 37° C for 5 min. and analysed as above. The pellet contained 4 per cent of the input absorbancy. (*c*) *C* ribosomes were treated as in (*b*), except that the incubation medium (1·0 ml.) contained 0·012 μg 5x-crystallized pancreatic ribonuclease. No pellet was observed. In all three samples the absorbancy near the top may be attributed to the presence of β-mercaptoethanol, added to the ribosome solutions before storage

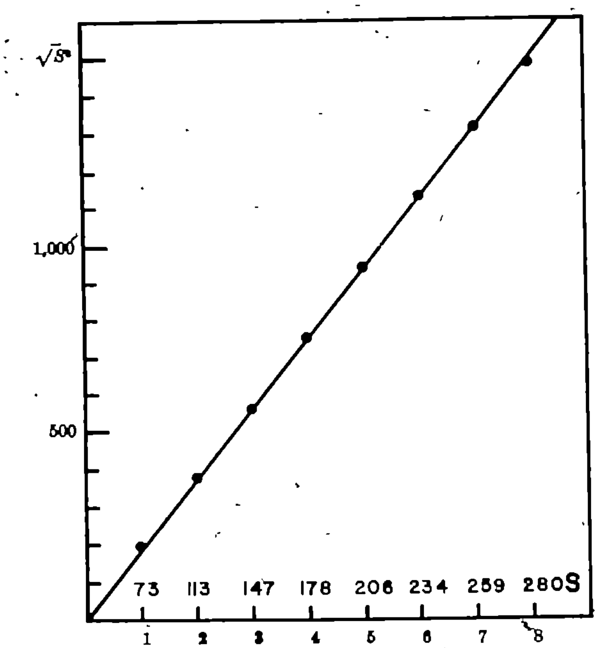

Fig. 5. Relationship between sedimentation rate and particle mass of satellite peaks. The sedimentation constants were estimated by comparison of the peak positions with an experimental reference curve obtained by calibration of the sucrose gradient with the monomeric particle as standard. The numerical S values were computed on the basis of 73 S for the monomer, representing an average of published values

Aliquots were removed to determine the absorbancy distribution pattern (Fig. 6*a*). Every three consecutive 1·0-ml. fractions were then pooled in ascending order, so as to give 8 cuts (pool fractions 1–8) covering the range of particle sizes from about 50–500 S. The ribosomes of each pool fraction were then sedimented into a pellet and redissolved in medium A salt buffer. The pellet from the original sucrose gradient was included in this series. In order to check whether the physical state of the resuspended particles had changed during the concentration procedures preceding the incorporation assay, aliquots were removed from the concentrated pool fractions 2, 4 and 7 and subjected separately to zone centrifugation analysis in a sucrose gradient. The resulting patterns are shown in Fig. 6*b*, *c* and *d*. The amino-acid incorporation activity of each pool fraction was measured, using duplicate samples and different ribosome concentrations ranging from 0·15 to 0·60 mg RNA per 1-ml. incorporation mixture. An excess of rat liver supernatant was present in all incorporation tubes, so that the amount of protein formed was always proportional to the concentration of the ribosomes in the incubation mixtures. All samples were treated with alkali to remove radioactivity bound to transfer RNA.

In Fig. 6*a*, the specific incorporation activity (c.p.m. ^{14}C-leucine incorporated/0·15 mg RNA) has been plotted against the effluent volume corresponding to the various pool fractions. The range of particle sizes contained in these fractions is indicated on the abscissa. The recording of a calibration run is included for comparison. It is evident from the curve in Fig. 6*a* that the specific activity increases with aggregate size over a range corresponding to 100–250 S, reaching a constant level for particles sedimenting between about 250–600 S. This range included 80–90 per cent of the total C ribosome population, including the particles obtained from the pellet of the original gradient. The results show clearly that the 73 S monomers are inactive. Partial activity is perhaps associated with the dimers $(73\ S)_2$, certainly with the trimers $(73\ S)_3$; it continues to rise rapidly through the following two stages and then becomes constant. It is difficult, however, to pinpoint the state of aggregation at which full activity is reached. The data shown in Fig. 6 suggest the pentamers $(73\ S)_5$ as lower and the heptamers $(73\ S)_7$ as upper limit.

Of particular interest is the redistribution of particle sizes observed after concentration and recentrifugation of the three samples taken from different regions of the original gradient (Fig. 6*b*-*d*). Although in each case a main distribution peak is centred near the position of the parent fraction in the original gradient, a large proportion of the input has been dispersed into both heavier and lighter fractions. It should be noted that the resulting spectrum of particle sizes is not continuous but contains several peaks in the seemingly polydisperse region (250–500 S). The apparent periodicity of the heavier peaks may reflect unspecific aggregation of the most frequent and/or stable particle size contained in the parent fraction, for example, $(73\ S)_5$ in Fig. 6*c*.

The foregoing experiments have shown that: (1) fully active ribosomes exist in the form of aggregates consisting

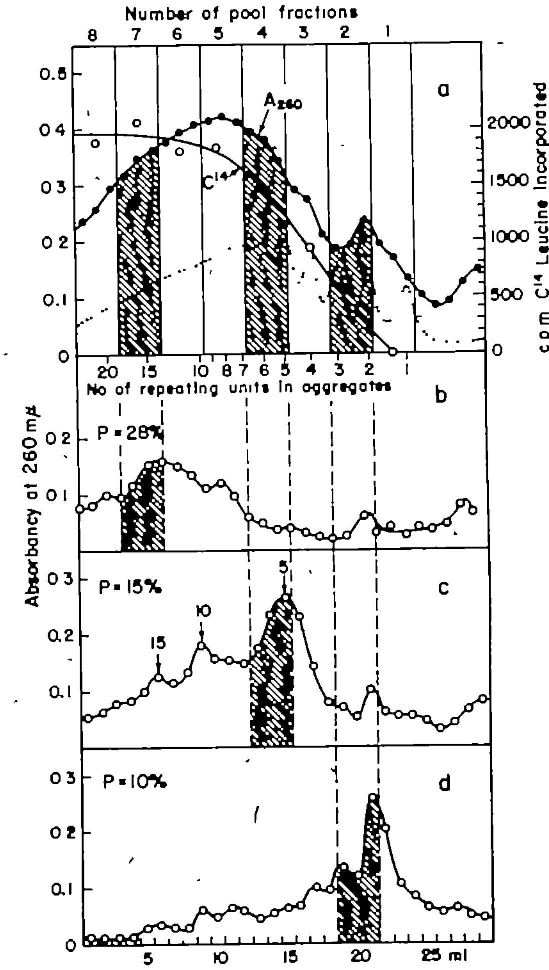

Fig. 6. Amino-acid incorporation activity of C ribosomes as a function of particle weight. (*a*) C ribosomes (4 mg RNA input per tube, three tubes per run) were fractionated in a sucrose gradient as described under Fig. 4. The resulting sedimentation pattern, measured spectrophotometrically, is shown in the curve marked $A260$. The pellets contained 40 per cent of the input. The fractions were pooled as indicated in the graph (pool fractions 1–8), the particles spun down and the pellets from each pool resuspended in 1·1 ml. medium A salt buffer. Aliquots from these concentrates, containing 0·15–0·60 mg RNA, were used for incorporation assays. The incorporation mixtures contained 0·02 μmoles L-leucine-1-^{14}C (25 mc./m.mole) and non-dialysed post-microsomal supernatant equivalent to 0·12 g liver. Addition of 19 L-amino-acids was omitted. The incubation time was 30 min, all other conditions as described under Fig. 3. The specific activity, expressed as alkali stable, acid-insoluble radioactivity incorporated per 0·15 mg RNA has been plotted against the corresponding pool fraction (curve marked ^{14}C). The specific activity of the pooled pellets from the original gradient tubes was 1,900 c.p.m./0·15 mg RNA. The dotted curve represents the sedimentation patterns of a similar run determined by the continuous recording method. The abscissa is calibrated in multiples of the 73 S sub-unit on basis of the data in Fig. 5. (*b*–*d*) Sedimentation patterns obtained with aliquots from pool fractions 2, 4 and 7. P indicates the percentage values of the total input recovered in the pellets

of at least 5–7 73 *S* particles held together by an RNase sensitive structure; (2) during incubation of *C* ribosomes at 37° C, a slow degradation of heavy aggregates into smaller particles is taking place, apparently because the preparations are still contaminated with traces of RNase; (3) the amino-acid incorporation activity of a given ribosome preparation is directly related to the proportion of heavy aggregates present in the population. Viewed together, these results suggested another approach for determining the size of the basic unit of protein synthesis. Thus, it was to be expected that the amino-acid incorporation, measured after various periods of pre-incubation, should be proportional to the surviving fraction of active particles, namely, those aggregates which are equal to or larger than the critical size required for full biological activity. In an experimental test of this relationship, *C* ribosomes were incubated at 37° C in medium *A* salt buffer for 0, 5, 10 and 30 min. At the end of incubation aliquots were removed for determination of the particle size distribution in a sucrose gradient, and the remaining samples incubated for an additional 30-min period in the presence of the complete amino-acid incorporation mixture.

From sedimentation diagrams similar to those shown in Fig. 4, the relative decrease in the population of heavy aggregates, observed after various preincubation periods, was computed for several cut-off points covering the critical range from $\geqslant (73\ S)_4$ to $\geqslant (73\ S)_7$. These values are listed in Table 2 together with the relative decrease of the ^{14}C-leucine incorporation. It is evident that the breakdown rate of the aggregate populations defined by the cut-off points $\geqslant (73\ S)_5$ and $\geqslant (73\ S)_6$ roughly parallels the rate at which the incorporation yield is reduced. Some marked deviations, however, are noted. Thus, the rate at which the incorporation yield decreases is rapid at the beginning, then levels off between 10 and 30 min, whereas the breakdown rate of heavy particles lags behind at first and continues with little change after the decrease in incorporation yield has nearly ceased. The initial lag of aggregate breakdown is especially pronounced for populations $\geqslant (73\ S)_4$–$(73\ S)_6$. Apparently, the rate of reduction in the amount of protein synthesized after various intervals of preincubation reflects the rate at which the trace of RNase originally present in the preparation is inactivated.

Table 2. EFFECT OF PREINCUBATION ON AGGREGATE SIZE AND AMINO-ACID INCORPORATION ACTIVITY OF *C* RIBOSOMES

Pre-incubation time (min)	Amount of ^{14}C-leucine incorporated into protein: C.p.m.	Amount of ^{14}C-leucine incorporated into protein: Decrease (per cent)	Decrease in fraction of particles with aggregate size *n* (per cent), *n* = $(73\ S)_4$	$(73\ S)_5$	$(73\ S)_6$	$(73\ S)_7$
0	5,110	0	0	0	0	0
5	4,140	19	5·5	6·5	8·5	14
10	3,680	28	10	12	16	23
30	3,210	37	27	32·5	39	48

A concentrated solution of *C* ribosomes (1·75 mg RNA/ml.) in medium *A* salt buffer containing β-mercaptoethanol (0·005 M) was preincubated at 37° C and aliquots removed, at the time-intervals indicated in the table, for sedimentation analysis in a sucrose gradient (0·6 ml.) and for amino-acid incorporation (0·2 ml.). The incorporation mixtures contained 0·02 μmoles L-leucine-1-^{14}C (25 mc./mmole) and dialysed postmicrosomal supernatant equivalent to 0·18 g liver. The incubation time was 30 min, all other conditions as described under Fig. 3. The particle size distribution was computed from the appropriate integrated areas in the automatically recorded sedimentation patterns.

The apparent delay in the shift of the particle size distribution, on the other hand, may be due to an unspecific attachment to the heavy aggregates of the small, biologically relatively inactive, particles formed in the beginning of the incubation period. This interpretation is favoured by the results of the previous experiment shown in Fig. 6. On the basis of this interpretation, we conclude from these results that the size of the basic active particle is either $(73\ S)_5$ or $(73\ S)_6$. An unambiguous decision that the basic unit is the pentamer $(73\ S)_5$ was possible by a more direct method, the details of which will be reported elsewhere. In these experiments the specific activity of the nascent protein, expressed as ^{14}C-leucine incorporated per mg ribosomal RNA, was determined as a function of particle size after short incubation pulses followed by fractionation in a sucrose gradient. It was found that the specific activity increased through the satellite peaks, reaching a maximum in the peak corresponding to the pentamers; it declined somewhat in the peak containing the hexamers and increased again to the original level near the position of the decamers, remaining nearly constant throughout the region of the heavier aggregates.

Discussion

In this article we have described a novel ribosomal particle which appears to be the functional unit of protein synthesis and which we therefore propose to call 'ergosome'. In the following we have made an attempt to combine our observations into a model of the ergosome. Although this model contains many speculative features, we believe it nevertheless to be useful, both as a working hypothesis and a basis for discussion.

We visualize the ergosome as a roughly spherical or doughnut-shaped particle with a sedimentation constant of about 200 *S* corresponding to a molecular weight of about 20 million. It is composed of five 73 *S* particles whose 30 *S* sub-units, oriented toward the centre of the aggregate, are adjacent to each other. The five 73 *S* monomers are held together by one messenger-RNA (*m*RNA) molecule which may be pictured as running through the groove between the 30 *S* and 50 *S* sub-units. The spaces between the 73 *S* monomers expose single stranded regions which are extremely sensitive to enzymatic cleavage. Single breaks in these regions result in a stepwise fragmentation of the ergosome into smaller oligomers with a final liberation of free 73 *S* particles.

The rapid fragmentation of the ergosome by RNase indicates that Mg^{++} ions are not primarily responsible for its structural integrity. This also applies to the larger aggregates which we regard as resulting from an unspecific aggregation of ergosomes with each other and with their smaller breakdown products. For gradual removal of Mg^{++} does not result in a significant shift to smaller aggregate sizes. However, when the Mg^{++} concentration is reduced to less than 10^{-3} M, 50 *S* and 30 *S* particles appear in addition to the entire spectrum of heavy aggregates, indicating that Mg^{++} ions are specifically required only for the integrity of the 73 *S* particle as first demonstrated by Tissières and Watson[1]. Rapid removal of Mg^{++} by addition of ethylenediamine tetraacetic acid causes immediate dissociation of the entire aggregate population into 50 *S* and 30 *S* sub-units.

More detailed information concerning the attachment of *m*RNA to the ribosomal sub-units and its structural relationship to the growing peptide chain has been obtained from studies on the mechanism of breakdown at low Mg^{++} concentrations of ergosomes containing labelled *m*RNA and nascent protein. A preliminary account of such studies has been presented previously[15], a more detailed report will be given in a forthcoming paper. On the basis of these results we may further elaborate our hypothetical model: The stretches of *m*RNA that we have pictured as being embedded in the groove between the two sub-units of the 73 *S* particle are attached to the 30 *S* sub-units. During protein synthesis the information of the *m*RNA is read by transfer RNA molecules moving successively through this groove. The end of the growing peptide chain is in contact with the 50 *S* sub-unit lining the groove along the side opposing the 30 *S* particle. The 50 *S* face of the groove may also play an important part as surface for the attachment of the enzymes participating in the amino-acid polymerization. Near the end of the growing peptide chain, the gap between the two sub-units of the 73 *S* particle is thus bridged by one or several transfer RNA molecules, resulting in an increased stability of the particles containing the nascent protein against dissociation at low Mg^{++} concentrations. Such an effect has indeed been observed with *E. coli* ribosomes by Tissières *et al.*[5] and with rat liver ribosomes in our own experiments[15,16]. In addition, this picture would explain the observation that on complete dissociation of the 73 *S* particles, brought about by further reduction of the Mg^{++} concentration, most of the nascent protein moves with the heavy shoulder of the 50 *S* peak in a sucrose gradient, whereas the rapidly labelled *m*RNA coincides with the 30 *S* peak[4,15]. Our model also predicts that under these conditions of dissociation the transfer RNA molecule at the growing end of the peptide chain should remain attached to the 50 *S* particle carrying the nascent protein, since it is linked to the carboxy group of the terminal amino-acid through a covalent bond. This interpretation is supported by findings of Elson[17].

In our hypothetical model of the ergosome, the functional unit of protein synthesis is represented as a structure of uniform size consisting of five 73 *S* particles held together by one *m*RNA molecule, which is assumed to direct the synthesis of one protein sub-unit. Such a model seems to conflict with the apparent heterogeneity with respect to the size of the protein sub-units and their messengers that have been encountered[18]. This difficulty may be overcome by postulating that ergosomes of constant size, for example, the pentamer $(73\ S)_5$ considered in our model, may contain either one large or several smaller molecules of *m*RNA, depending on the size of the protein sub-unit to be synthesized. Alternatively, the ergosomes themselves may vary in size according to the size of their messenger. A decision between these two possibilities would require information about the size of the protein molecule synthesized by our smallest fully active unit $(73\ S)_5$. From the specific activity incorporated in our experiments after a 30-min incubation period we obtain a molecular weight of about 20,000, corresponding to the addition of 30 amino-acids per 73 *S* particle (mol. wt. 4×10^6). This calculation assumes that the ergosome fraction accounts for all of the activity and represents 66 per cent of the total ribosomal population present in our incubation mixtures. Since in our incorporation system about 80 per cent of the nascent protein remains attached to the ribosomes, we must further assume that at the beginning of the incubation the ribosomes are on the average half-filled with non-radioactive peptides. Hence, each ergosome would be capable of synthesizing one protein molecule corresponding to a molecular weight of at least 40,000. This value is probably still too low, since no correction has been made for the breakdown of active aggregates taking place during incubation. It is reasonable to assume, therefore, that an ergosome of the postulated size would be capable of synthesizing protein molecules of molecular weights as large as 50,000–100,000. If we assume a coding ratio of 3 (ref. 19), the ergosome would be large enough to accommodate a messenger of approximately 500,000 molecular weight, which is well within the range of values suggested in the literature[6,18].

If, on the other hand, the ergosome is engaged in the synthesis of several identical protein sub-units, our model further predicts that for structural reasons the sizes of these sub-units and their corresponding messengers would have to follow the series *M*/1, *M*/2, *M*/3, etc., in which *M* represents the largest polymer size that can be accommodated by the active aggregate. Again, it would seem that the different sedimentation constants reported for isolated *m*RNA are not incompatible with this interpretation, although some of these preparations may have been considerably contaminated by breakdown products resulting from RNase action[5,6,11,20–27].

Of particular interest is our finding that aggregates that are smaller than the ergosome exhibit partial activity when their incorporation yield is computed per particle mass. Since these smaller aggregates have been shown to represent breakdown products of the ergosome, we assume that they contain only a fragment of the original template. Consequently, we would conclude that only those of the smaller aggregates would be active that carry unfinished peptide chains attached to a partially filled fragment of the template. This interpretation is in harmony with other evidence indicating that peptide synthesis must proceed in one direction from a fixed starting-point on the template[19]. It is likely that the ribosome preparations described in the literature consist largely of such breakdown products. This interpretation would explain both the small proportion and more rapid sedimentation of the so-called 'active' particles[6]. An indication of the biological significance of ribosomal aggregates may be found in the observations of Arnstein with rabbit reticulocyte ribosomes[3] and, most recently, in studies with bacterial ribosomes and synthetic messengers, published after this work had been concluded[28,29].

In conclusion, we wish to emphasize that the model which we propose is tentative. We are aware that it presents a number of difficulties which could not be discussed within this limited space. It is our hope that they will be resolved by further experiments which are now in progress.

We thank Dr. G. Attardi for kindly giving us a copy of his manuscript before publication. This work was supported by grant *IN58B* from the American Cancer Society Institutional Research Grant Committee and by research grants *E*–1500 and *E*–4303 from the U.S. Public Health Service. In addition, one of us (F. O. W.) was supported by training grant 2*E*–80 and another (H. N.) by senior research fellowship *SF*–274 from the U.S. Public Health Service.

Note added in proof. After this manuscript went to press (December 12, 1962), the general structure of the ergosome proposed here has been confirmed by electron-micrographs of ribonucleoprotein particles from rabbit reticulocytes (Warner *et al.*, *Science*, 138, 1399 ; 1962).

NEWS and VIEWS

Instruments and Electrical Engineering at the Royal Aircraft Establishment : Mr. W. J. Charnley

MR. W. J. CHARNLEY, who was recently promoted to deputy chief scientific officer, has been appointed head of Instruments and Electrical Engineering Department, the Royal Aircraft Establishment, Farnborough. Mr. Charnley graduated in civil engineering at the University of London, qualifying with honours, B.Eng. in 1940. In 1943 he joined the Aerodynamics Department of the Royal Aircraft Establishment, Farnborough, and after a brief period in the Low-Speed Wind Tunnel Division was moved to the Flight Division, where he was engaged on all aspects of aerodynamic research in flight on high-speed aircraft. In 1953 he was placed in charge of the High-Speed Section of the Department. He was transferred in 1955 to the Blind Landing Experimental Unit at Martlesham Heath as superintendent. This Unit is the department of the Royal Aircraft Establishment responsible for research and development of systems to enable aircraft to land in bad weather, and Mr. Charnley was directly concerned with the successful development of the Blind Landing Experimental Unit system of automatic landing. Mr. Charnley was awarded M.Eng. in 1945, and in 1949 became an Associate Fellow of the Royal Aeronautical Society. He was awarded the Bronze Medal of the Institution of Navigation in 1959 for a paper on blind landing. Mr. Charnley recently completed the 1962 course at the Imperial Defence College.

Military and Civil Systems Department, the Radar Research Establishment: Dr. E. V. D. Glazier

DR. E. V. D. GLAZIER, chief scientific officer, has been appointed head of Military and Civil Systems Department of the Radar Research Establishment. Dr. Glazier gained both his B.Sc. and Ph.D. degrees in electrical engineering at the University of London. His early training was in general electrical and mechanical engineering in industry followed by appointments in the engineer-in-chief's office of the General Post Office, where he was engaged on the development of telephone systems and defence communications. In 1942 Dr. Glazier was transferred, under war-time arrangements, to the Signals Research and Development Establishment, where he was responsible for the development of a wide range of signals equipment for the Army. After a short period in Headquarters at the end of the War, he was appointed as head of the Line and Acoustic Group at the Signals Research and Development Establishment, and in 1952 promoted to lead the Research Division of that Establishment, where he was responsible for research into a number of problems in Army radio and electronics. In 1957 he returned to Headquarters of the Ministry of Aviation as director of scientific research (electronics and guided weapons), where he was responsible for advising in research programmes and organizing the early Ministry of Aviation programme for satellite observations. During this period he was secretary of the Radar and Signals Board of the Scientific Advisory Council. In 1959 Dr. Glazier transferred to the Radar Research Establishment as head of the Ground Radar Department, where he was responsible for the development of ground radar and data handling equipment and for collaboration with the French Air Ministry on the development of radar systems. In 1962 he was transferred to head of Airborne Radar Department. He is at present a member of the Institution of Electrical Engineers' Electronics Divisional Board.

The Harrison Memorial Prize, 1962 : Dr. A. Carrington

DR. ALAN CARRINGTON has been awarded the Harrison Memorial Prize of the Chemical Society for 1962 in consideration of his contribution to the study of theoretical chemistry, especially his work on electron spin resonance. Dr. Carrington is a graduate of the University of Southampton. He obtained the B.Sc. degree in 1955 and has since undertaken postgraduate research at the Universities of Southampton, Minnesota and Cambridge, where he now holds a research fellowship at Downing College. The Harrison Memorial Prize is awarded for outstanding merit in any branch of pure or applied chemistry. It was created in 1922 to commemorate the services of the late Colonel Edward Frank Harrison, formerly deputy controller of the Chemical Warfare Department, for the protection of the British Forces from poison gas in the First World War. It is awarded to the British chemist, under thirty years of age, who, in the opinion of the Selection Committee, has during the previous five years conducted the most meritorious and promising original investigations in chemistry and published the results.

Ninetieth Birthday of Prof. Hans K. A. S. von Euler

PROF. HANS K. A. S. VON EULER, one of the pioneers of modern biochemistry, in particular enzymology, celebrates his ninetieth birthday in Stockholm on February 15. He was born in Augsberg, Bavaria, to a German aristocratic family. Although at first he had intended to be a painter, he went to Sweden as a young graduate to study under the great physicochemist Svante Arrhenius, and thus began his scientific career. In 1909 he became professor of general and organic chemistry at the Stockholm Royal University and founded the well-known Biochemical Institute there. Dominant among the research carried out there on enzyme chemistry was alcoholic fermentation, for which Euler received the 1929 Nobel Prize for Chemistry together with A. Harden. The immense amount of work carried out in the enzymological field by Euler is crowned by his great "Chemistry of Enzymes" (*Allgemeine Chemie der Enzyme*, 1910–34), the first modern monograph on this field. On one hand, the research of the codehydrase I joins Euler's enzymological work with his numerous studies on the biochemistry of vitamins, and, on the other hand, with his later studies of the biochemistry of tumours. Concerning the latter, he especially undertook investigations of the turnover of nucleic acids in tumours by means of labelled compounds—a technique which he had initiated together with G. v. Hevesy. Von Euler's work dealing with tumour research includes two important monographs, the "Biochemistry of Tumours" (*Biochemie der Tumoren*, 1942) and the "Chemotherapy and Prophylaxis of Cancer" (*Chemotherapie und Prophylaxe des Krebses*, 1962). Von Euler retired from teaching in 1941 but continued to carry out research work at the Stockholm Institute. He has been responsible for inspiring and teaching a great number of scientists now working in the field of biochemistry in all parts of the world. All have found him a careful teacher, an excellent example and a fatherly friend.

The Institution of Chemical Engineers : Committee in Ireland

THE Institution of Chemical Engineers has established a Committee in Ireland, constituted as follows: *Chairman*, Prof. J. P. O'Donnell, University College, Dublin; *Honorary Secretary/Treasurer*, Mr. J. Kelleher, Shamrock Fertilizers, Wicklow; *Assistant Honorary Secretary*, Mr. R. K. Sinnott, Du Pont (U.K.) Ltd., Londonderry; Mr. E. V. Casburn, Seaweed Ltd., Galway; Dr. F. L. Kafka, Du Pont (U.K.) Ltd., Londonderry; Mr. I. McCallum, Irish Refining Co. Ltd., Whitegate, Co. Cork; Mr. P. H. Whitaker, Chemstrand Ltd., Coleraine, Co. Derry; Mr. W. A. D. Windham, Arthur Guinness Son and Co. Ltd., Dublin. The objects of the Committee are "(*a*) to promote an interest in chemical engineering in Ireland, including interest in the schools; (*b*) to bring chemical engineers together for discussions on matters of technical interest; (*c*) to provide a representative opinion of chemical engineers in Ireland". Further information can be obtained from: Mr. J. Kelleher, "Fernhurst", Hillside Road, Greystones, Co. Wicklow, or the General Secretary, the Institution of Chemical Engineers, 16 Belgrave Square, London, S.W.1.

Science and the Public Mind

A MEMORANDUM by W. Schramm, *Science and the Public Mind*, based on various studies in the United States of public knowledge of science and scientists, supports the view that knowledge of science is widely, but not deeply, distributed in the United States (American Association for the Advancement of Science. Miscellaneous Publication No. 62–3: *Science and the Public Mind: A Memorandum for B. G. Sherburne, Jr., from Wilbur Schramm*. Pp. 20. Washington, D.C.: American Association for the Advancement of Science, 1962). There are still large areas of ignorance and an individual's education is the chief predictor of his knowledge of science, followed by use of mass media; after leaving school, mass media supply most of the increment in knowledge. Where such information is sought depends largely on the topic and on the characteristics of the individual. The more personalized and/or sensational is a scientific article the larger is its audience, and mass media tend to use these techniques in reporting science and to select material that can be so treated. It is to be regretted that they do not apply to material for entertainment the same standards of scientific accuracy that they apply to advice and reporting. Public attitudes towards science and scientists are generally favourable, although not very accurately informed. The public is interested in getting more scientific information, but the acquisition of new scientific information does not necessarily result in a logical chain of belief, attitude and behaviour. Besides noting some negative indicators as to what information on science should be provided for the public, Mr. Schramm suggests ways in which scientists themselves can help, for example, by paying closer attention to school curricula in science and to the level of science teaching, contributing to the training of science writers, facilitating the dissemination of information about their work and encouraging the study of the processes by which scientific knowledge is conveyed and applied.

Incomes Policy and the Professional Employee in Britain

IN a pamphlet, *Incomes Policy and the Professional Employee*, issued by the National Union of Teachers, Mr. M. Shanks, reviewing critically the Government's attempt to operate an incomes policy, suggests that the National Incomes Commission should be made a representative body (Pp. 15. London: National Union of Teachers, 1962). He argues that the National Economic Development Council is the most logical agent to formulate an incomes policy, and that under such a policy the salaries of professional employees would be determined by assessing the nation's need for such services and a formula designed to keep these salaries in a proper relation to industrial wages. This relation needs first of all to be agreed, and Mr. Shanks refers to the belief that in Western democracies there is a built-in distortion in favour of the private sector as against the public sector.

The British Hat and Allied Feltmakers Research Association

THE fifteenth annual report of the Director of Research of the British Hat and Allied Feltmakers Research Association, covering the year ended August 1962, refers to a survey of the storage cellars of members which established the general pattern of bacterial infection and showed a highly significant relation between the degree of infection and the season of delivery (Pp. 22. Droylsden, Manchester: British Hat and Allied Feltmakers Research Association, 1962). This programme limited progress on the carrotting of fur, but the Blankenburg and Zahn method of assessing the felting ability of wool was examined. Work continued on dyeing felt with acid milling dyes for fully-planked fur felt and half-planked wool felt and a study was made of the incidence of gas-fume fading of dyed fur and wool felts, while the problem of hat sizes has been further investigated and the geometrical properties of hatters' ovals have been summarized in a technical report. Factors likely to influence the development of static electricity in the forming machines were examined, and anomalous results of the coefficients of friction of felt have been attributed to contamination of the contact services with grease, while the programme comparing other possible materials with felt as padding in protective headgear was completed. A list of publications is appended.

Trade Associations and Professional Bodies of the United Kingdom

THE directory *Trade Associations and Professional Bodies of the United Kingdom*, compiled by Patricia Millard, is designed to provide a ready means of finding the address and telephone number of any nationally important trade, professional or technical association in the United Kingdom and of identifying the associations with any specific field of activity. With few exceptions, only national organizations are included, but trade unions, livery companies and chambers of commerce are excluded. The directory is in two parts: an alphabetical directory and a classified index with cross-headings (Pp. viii+128. London: C.B.D. Research, Ltd., 24 Holborn Viaduct, 1962. 30*s*.).

A Bibliography of Personnel Management

A BIBLIOGRAPHY recently published by the Institute of Personnel Management replaces that published by the Institute in 1950 and its subsequent supplements (*Personnel Management: a Bibliography*. Pp. 39. London: Institute of Personnel Management, 1962. 7*s*. 6*d*.). The books have been selected as helpful to the personnel manager who wishes to broaden his knowledge of the background of his job, and those included in the Institute's examination book list for students are marked. The books are arranged in eleven sections, the last dealing with sources of information, and the selection appears to be well-balanced and representative within the broad headings.

Dogs and Stilboestrol

DOGS (18 female, 4 male) were given subcutaneous injections of diethylstilboestrol at intervals of 4–6 weeks by Dr. Anne G. Jabara, of the Department of Pathology, University of Melbourne, and developed alopecia after 11 months (*Austral. J. Exp. Biol.*, 40; 1962). All areas except the head and distal parts of the legs were affected and the denuded skin became dry, scaly and excoriated. Microscopic changes were observed in all elements of the skin, and the hair follicles were atrophic. The hair grew again 3–7 months after injections were stopped, and at necropsy 11–14·5 months later the skin was histologically normal. Other findings included testicular atrophy, a high incidence of inguinal hernia, and endometrial hyperplasia which progressed to a cystic stage and eventually to pyometra. When injections were stopped, the endometrium regenerated after an interval the duration of which was independent of the duration of treatment or of total dose administered, but may have been related to the time taken to deplete the residual depot. Treated dogs also showed an increase of pituitary acidophils and a reduction in basophils and chromophobes; these changes were reversed on hormone withdrawal. Generalized or focal atrophy of the pancreas occurred in four of the longer surviving dogs; this was regarded as a toxic effect of stilbœstrol.

The American Society of Pharmacognosy

THE following have been elected officers of the American Society of Pharmacognosy: *President*, Dr. Gordon H. Svoboda, Eli Lilly and Co.; *Vice-President*, Dr. Melvin R. Gibson, professor of pharmacognosy, Washington State University. Dr. Varro E. Tyler, jun., professor of pharmacognosy, University of Washington, was elected to the Executive Committee. The Society's secretary and treasurer are elected for three years; neither term expires in 1963. Mr. Rolf Westby of Eli Lilly and Co. is secretary, and Dr. Frank A. Crane of the University of Illinois is treasurer.

The Iron and Steel Institute: Indian Elections and Awards

THE following elections and awards have been announced in connexion with the Iron and Steel Institute's special meeting in India during January 21–February 12 (see *Nature*, 196, 816; 1962): *Honorary Members*, Sir Jehangir J. Ghandy, director-in-charge, the Tata Iron and Steel Co., Ltd.; Sir Biren Mookerjee, chairman, the Indian Iron and Steel Co., Ltd., and governing director, Martin Burn, Ltd.; Mr. J. R. D. Tata, chairman, the Tata Iron and Steel Co., Ltd., and chairman of the Tata Group. *Honorary Vice-presidents*, Dr. D. P. Antia, president, the Indian Institute of Metals, and general manager, Industrial Projects Division, Union Carbide, India, Ltd.; Dr. B. R. Nijhawan, director, National Metallurgical Laboratory, Jamshedpur, and vice-president, the Indian Institute of Metals. *Award of a Scroll of Honour*, Mr. R. D. Lalkaka, honorary secretary, the Indian Institute of Metals.

The Institute of Metals: Awards

THE following awards of the Institute of Metals for 1963 have been announced: the Institute of Metals (Platinum) Medal, to Mr. G. L. Bailey, director of the British Non-Ferrous Metals Research Association, London, and a past-president of the Institute, in recognition of his outstanding services to the non-ferrous metal industries; the Rosenhain Medal, to Dr. B. A. Bailey, professor of theoretical metallurgy at the University of Sheffield, in recognition of his outstanding contributions in the field of physical metallurgy.

Electron Microscopy of Thin Crystals

A SUMMER school in electron microscopy of thin crystals will be held in the Department of Metallurgy, University of Cambridge, during June 23–July 1. The school is intended for research workers from industry and universities who already have some basic knowledge and operational experience of electron microscopy, and will include lectures and demonstrations on the specialized operation of electron microscopes, the theory of electron diffraction and image contrast and the interpretation of electron diffraction patterns and micrographs from metal and ceramic specimens. The lecturers will be Dr. P. B. Hirsch, Dr. A. Howie, Dr. R. B. Nicholson, Dr. D. W. Pashley and Dr. M. J. Whelan. The fee for the course will be £24, and college accommodation will be provided at an inclusive cost of £21. Further information can be obtained from the Board of Extra-Mural Studies, Stuart House, Mill Lane, Cambridge.

Lady Tata Scholarships and Fellowships in Leukæmia

THE Trustees of the Lady Tata Memorial Trust invite applications for fellowships, scholarships and grants for research on leukæmia, in the academic year beginning October 1. In view of the affinity between leukæmia and other forms of neoplastic disease, candidates with programmes of research on any aspects of malignant disease which may throw light on problems of leukæmia will be eligible for consideration, and especially those studying leukæmogenic viruses in mammals, the epidemiology and natural history of leukæmia, and the genetical and cytological aspects. Applications should be submitted before March 31. Further information can be obtained from the Secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London, S.W.3.

Announcements

DR. T. E. ALLIBONE, director of the Associated Electrical Industries Research Laboratory, Aldermaston, Berkshire, and director for Research and Education, Associated Electrical Industries (Woolwich) Ltd., has been appointed Rutherford Memorial Lecturer during a period to be arranged in the winter of 1963–64 in India and Pakistan, under the terms of the scheme to commemorate the late Lord Rutherford of Nelson.

MR. A. A. PART, deputy secretary in the Ministry of Education, has also been appointed deputy secretary in the newly created Ministry of Public Buildings and Works (see *Nature*, 196, 724, 937; 1962). Mr. Part will be responsible for policy matters affecting programmes of work carried out by the Ministry and, in particular, for matters arising from the forthcoming amalgamation with the Ministry of Works Directorates of the three Service Departments.

As from January 1, Dr. P. R. Day became secretary of the British Mycological Society. All communications for the secretary should in future be sent to him at the John Innes Institute, Bayfordbury, Hertford.

"CLIMATIC Factors and Agricultural Productivity" is the title of a symposium to be held at the Department of Geography and Anthropology, University College of Wales, Aberystwyth, on March 13. Further information can be obtained from Mr. J. A. Taylor, Department of Geography and Anthropology, Alexander Road, Aberystwyth, Cards.

THE Institute of Fuel, in collaboration with the City and Guilds of London Institute, is organizing a conference, "Education and Training in Fuel Technology in Relation to National Needs", at Borough Polytechnic, Borough Road, London, S.E.1, on March 8. Dr. A. Parker, lately director of fuel research of the Department of Scientific and Industrial Research, will give an address, "The Importance of Fuel Technology to Productivity". Further information can be obtained from the Secretary, Institute of Fuel, 18 Devonshire Street, London, W.1.

AN Anglo-Japanese symposium on "Nuclear Power", jointly organized by the United Kingdom Atomic Energy Authority and the Japan Atomic Industrial Forum, Inc., will be held in Tokyo during March 26–28. The British delegation will include representatives of the Authority, the Central Electricity Generating Board and the British nuclear industry. The delegation will present a symposium on "British Nuclear Power Station Development". Further information can be obtained from the United Kingdom Atomic Energy Authority, 11 Charles II Street, London, S.W.1.

THE FERMI CHICAGO PILE

On December 2, 1942, at 3.25 p.m. Chicago time, the first self-sustaining nuclear chain reaction was initiated and controlled. The success of the experiment was mainly due to Enrico Fermi. He directed the construction and the operation of the pile situated in the West Stands, Stagg Field, University of Chicago, in what had been a squash-rackets court. To mark the twentieth anniversary of this historical occasion and as a tribute to the memory of Enrico Fermi the International Atomic Energy Agency has issued a special number of its *Bulletin* (December 2, 1962) containing an introductory article by S. Eklund, director general of the Agency, and thirteen other articles, by distinguished scientists, devoted to descriptions of the first atomic pile or developments in the field of nuclear energy in various countries. English, French, German, Russian and Spanish editions of the *Bulletin* are to be published.

In his introductory remarks, the director general comments that immediately after the Second World War when the basic knowledge of atomic energy spread all over the world it was thought that the new source of energy could be put to widespread practical use within a very short time. But now, twenty years after the first reactor was put into operation, we have learned that development in nuclear energy must follow the same sequence as in every other major technological advance and involve only small steps at a time. The introduction of nuclear power will not be a sudden event, but instead a gradual process. However, the benefits already accruing from radioisotopes, an important by-product of nuclear energy, and their wide use in research and industry, require especial mention.

All the articles, except the simple descriptive account of the first atomic pile entitled "The First Pile" by C. Allardice and E. R. Trapnell, which was written in 1946 and is reprinted in the *Bulletin*, are original contributions. They include a brief personal account by Laura Fermi of her husband during the period he was working on the so-called 'metallurgical project' and of the absolute secrecy he maintained, even from her, of the work he was doing. Lise Meitner writes about the right and wrong roads to the discovery of nuclear energy; Otto Hahn on "Enrico Fermi and Uranium Fission"; H. D. Smyth on the publication of the "Smyth Report"; S. K. Allison on the "Initiation of the Chain Reaction" and his own particular task, the search for pure materials required for the pile; and G. T. Seaborg on the production of plutonium and its chemical extraction. Sir John Cockcroft describes the early days of the Canadian and British atomic energy projects. B. Goldschmidt discusses France's contribution to the discovery of the chain reaction and shows that the work of French scientists, while it did not contribute directly to the success of December 2, 1942, did nevertheless back up the efforts of Great Britain to persuade the United States to tackle the uranium problem on an industrial scale, and played a large part in the birth of nuclear activities in Canada and in the development of heavy water reactors. V. S. Emelyanov gives some historical details of the study of radioactive materials, and uranium, and graphite, by Soviet scientists leading up to the production of uranium and graphite for the first atomic reactor in the U.S.S.R.

In his article entitled "Thoughts on the 20th Anniversary of *CP*–1" E. P. Wigner states that on the memorable occasion of December 2, 1942, the scientists involved in the nuclear project realized that both the economic and political world would be affected by their great achievement. Economically they thought that the main effect would be cheaper energy, but so far this objective has not been realized. In the political field they hoped and expected that the terrible nature of nuclear weapons would have such a sobering effect on the Governments of all nations that they would forsake their conflicting aspirations and submit to a larger community of law and order. This was based on a misunderstanding. The issues of war and peace are governed not by the nature of weapons but by the conflicting desires of Governments.

The remaining two articles are by J. A. Wheeler and G. de Hevesy, who discuss "Fission, Then and Now" and "The Reactor and the Production of Isotopes", respectively.

S. Weintroub

THE BRITISH COUNCIL

The annual report for 1961–62 of the British Council * is in two parts, the general survey of the year being accompanied by an article "Teaching Courses" which, besides describing the Council's part in recruiting British teachers to serve overseas, seeks to answer some questions asked by potential candidates for overseas teaching posts. In addition to filling teaching posts in its own permanent service the Council recruited 226 teachers on short-term contract, of which 140 were for schools and 45 for universities and training colleges, about 25 per cent of those in universities being at the professorial level and rather more than half in English departments. Most of the Council's educational work in developing countries is complementary to technical co-operation, and experience in Nigeria and Ghana has clearly indicated that the opportunities open to the Council for educational work—especially in English language teaching—increase as the number of expatriate civil servants decreases. Arrangements have already been made for collaboration with the Department of Technical Co-operation in Nigeria which may become the pattern for similar co-operation elsewhere in Africa.

The Council's English Teaching Information Centre, formed in 1960 to collect and co-ordinate experience and information about teaching English as a second or foreign language, now distributes about 1,000 copies of its *English-Teaching Abstracts and English-Teaching Bibliography* in more than ninety countries. Moreover, the Council has maintained close contact with the British Broadcasting Corporation and with the Centre for Educational Television Overseas in its investigations on the production of English language teaching films for television and for classroom work. A substantial financial contribution is being made towards the running costs over the next five years of the English schools in Nicosia; £34,000 was contributed for a library building in Port Harcourt, Eastern Nigeria; £12,000 towards one at Kaduna, Northern Nigeria; a grant of £35,000 was made to the Sierra Leone Library Board towards the capital cost of a Central Library and headquarters building in Freetown; late in 1961, £27,000 was granted towards the establishment of a central and headquarters library at Ibadan, Western Nigeria. In all, during two and a half years, grants totalling £175,000 have been allocated for library development in seven centres.

---

* *The British Council.* Annual Report, 1961–1962. Pp. vii+107+12 plates. (London: The British Council, 1962.) 2*s*. 6*d*. net.

There are now estimated to be some 60,000 overseas students in Britain and during the year the Council met and assisted 10,407 on arrival, of whom 5,127 were from the Commonwealth and 3,601 were colonial. Permanent accommodation was arranged for 320 in Council residences, 874 in university and other hostels or halls of residence, and 6,301 in lodgings, as well as transit accommodation on first arrival for more than 4,500 and temporary accommodation when away from place of study for nearly 7,000. Hospitality was arranged for and accepted by 13,547, more than 20,000 attended week-end courses, study visits and surveys, nearly 2,500 holiday courses of 7–15 days, more than 12,000 Council centres and 4,000 introduction courses. With the capital fund of £3 million which the Council is administering for the Government, a target of an additional 5,000 hostel places has been set, wherever possible by voluntary societies and other organizations, and 37 projects for hostel development (providing an additional 1,382 places) have been approved. There are also plans for some expansion of the Council's social and cultural centres for overseas students and trainees. About half the overseas students and trainees in Britain are studying some branch of science, technology or medicine and about half the advisory visits arranged by the Council overseas are concerned with these subjects.

Of 7,522 overseas visitors in Britain assisted by the Council (including 646 Colombo Plan trainees, 633 United Nations Fellows and 378 Scholars and 416 Teacher-Bursars under the Commonwealth Educational Co-operation), 1,030 were in medicine, 1,717 in science and technology and 1,535 in social science. Besides 73 university interchange visits (54 to Britain) arranged under the Commonwealth Scheme, 134 short visits were arranged under the Foreign Scheme (65 to Britain) as well as 4 longer teaching visits by guest professors and lecturers to university departments, and 99 visits of younger research workers between British and foreign universities (53 to Britain). In all 358 specialist tours, advisory visits and delegations were arranged during the year, of which 52 were in science and technology, 51 in medicine and 25 in social science, and the Council assisted in the selection of candidates for 113 scholarships offered to British students in 21 centres.

THE NATURE CONSERVANCY

THE thirteenth annual report of the Nature Conservancy for the year ended September 30, 1962[*], records a total of 100 National Nature Reserves with an acreage exceeding 190,000, and the Conservancy has thus completed the greater part of its original acquisition programme of some 140 reserves and an area of about 250,000 acres. Difficult acquisition problems are presented by some of the proposed reserves and completion may still be considerably delayed. However, these figures do not include some nine local and eleven forest nature reserves or two wildfowl refuges, many more of which will be required, but it is already clear that the programme set forth in 1947 in the report of the Wild Life Conservation Special Committee was fundamentally sound.

With the substantial progress in acquisition, the focus of effort shifts progressively from the acquisition of reserves and their rehabilitation to the formulation of comprehensive plans of management and the development of research projects, although the report refers to progress during the year in making management plans as disappointing. On the other hand, encouraging progress is reported in working co-operative arrangements, particularly with the new county naturalists' trusts which are emerging on a national scale as effective organizations for acquiring reserves and furthering conservation. A much wider spread of informed public interest is, however, desirable, although the launching of the British national appeal for the World Wildlife Fund has encouraged hopes of placing the voluntary movement on a firmer basis. Conservation requires large financial and practical support from voluntary sources and this requires education, guidance and self-restraint by citizens, which are imbued preferably through voluntary and elected bodies.

Nevertheless, despite encouraging indications of growing co-operation and such signs of progress as the issue of the Conservancy's first monograph, *Plant Communities of the Scottish Highlands* (see *Nature*, 196, 206; 1962), the striking advance in the amount of advice on specific problems, such as toxic chemicals and wildlife, provided for authorities and organizations concerned, a careful reading of the report suggests that the national contribution to conservancy is too small. The report itself admits to a difficult year financially. The grant-in-aid was £535,000, of which £465,000 was for general purposes and £70,000 for capital expenditure. Receipts amounted to just more than £14,000, but it was necessary to transfer £14,000 from the capital expenditure to the general expenses account, and the increase of £55,000 in the income for 1962–63 is almost entirely absorbed by rising salaries and general expenses. Expenditure on research, training and special surveys amounted to no more than £76,626, of which £33,782 was for grants and research and £22,149 for studentships and training grants, figures which compare with £65,414, £28,965 and £18,428, respectively, in 1960–61.

In this connexion, a sub-committee under the chairmanship of Prof. W. H. Pearsall, after reviewing the responsibilities of the Conservancy for grant-aided research, including the present status of biological research and of support for all aspects of ecology, concluded that the Conservancy's responsibilities should be broadened. This would permit stronger liaison with the universities, the desirability of which was emphasized by the Select Committee on Estimates in its 1957–58 report, and would provide greater and more flexible support for research into natural biological resources and the fundamental aspects of biology underlying it. The Conservancy has accepted this recommendation in principle, but its implementation depends on the outcome of other current reviews of Government support for biological sciences. Eight new grants were approved during the year and ten existing grants renewed or extended. Provision for research studentships is also at present under review; fourteen awards were made during the year and thirteen applications for third-year extensions were approved. Six awards were again made for the one-year diploma course on conservation.

A feature of the report is the increasing attention given to international and overseas activities. The Conservancy is an active member of the International Union for the Conservation of Nature and Natural Resources, and besides reporting on meetings of the Commissions on Ecology and on Education of that body, the present report includes notes on the first world conference on national parks at Seattle, the International Council for Bird Preservation, the thirteenth International Ornithological Congress, the fifteenth Limnological Congress, and an international conference in May 1962 at which the feasibility was agreed of an International Biological Programme on the biological basis of productivity and human welfare.

---

[*] *The Nature Conservancy.* Report of the Nature Conservancy for the year ended 30th September, 1962. Pp. viii+153+15 plates. (London: H.M.S.O., 1962.) 10s. net.

Some thirty pages of the report are now occupied by accounts of scientific research in progress at the Merlewood Research Station and Moor House Field Station, the Furzebrook Research Station, the Monks Wood Experimental Station, the Speyside Research Station, the Bangor Research Station and in Scotland. Botanical studies on low-level woodlands embrace studies of nutrient cycles in oak woodlands, those of the invertebrate fauna of woodlands, the nutrient and energy-cycles in woodlands and the effect of management on invertebrates. The establishment of trees on Pennine moorland, woodland mycology and chemical studies on organic matter all received attention. Other investigations were concerned with moorland plants, the ecology of southern heaths, coast physiography and ecology, climatology and hydrology, sheep-grazing and vegetation, the productivity of mountain grasslands and biometrics. In Scotland, besides botanical research on woodlands, the assessment of the vegetational productivity of Rhum continued, as did zoological work on the red grouse, a study of the food of the red deer and detailed studies of the grey seal breeding colonies in Orkney and North Rona.

The Scientific Advisory Services were concerned with the factors to be taken into account in afforestation of national parks, and, besides the monograph already noted and a second which has now been sent to press, they were also concerned with publication of a new edition of the *Flora of the British Isles* and the *Atlas of the British Flora*. The Conservancy is represented on the Committee on Hydrological Research by Dr. E. B. Worthington, and in the planning and execution stage of the proposed catchment area research a member of the Conservancy's staff will be attached to the Hydrological Research Unit. The Conservancy has also co-operated in the West Midlands Inland Water Survey, and in April 1962 it issued an important statement of policy on the introduction of species, affirming the importance of wider public recognition of the basic principle that in any area the integrity of the natural fauna and flora is in itself a vital natural resource, the conservation of which ought to be an object of national policy.

Nearly all the National Nature Reserves in Scotland, more than half of those in England, and a third of those in Wales are now being managed under approved plans, and about half a dozen of those prepared more than five years ago are being revised for the next quinquennium. The Conservancy is convinced of the need for a concerted approach by land-using interests to the problems involved in making the best use of the hill ground of Scotland—the need for much more fundamental and applied scientific research is stressed. Steps have been initiated to review existing knowledge, work in progress, identify gaps and build up efforts into a comprehensive programme. Following a study of the status, amenities and scientific interest of about thirty-eight surviving named areas of the Norfolk Broads in a survey of the impact of contemporary developments, the Conservancy is anxious to initiate research into problems of pollution in the Broads and towards a better understanding of water movements, tidal effects and rate of mud deposition on water depths and marginal effects. It is seeking to organize a wardening service in Snowdonia based on voluntary agreement with safeguards for landowners and tenants, the National Park authorities, public access and the Conservancy, and it has also recently expressed concern about possible disturbances due to the use of 'hovercraft' over tidal flats, shallow lagoons and rivers and marshes. The Ministry of Transport and the Ministry of Aviation have agreed to keep the Conservancy informed regarding permits to fly hovercraft and proposals for legislation. Full agreement was also reached with the Post Office to find an alternative route for a submarine cable which it was proposed to bring ashore on the Norfolk coast and which threatened scientific interests. Some concern is again expressed regarding damage and litter on reserves and wildfowl refuges which present serious problems.

POSSIBLE APPLICATION OF THE MASS-ENERGY CYCLE ON A MICRO- AND MACRO-SCOPIC SCALE IN THE UNIVERSE

By J. L. HUGHES

Department of Physics, University College of North Wales, Bangor

ONE form of the mass-energy cycle is shown in Fig. 1. Experimental support for the cycle comes from the fact that all known particles of lower energy may be created from a 10-BeV electron. The only particle interactions allowed by the cycle which have not been observed experimentally are the build-up and decay of photons although these are not essential to the concept when applied on a macroscopic scale.

It will be assumed that the cyclic reactions occur in the positive Dirac states and since the negative states are normally filled the creation of antiparticles will be considered as abnormal events in the universe. (Dipping into the negative Dirac states could nevertheless provide an important and convenient means of approaching the ideal equilibrium ratio under abnormal conditions such as those existing in a cosmic ray air shower. For example:

primary particle→
x_1 secondary particles and antiparticles→
x_2 secondary particles ($x_2 > x_1$).)

The basic postulate of the present work is as follows.

In any region of the universe the ratio of mass to energy will always tend to a constant value. That is:

$$\frac{\text{Mass}}{\text{Energy}} \rightarrow \text{const.}$$

(This refers to the ratio of the amount of mass and energy in any region and not the Einstein equivalence ratio of $\frac{1}{c^2}$.)

If this constant be put equal to unity, then: (*a*) in any region of the universe where mass/energy > 1 the conversion of mass into energy will be favoured; (*b*) in any region of the universe where mass/energy < 1 the conversion of energy into mass will be favoured.

Due to the large velocity of photons and the mutual gravitational attraction of the mass $> o$ particles, it is unlikely that a stable equilibrium would ever be attained locally, the fluctuations about the ideal mass/energy ratio representing the mass-energy cycle.

Eddington[1] objected to the cyclic concept since it was not consistent with the second law of thermodynamics in an expanding universe. Applying the cycle on a macroscopic scale, however, it can be seen that the observed expansion of the universe turns out to be only an apparent one. It is true that clusters of galaxies move away from each other but this is so only for their mass content. The equally important photon content actually move towards each other into interclusteral space cancelling the observed expansion. The photons are then transformed in accordance with *b*, while the mass $> o$ particles in the clusters themselves condensing under mutual gravitational attraction transform according to *a*.

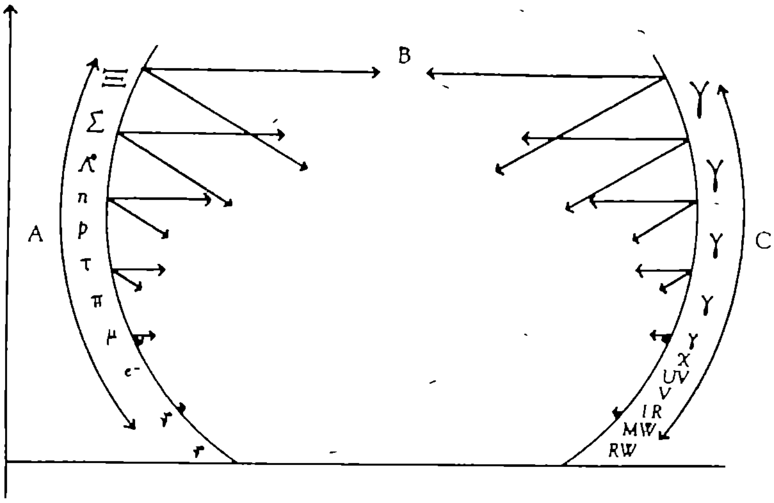

Fig. 1. One form of the mass–energy cycle. *A* and *C* represent the build-up and decay of mass and energy, respectively, and *B* their interconversion
Ξ, Σ, Λ°, hyperons; *n*, neutron; *p*, proton; τ, tau meson; π, pi meson; μ, mu meson; e^-, electron; ν^0, neutrino. Photons: *RW*, radio-wave; *MW*, micro-wave; *I.R.*, infra-red; *V*, visible; *UV*, ultra-violet; *X*, X-ray; γ, gamma-ray

Any sufficiently large volume *V* of the universe would lose particles by the outward flow of photons and clusters of galaxies but gain by the inward flow of particles from the surrounding space, these eventually forming new clusters in accordance with *b*, in the interclusteral regions of *V*.

The density of matter in *V* would on the average be constant both in space and time and it could be considered as an isolated system involving thermodynamically perfectly reversible reactions between mass and energy, basic postulate. The universe based on the mass-energy cycle would thus satisfy the second law of thermodynamics, its entropy remaining constant.

Possible experimental proof of the basic postulate. According to the present postulate the ratio of mass to energy in any region of the universe tends to a constant value. By analogy with other equilibrium systems it has been assumed that the greater the departure of the mass/energy ratio from the ideal value the more unstable does the matter in the region concerned become.

The electron offers a means of verifying the postulate experimentally since above 1 MeV it travels at essentially the velocity of light, any further gain appearing as mass. Under these relativistic conditions the dimensions of the electron decrease as its mass increases, hence its mass density becomes extremely large. Infinite mass is prohibited by the postulate so that the electron eventually would have to reach a critical density after which it becomes unstable and transforms in accordance with *a*. The critical density is likely to be attained sooner in an environment predominant in mass than one predominant in energy such as the envelope of a supernova. It is of interest to note that electrons of 10^{12} eV have been observed in supernovæ via their instability, while no electrons of primary origin greater than 10^{10} eV have been observed in cosmic rays striking the Earth. The linear accelerator at Stanford producing 50-BeV electrons will probe this apparent gap in the electron spectrum at a beam current of 100 microamps, representing close packing of electrons which may well have attained the critical density and become unstable.

The postulate results in the stability of a particle being dependent on its individual characteristics and those of its surroundings. Assuming all else to be constant with only a change in environment, differences should occur in the mean life-times of particles such as mesons and hyperons if the postulate is correct. A relatively large spread in mean life-times of such particles does exist which may be within experimental error.

The observational consequence of the cyclic concept would result in distant galaxies being visible only in the radio frequency range since the more energetic photons would have transformed *en route* (*b*), thus also satisfying Olbers' paradox.

SLOWLY VARYING COMPONENT OF SOLAR RADIO EMISSION

By Dr. M. K. DAS GUPTA and D. BASU
Institute of Radio Physics and Electronics, University of Calcutta

IT is well established that the solar radio emission can be broadly classified as: (1) a fairly constant basic component (quiet sun emission—thermal origin); (2) highly variable components of different types (disturbed sun emission—non-thermal origin); (3) a distinct type of slowly varying radiation only at centimetre and lower decimetre wave-lengths. The last one shows a slow day-to-day variation in intensity closely correlated with sunspot numbers exhibiting roughly a 27-day recurrence period, and as such is usually called the slowly varying component of solar radio emission. The close association of the centimetre radiation from the Sun with the sunspots was first detected by Covington[1] at a frequency of 2,800 Mc/s. Subsequent observations by other workers[2–5] at different frequencies showed the same effect. It was revealed that this characteristic type of solar radio emission is limited to a certain range of frequencies. But as yet this range is not clearly defined, and the two limiting frequencies beyond which the slow variations are undetectable are not precisely known. However, according to Hachenberg[6], this component extends over the frequency-range of 500 Mc/s–30,000 Mc/s, while according to Pawsey and Smerd[7] the range is 500 Mc/s–10,000 Mc/s. Moreover, the frequency at which the correlation between the slowly varying radio emission and the relative sunspot numbers would be a maximum, if there be any, is not clearly known. We were thus prompted to examine these aspects of the slowly varying component of solar radio emission in relation to recent data.

In our analysis we first plotted the daily mean flux of solar radio emission at five different frequencies—9,400, 3,750, 2,800, 2,000 and 1,000 Mc/s for the International Geophysical Year period (July 1957–December 1958). Fig. 1 shows these plots at four different frequencies along with the plot of Zurich relative sunspot numbers R_Z for the same period. All the five curves show substantially similar variations and indicate pronounced maxima and minima following roughly the so-called 27-day cycle. The close correlation between the daily mean flux with the relative sunspot number is also quite clear. An additional striking feature exhibited by the daily mean flux curves is that the pronounced maximum to minimum amplitude of this variation changes rather systematically with frequency. This phenomenon led us to examine the matter

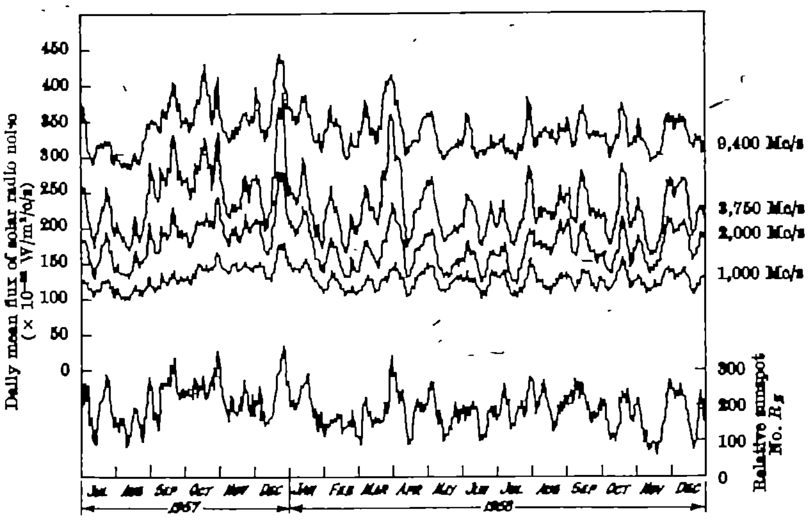

Fig. 1. Plots showing the variation with time of the daily mean flux of solar radio noise at frequencies 9,400, 3,750, 2,000 and 1,000 Mc/s together with that of the Zurich relative sunspot numbers for the International Geophysical Year period (July 1957–December 1958)

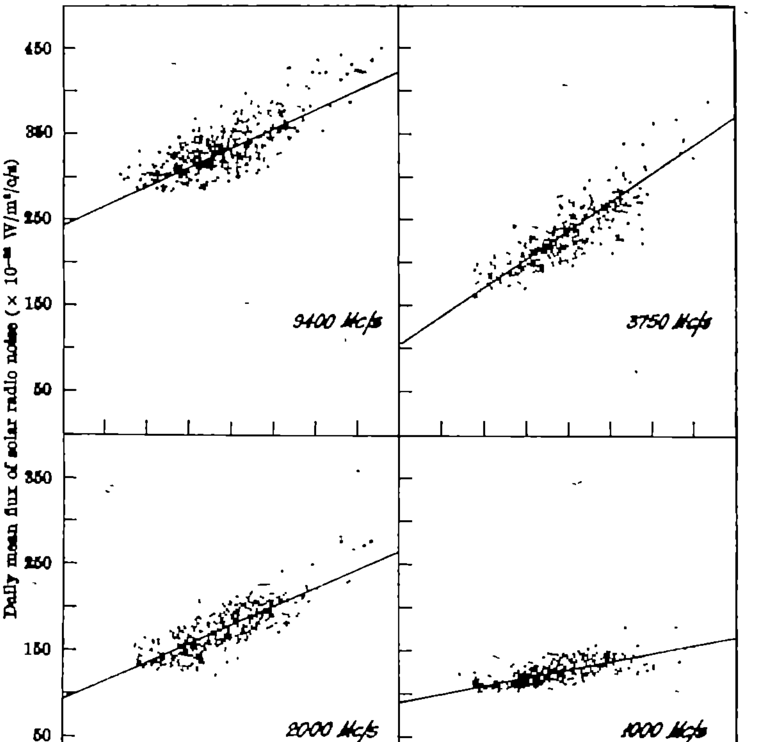

Fig. 2. Scatter diagrams showing the correlation between observed daily mean flux of solar radio noise, at frequencies 9,400, 3,750, 2,000 and 1,000 Mc/s and the Zurich relative sunspot numbers for the International Geophysical Year period. The corresponding regression lines are also indicated in the diagrams

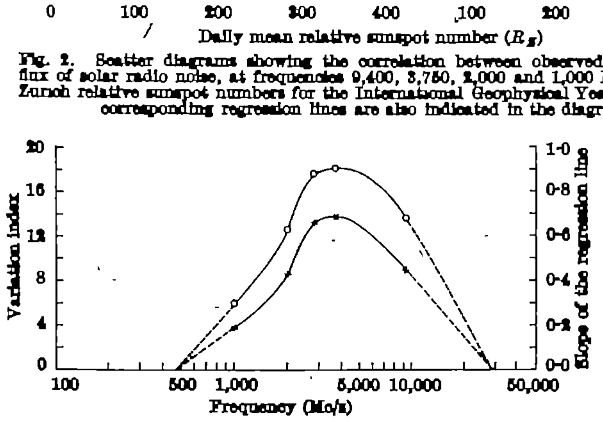

Fig. 3. The curves showing the relation of the variation index (○) and the slope of the regression line (×) with frequency

in some detail and as such a variation index had to be adopted. For any particular frequency, the changes in amplitude between the pronounced maxima and the corresponding minima showing roughly the 27-day cycle were first carefully measured from the daily mean flux curve for the entire period under study. The average value of these changes has for convenience been termed the 'variation index' for that frequency. The variation indices for the different frequencies as mentioned here were thus calculated separately.

Secondly, scatter diagrams showing the correlation between daily mean flux of solar radio emission and the relative sunspot numbers were drawn for all these different frequencies as shown in Fig. 2. (The corresponding diagram for 2,800 Mc/s drawn separately is not shown here.) The respective regression lines are also indicated in these diagrams. A very striking feature as revealed from these diagrams is that the slope of the regression line also changes systematically with frequency. The slopes in the different cases were calculated.

Fig. 3 shows a plot of the variation index as already mentioned (upper curve) and that of the slope of the regression line (lower curve) versus the frequency. It is interesting to note that both these curves are identical, showing a maximum near about 4,000 Mc/s. It may be logically assumed that both the variation indices as well as the slopes of the regression lines will have uniform distributions as shown by the continuous lines through the two sets of points. On extrapolation, the continuous curves in both the cases are found to intersect the frequency axis at 470 Mc/s on the low-frequency side and near about 29,000 Mc/s on the high-frequency side. Hence our analysis led us to draw the following conclusions regarding the slowly varying component of solar radio emission mainly in relation to the frequency:

(1) The two limiting frequencies for which both the variation index as well as the slope of the regression line will be zero are 470 Mc/s and 29,000 Mc/s. These are, therefore, the two frequency limits beyond which the characteristic slow variations of solar radio emission will ultimately subside.

(2) The correlation between the daily mean flux of solar radio emission and the relative sunspot numbers will be maximum at a frequency near about 4,000 Mc/s.

(3) The variation index as already mentioned will be roughly proportional to the slope of the regression line and hence to the correlation. The index, therefore, might conveniently be used as a measure of the correlation between the two phenomena.

It should be noted in connexion with the limiting frequencies as already mentioned that so far as the low-frequency side is concerned the experimental observations at 450 Mc/s at Boulder do not show the presence of the typical variations, but Lehany and Yabsley[3] observed these at 600 Mc/s. On the high-frequency side, however, the data are insufficient for any definite conclusion. Nevertheless, it appears from our analysis that the estimates of Hachenberg[4] as regards the high-frequency cut-off is a better approximation than that given by Pawsey and Smerd[7].

We thank Prof. S. K. Mitra and Prof. J. N. Bhar for helpful discussions. One of us (D. B.) thanks the C.S.I.R., Government of India, for financial assistance. Data used in our analysis were obtained from International Geophysical Year data published by the Science Council of Japan, and *CRPL-Solar Geophysical* data books.

DEMONSTRATION OF THE PRODUCTION OF A NEW TYPE OF REMANENT MAGNETIZATION: INVERSED TYPE OF THERMO-REMANENT MAGNETIZATION

By TAKESI NAGATA, MINORU OZIMA and MITUKO YAMA-AI
Geophysical Institute, University of Tokyo

It is conventionally understood that thermo-remanent magnetization (TRM) is produced by cooling a ferromagnetic body from a certain high temperature in a magnetic field[1].

However, in the course of an investigation of the magnetic behaviour of magnetite at low temperatures (from liquid nitrogen temperature to room temperature), we found that a fairly intense and stable remanent magnetization was acquired by heating magnetite grains from − 150° C to room temperature in a moderate magnetic field (10 oe). This is quite striking, since a heating process is usually understood to loosen a magnetic domain configuration while magnetic domains are 'frozen in' in a cooling process. The remanent magnetization thus acquired is tentatively called here an inversed type of thermo-remanent magnetization or ITRM, as the direction of the temperature change in which the remanent magnetization is acquired is just opposite to the case of an ordinary type of thermo-remanent magnetization. This article presents some characteristics of the ITRM as well as the qualitative interpretation of the acquisition mechanism.

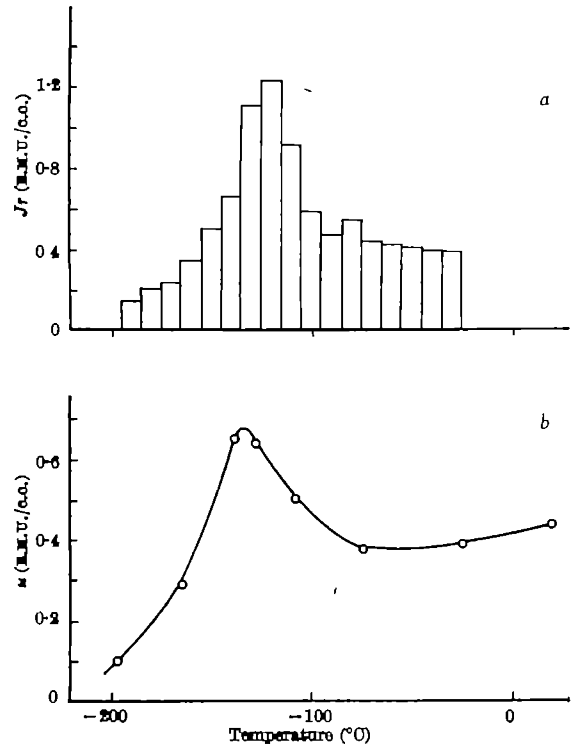

Fig. 1*a*, Intensity spectrum of partial ITRM's produced over a temperature range of 10° C at $h = 10$ oe; *b*, temperature change of susceptibility of magnetite measured at $h = 10$ oe

Table 1

Remanent magnetization	Temperature-range in which remanent magnetization is acquired	Direction of temperature change in which remanent magnetization is acquired	Intensity of the remanent magnetization measured at room temperature ($h = 10$ oe)
IRM	Isothermally at room temperature	Isothermal	0 51 E.M.U./c.c.
TRM	Curie point to room temperature	Cooling	7 27 E.M.U./c.c.
ITRM	−150° C to room temperature	Heating	3 61 E.M.U./c.c.

Experiments were carried out with synthesized stoichiometric magnetite (Fe_3O_4) of which grain sizes range over several tenths of a millimetre. Magnetic intensity measurements were made with a ballistic magnetometer. The magnetite grain were packed in a glass tube (diameter 0·2 cm; length 2 cm) for measurement. In Table 1 some characteristics of ITRM are compared with those of isothermal-remanent magnetization (IRM) and thermo-remanent magnetization. The intensity of ITRM is about one-half of TRM produced at the same magnetic field. Fig. 1*a* shows the intensities of partial ITRM's, each of which is produced by heating the sample over a temperature-range of 10° C at a d.-c. field of 10 oe and afterwards heating to room temperature in zero magnetic field. From the figure the maximum production of the partial ITRM is clearly seen to lie at about −130° C. In order to examine the stability, all the partial ITRM's were demagnetized by an a.-c. field (Fig. 2). In the same figure the a.c. demagnetization curves of an IRM and an ordinary type of TRM produced by field-cooling from the Curie point to room temperature at $h = 10$ oe are also shown for comparison. It is to be noted that the partial ITRM produced at the temperature-range of −125° C to −115° C is as stable against a.-c. demagnetization as TRM, while the stability is much poorer in the case of the ITRM's produced at higher temperature-ranges. Both experiments clearly show that a fairly intense and stable remanent magnetization is acquired by field-

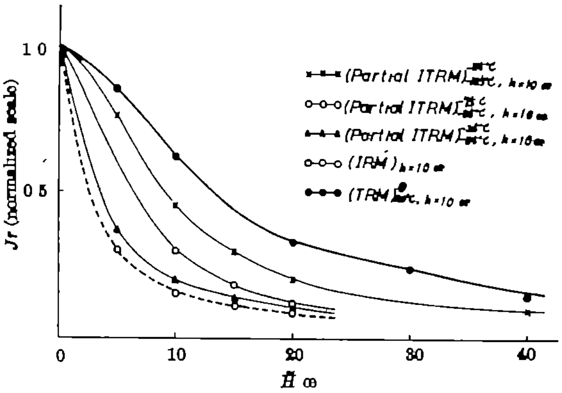

Fig. 2. a.-c. field demagnetization of partial ITRM's IRM and TRM

heating over a relatively narrow range of temperature, that is, from −150° C to −120° C.

The acquisition mechanism of ITRM can be explained if we take account of the marked change of the crystal anisotropy constants of magnetite at low temperature. It is well established that the crystal anisotropy constants of magnetite vanish at −143° C (ref. 2). Fig. 1*b* shows the temperature variation of the susceptibility of magnetite measured at $h = 10$ oe. The marked increase of the susceptibility at about −140° C is due to the sharp change of the crystal anisotropy constants from finite values to zero for this temperature. As inferred from the susceptibility–temperature curve the domain walls would be largely displaced under the influence of a magnetic field to result in the marked enhancement of the magnetization at this temperature. If the temperature is then raised while the magnetite grains are still subjected to the magnetic field, the rapid change of the crystal anisotropy energy with increase of temperature tends to constrain the domain walls to the displaced positions at lower temperatures. After the removal of the magnetic field at room temperature we observe a fairly intense and stable remanent magnetization, that is, the inversed type of thermoremanent magnetization.

It should be noted here that any ferromagnetic body of which coercivity is mainly governed by the crystal anisotropy energy may acquire a stable remanent magnetization in a process of a temperature change in a magnetic field, provided that the temperature change (irrespective of the direction) causes a sharp increase of the crystal anisotropy energy. This argument is strengthened by a further observation on cobalt chips. Cobalt (Curie point = 1,115° C) is known to have crystal anisotropy constants which vanish at about 250° C (ref. 3). A fairly intense and stable remanent magnetization was observed at room temperature by cooling cobalt chips from 250° C to 200° C at $h = 5$ oe and afterwards cooling to room temperature in zero magnetic field. A detailed report of this result will be given elsewhere.

Finally, in connexion with rock magnetism it is interesting to speculate that the ITRM might be responsible for the origin of the stable natural remanent magnetization observed in some stony meteorites[4], as the environmental temperature in which meteorites were held before the entry into the Earth's atmosphere is suggested to be very low[5].

FRESH NATRO CARBONATITE LAVA FROM OLDOINYO L'ENGAI

By DR. C. G. B. Du BOIS, J. FURST, DR. N. J. GUEST and D. J. JENNINGS

Mines and Geological Department, Nairobi, Kenya

OLDOINYO L'ENGAI has the distinction of being the only active volcano in East Africa. It forms a striking steep-sided cone rising to 9,443 ft. at the south end of Lake Natron in northern Tanganyika in the Rift Valley.

Immediately south of L'Engai lies the carbonatite volcano Kerimasi. The petrography of both, together with that of rocks collected during geological mapping in the surrounding area, including the volcanoes of Mosonik and Shombole north of L'Engai, indicate that all occur in a petrographic province characterized by richness in sodium and calcium. Among the rock types described are phonolites, nephelinites, melitite-basalt, rocks of the ijolite–melteigite–urtite series and biotite–pyroxenite. The presence of fenites and tveitåsites at L'Engai suggested that it may have a carbonatite at its heart[1].

Around the summit of the cone is a white mantle of 'soda' which increased in extent immediately after an eruption in 1954, when the upper reaches of the volcano and the interior of the latest crater resembled a snow-scape[2]. At that time a cone of dark lava grew on the newer crater floor but has now almost disappeared partly due to weathering and partly owing to subsequent fairly regular eruptions involving conelet formation.

The 1954 eruption at L'Engai was studied by Guest[2]. A specimen of soda crust collected shortly after an eruption was found to contain about 50 per cent of material insoluble in water of which 70 per cent was identified as calcium carbonate by J. R. Harpum, adding support to the idea that the volcano may overlie a carbonatite. In two samples of soda crust the Geological Survey Laboratories in Tanganyika determined the two major soluble salts as sodium carbonate 23·6 per cent and 40·2 per cent, and sodium carbonate 3·4 per cent and 8·5 per cent, respectively.

In August 1961, L'Engai was climbed by a party of six, three of whom descended several hundred feet, mostly on soda-covered ash, on to the floor of the inner crater. Guest observed that the latter had changed considerably since 1954. Several new cones were present, all eroded to a greater or lesser degree, and small flows on the crater floor showed many of the classical structures characteristic of lavas. Some activity was in progress, ash and boulders being ejected from at least one vent while fumaroles and solfatara were vigorously in action elsewhere. Rock samples collected varied from fresh, hot dark lava types to paler-coloured not so fresh types. To avoid further exposure to the atmosphere the samples were immediately sealed in stout polythene containers for transporting to the laboratory.

The fresh rock is soft, dark grey, holocrystalline medium- to fine-grained and granular in texture. On exposure to the air the surface becomes white within two days. Left for a few weeks it crumbles to a damp white powder which X-ray analysis shows consists of a mixture of calcite and trona. Thin sections were prepared in the usual manner except that paraffin was used throughout in place of water because some 40 per cent of the rock consists of water-soluble carbonates. The thin sections were examined by Du Bois.

The chief mineral present appears to be a new carbonate similar in some respects to the artificial double carbonate of calcium and sodium described by Winchell[3], but showing some important differences. It is colourless, highly birefringent, length-slow, uniaxial negative and occurs as euhedral laths 0·25–1 mm long having a length/breadth ratio of between 6 : 1 and 3 : 1. Some basal sections show complex multiple twinning reminiscent of leucite. Cloudy rounded crystals of comparable size yield a similar X-ray pattern and may represent a previous generation of the same mineral which has undergone partial alteration and magmatic abrasion. Black dust and minute grains, possibly of pyrite, are present interstitially and also as inclusions. Purple fluorite is present as tiny crystals in some sections, and X-ray study of acid-insoluble residues of some lava specimens shows up to 1·4 per cent calcium fluoride although no fluorine was detected in the particular samples analysed. Flow textures are developed locally, the lathy crystals having sub-parallel arrangement. Some voids occur between boundaries of adjacent crystals and account for the differences in the true and apparent specific gravity of the rock.

Chemical analyses of two samples of fresh lava are given in Table 1.

Table 1

	*L*1	*L*4
SiO_2	1·18	1·12
R_2O_3	1·64	1 70

S	0 08	0·13
	99 91	100·74
Less O for S and Cl	0·57	0·75
Total	99·34	99·99

Analyst: J. Furst

Specific gravity of *L*1, 2·38 (apparent); 2·51 (true); 2·55 (calculated).

*L*1: Natro-carbonatite collected from uppermost flow on the south-westerly side of a cluster of cones on the east side of crater floor.

*L*4: Natro-carbonatite collected very hot from lava flow beneath *L*1.

These can be compared with results obtained by von Knorring and Du Bois[4], who described a carbonatitic lava from Uganda containing about 13 per cent silica. It is of particular interest that both samples contain less than 2 per cent silica and 78–80 per cent total calcium oxide, sodium oxide and carbon dioxide. Both samples have high barium and strontium content, which is characteristic of carbonatite and certain related rocks[5–7]. The water content of 1·8–1·9 per cent is very considerably less than that reported elsewhere[8], and part or all of this may in fact be hygroscopic water drawn from the atmosphere during crushing of the samples for analysis.

In order to calculate the composition of the lava from the chemical analysis using only known minerals, the need arises to include 6–8 per cent of lime. Assuming for the moment that modal lime is present in the fresh lava an explanation for its existence could be provided by postulating the partial breakdown of a complex calcium–sodium carbonate to yield lime and some carbon dioxide. Winchell[3] mentions that $Na_2Ca_2(CO_3)_3$ fuses at 812° C in an atmosphere of carbon dioxide; but if an attempt is made to synthesize this compound by mixing together stoichiometric proportions of anhydrous sodium and calcium carbonates, and heating to that temperature in air, the result is a loss of some carbon dioxide and a white residue which shows strong CaO lines when an X-ray powder photograph is taken. Photographs of fresh L'Engai lava, however, show no such lines, neither are there any present attributable to calcium hydroxide. Other tests, both physical and chemical, also fail to reveal the presence of calcium oxide, hydroxide or bicarbonate in the fresh rock. The inference is that the lava was formed under PT conditions which very probably included an atmosphere of carbon dioxide which, in turn, permitted the formation of a new carbonate mineral. This is believed to be a complex carbonate of calcium and sodium with perhaps some potassium. Because of its rapid alteration to calcite and trona by atmospheric water and carbon dioxide its existence has probably escaped notice in the past.

In view of the extraordinary nature of this new lava[7] it is proposed to call it 'natro-carbonatite'.

We thank Dr. William Pulfrey, Commissioner, Mines and Geological Department, Kenya, for advice, and Mr. P. Wentzel for assistance with transport in 1961.

ACTIVATION ANALYSIS OF PAPER CHROMATOGRAMS FOR IODINE ($^{127}I \rightarrow {}^{128}I$)

By ALICE DIMITRIADOU*, P. C. R. TURNER and PROF. T. RUSSELL FRASER

Department of Medicine, Postgraduate Medical School and the Medical Research Council Cyclotron Unit, London

IN recent investigations of the iodoamino-acids extractable from human serum it became important to ascertain whether the ceric–arsenite method's indication of iodine (iodine-127) in the iodotyrosine spot really depended on iodine rather than on some unexpected artefact. Activation analysis of the chromatogram's spots was therefore performed, the paper being activated directly[1–3]. It soon emerged that such an analysis of paper required a stringent post-irradiation purification to eliminate from the sample the other more active radiochemical products also activated in the paper. The method finally evolved for this purpose is given here, as it may be of interest to other workers.

The chromatograms, prepared from extracts of human sera, as described elsewhere[5], were run in duplicate along with some blank strips. Preliminary staining of one chromatogram with ceric–arsenite provided a guide for cutting off the appropriate areas from the other strip; pieces up to 6 sq. in. could be used. From the blank strips, areas of similar size and distance from the origin were cut, one to be used as a standard after spotting with standard potassium iodide, and the other as a blank. All the papers were then sealed in polythene envelopes and placed together in aluminium screw cans, each of which contained two or three papers, usually a chromatogram spot and a standard. Blank strips were also included.

A series of such cans were inserted in the pile at a thermal neutron flux of 10^{12} n/cm²/sec, and irradiated for either 1 or 0·5 h. Our evidence given in this article now suggests 0·5 h as the preferable time. Iodine-128 (half-life = 25 min) was produced by an (n, γ) reaction on iodine-127.

In preliminary experiments[1], the Medical Research Council cyclotron had been used to produce a neutron beam by means of the beryllium-9 (d, n) beryllium-10 reaction, the fast neutrons produced being partially thermalized by a block of paraffin wax. However, although similar activation has been obtained, it was at a varying and insufficient activity due to the lower and less constant neutron flux (approximately 10^{10} n/cm²/sec).

Radiochemical separation (to separate radioactive iodine from other more abundant radioisotopes produced):

After preliminary trials had found that simpler methods, including that of Bowen[4], were inadequate for this purpose, the following method was evolved: (*a*) On removal,

* Wellcome Trust Research Fellow.

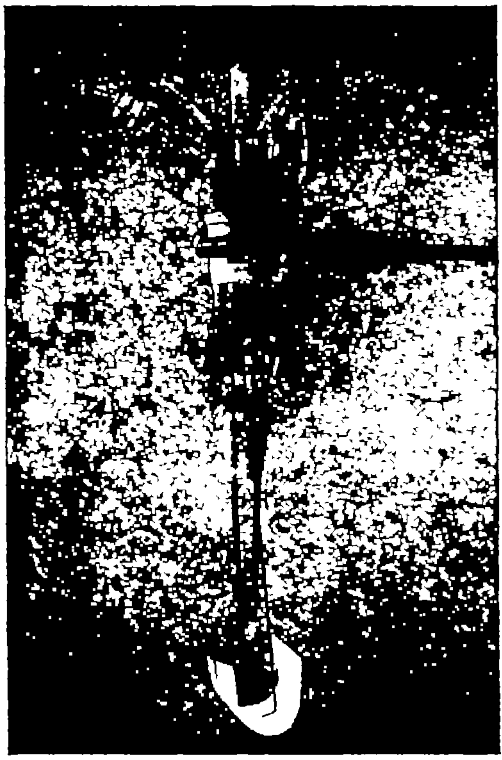

Fig. 1. Ignition head: 1, exhaust tube; 2a, electrode; 2b, electrode; 3a, to pressure gauge; 3b, to pressure gauge; 4, to oxygen cylinder; 5, fuse wire

each paper was spotted with 0·1 ml. of a concentrated 'carrier' solution containing 5-mg each of Cl⁻, Br⁻ and I⁻.

(*b*) A preliminary combustion of the paper was then carried out in a modified Shöniger flask in order to destroy the excess of reducing substances, unless the area of paper was less than 1 sq. in. The paper was fixed on a fuse wire and the ignition head (Fig. 1) was then placed in a 500-ml. flask, in the bottom of which had been placed a small beaker with 2 ml. saturated sodium hydroxide. By means of the exhaust tubing the flask was then evacuated (to < 100 mm mercury), and then filled with oxygen to 360 mm mercury, when ignition through the fuse from a 6-V battery could follow safely. After settling for 3 min, the flask was opened and the ignition head washed down with 10 ml. water and removed. After shaking, the flask was ready for use in the next step.

(c) Acid digestion was then carried out by adding 6 or 12 ml. 60 per cent chromium trioxide and 25 or 50 ml. 70 per cent sulphuric acid and heating to 190° C, and repeating this after cooling to 160° C.

(d) Distillation followed in a Chaney-type still; after adding 10 or 20 ml. phosphorous acid, distillation was continued for 15 min at 140°–150° C, a few ml. of hydrogen peroxide being added during this phase to facilitate transfer. The iodine evolved was trapped in 1 ml. 2 N sodium hydroxide and 2 ml. of 10 per cent sodium sulphite.

(e) Final purification of the distillate was effected first by precipitation as silver iodide by adding 1 per cent silver nitrate at 60° C after acidification with sulphuric acid, then by centrifugation, washing and drying the precipitate with acetone, followed by the addition of 11 ml. 10 per cent sodium sulphide, mixing and centrifuging and counting 10 ml. aliquots of supernatant.

The radioactive iodine was assayed in a well-type scintillation counter; a pulse height analyser, if available, would have improved the sensitivity of the assay. Preliminary experiments had shown that the counting efficiency was approximately equivalent whether an end-window Geiger–Müller counter was used for β-counting or a well-type scintillation counter for γ-counting, the counting efficiencies being estimated as 13·5 and 8·5 per cent respectively. Each sample was assayed to at least a 3 per cent statistical accuracy at frequent intervals, and the decay curves plotted in order to check radiochemical purity (see Figs. 2–4). Several of these curves had to be resolved into two components, but not those obtained after only half an hour's activation. Final estimates of the amount of iodine-127 were made by direct comparison of the unknown with the standard irradiated with it.

Some sample results are shown in Figs. 2–4. Note the single decay line after activation for 0·5 h (Fig. 2), and also of all standards, and that the paper blank did not reveal any iodine. The sensitivity is similar with either 0·5 h or 1 h activation, and corresponds to 3×10^{-9} g iodine-127. (This amount, that is, $2{\cdot}7$–$3{\cdot}7 \times 10^{-9}$ g iodine-127, was found to give count-rates twice those of background at 50 min after irradiation. We calculated that 0·29–0·39 μc. iodine-128/μg iodine-127 had been produced.) Recovery checks of the purification procedure showed, using iodine-131 as tracer, more than 80 per cent recovery (Table 1), and elimination of 99·9 per cent of bromine-82; the losses of chlorine should be at least as great.

Figs. 2–4 show that this is a practicable activation analysis. Our early experience had shown that it needed an adequate neutron flux (about 10^{12} n/cm^2/sec), and that if the entire paper was to be irradiated a stringent subsequent purification would be needed. The method described can be used to treat up to 6 sq. in. of paper, does not need a concurrent recovery check and apparently gives adequate purification. Other authors (Table 2) have described methods for activation analysis of iodine-127 applicable to blood, extracts or paper chromatograms, using equivalent or greater neutron fluxes and irradiation times of 30 min, but they obtained lower recoveries after less stringent purification procedures and were limited to small pieces of paper. Two of these have been applied to serum[4,5], and the third[6] to chromatograms. Their reported sensitivities were equivalent to our own, ranging from 10^{-9} to 10^{-10} g iodine.

The method described, needing 1 h for radiochemical purification, should be applicable with higher sensitivity than we found, for our counting had not usually begun until 2–2½ h (Figs. 2–4) after the sample left the pile, because of delay in their delivery to the laboratory. Following 1 h activation, evidence of a long-lived contaminant emerged in our rather delayed counts at 2½–4 h from the pile (Figs. 3 and 4); this may have been sodium-24 (half-life = 15 h), or iodine-126 (half-life = 13 days). Iodine-126 seems an unlikely product as the threshold for the iodine-127 (n, 2n) iodine-126 reaction is approximately 10 MeV, and the percentage of such fast neutrons in *Bepo* is very small. Samples obtained after activation for 0·5 h (Fig. 2) were free from this contaminant, which earlier assay should also minimize.

Activation analysis, although practicable, need not supplant the useful ceric–arsenite method. We have found[6] that this latter method can detect iodine compounds on chromatograms over the range 0·006–0·8 μg iodine, and so its sensitivity, reaching to 6×10^{-9} g iodine, is comparable with that of activation analysis. However, this ceric–arsenite method may give false indication of iodine, as, for example, with the reducing agents of the thiourea group, which had been recently found to give artefacts on chromatograms[1]. Fortunately, activation is available as a useful check whenever the specificity of the ceric–arsenite method comes in doubt.

We thank Dr. G. E. Harrison of the Medical Research Council Radiobiological Research Unit, Harwell, who put his laboratory at our disposal for these experiments.

ASSAY OF TRITIUM, CARBON-14 AND SULPHUR-35 IN WOOL BY LIQUID-SCINTILLATION COUNTING

By A. M. DOWNES and A. R. TILL

C.S.I.R.O., Division of Animal Physiology, The Ian Clunies Ross Animal Research Laboratory, Prospect, New South Wales, Australia

IN the past we have assayed sulphur-35 in wool, labelled biosynthetically, by end-window Geiger–Müller counting of the wool itself or of benzidine sulphate prepared from it[1]. Wool labelled with carbon-14 has been assayed either by the end-window technique or by combusting the sample and gas-counting the resulting carbon dioxide by the method of Bradley, Holloway and McFarlane[2].

Recently we have found that wool labelled with these isotopes or with tritium can be assayed directly by the liquid-scintillation method. Samples were clipped from three sheep which had received an intravenous injection of DL-[^{3}H]lysine, L-[^{14}C]phenylalanine and L-[^{35}S]cystine respectively. Each batch of wool was washed successively with ether, ethanol and water, and was dried overnight at 105° C. Samples were then weighed into screw-cap vials, and 18 ml. of toluene containing 2,5-diphenyloxazole (0·4 per cent w/v) and 1,4-*bis*-2-(5-phenyloxazolyl)-benzene (0·01 per cent w/v) was added to each. The radioactivity was then assayed in a liquid-scintillation counter ('Tri-Carb 314*EX*', Packard Instrument Co., La Grange, Illinois), at 0° C under 'balance point'[3] conditions, with background counting rates of 30–35 c.p.m. depending on the actual settings.

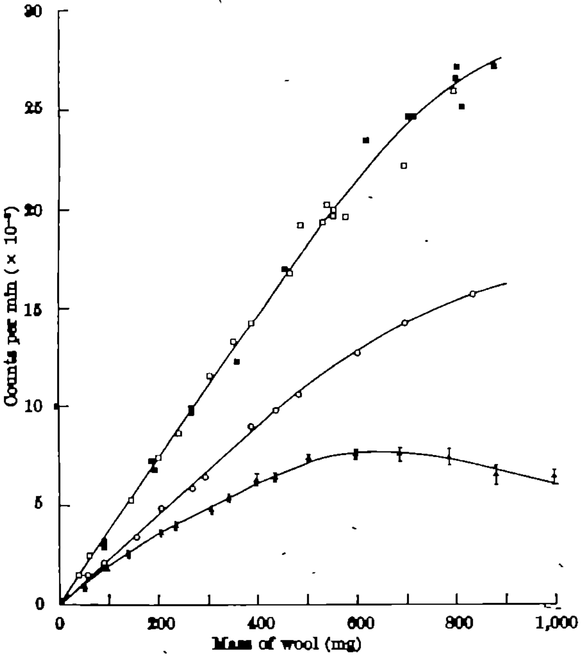

Fig. 1. Relationship between counting rate and mass of wool for three samples of wool labelled with single isotopes

○, ^{14}C-wool; ■, □ ^{35}S-wool samples counted 12 weeks apart; ▲, △ ^{3}H-wool samples counted 2 weeks apart; vertical lines are ± *S.D.*

The results are shown in Fig. 1. The counting rates were proportional to the mass of ^{14}C- or ^{35}S-labelled wool up to approximately 500 mg, but with larger amounts the counting rate per g fell progressively. In the case of the ^{3}H-labelled wool the relationship between counting rate and mass was almost linear up to about 200 mg. With larger amounts the counting rate per g fell much more rapidly than for ^{14}C- or ^{35}S-labelled wool until, over the range 500–800 mg, a plateau was reached over which the counting rate was practically constant. The departure from linearity in all cases is due to absorption of light photons with consequent loss of counts. Within the linear ranges for carbon-14 and sulphur-35, or within the plateau region for tritium, the results have a standard deviation of about ± 3 per cent. As indicated in Fig. 1 there was no change in the counting efficiency over a period of 12 weeks.

A linear relationship between counting rate and mass was also obtained with ^{14}C- and ^{35}S-labelled wool in a liquid-scintillation counter of the single-tube type (Ekco type *N*664) which was operated at room temperature with a background of 70 c.p.m. The efficiencies for these isotopes were comparable with those for the coincidence type of instrument, but the curves were linear only up to 200 mg of wool.

The counting efficiency was determined by comparing the results with those obtained by oxidizing samples (100 mg) of each lot of wool by the oxygen-flask technique, substantially as described by Kalberer and Rutschmann[4]. The combustion products from tritiated wool were shaken with 7 ml. methyl cellosolve. Those from wool labelled with carbon-14 or sulphur-35 were shaken with 12 ml. ethanolamine/methyl cellosolve (1 : 9, v/v). Measured amounts (5 and 10 ml. respectively) of the resulting solutions were then mixed with 9 ml. of the scintillating solution previously described, and the counting rates measured in the 'Tri-Carb' counter, again under balance-point conditions. The efficiency of counting tritium and carbon-14 under these conditions was established by assaying accurately weighed amounts of [^{3}H]hexadecane (2 μc./g) and of sodium [^{14}C]carbonate (0·9 μc./g aqueous solution), each of which was calibrated and supplied by the Radiochemical Centre, Amersham. The results in Table 1 show that carbon-14 and sulphur-35 were detected with approximately the same efficiency by the two methods, and that tritium was detected 6·6 times as efficiently by the oxidation technique as by the direct method. These results appear reasonable when the maximum ranges for the β-particles from tritium, carbon-14 and sulphur-35 (2·3, 285 and 317μ respectively[5] in material with a density of 1), are compared with the average radii of wool fibres (7–15μ) from fine- to strong-wool Merino sheep. (The apparent specific gravity of wool[6] in toluene is 1·306.)

Table 1. COMPARISON OF LIQUID-SCINTILLATION COUNTING OF WHOLE WOOL AND OF WOOL OXIDIZED BY THE OXYGEN FLASK TECHNIQUE

Isotope	Counts/min/mg wool ± *S.D.* Direct	Counts/min/mg wool ± *S.D.* Oxidized
^{3}H	2·01 ± 0·05	18·2 ± 0·4 (7·42% *)
^{14}C	21·5 ± 0·7	23·5 ± 0·5 (48·4% †)
^{35}S	42·9 ± 1·1	41·7 ± 1·8

* Efficiency measured by assay of standard [^{3}H]hexadecane.
† Efficiency measured by assay of standard sodium [^{14}C]carbonate.

Using Libby's equation[7] for the absorption of the β-particles from carbon-14 and sulphur-35 it may be calculated that a 50 per cent change in the average diameter of the wool fibres would produce no more than a 4 per cent change in the counting rate/g. Thus, reliable relative values for the specific activity of wool samples labelled with these isotopes can be obtained, even in experiments resulting in marked changes in fibre diameter.

Wool fibres labelled with tritium apparently behave as 'infinitely' thick sources. If the tritium is assumed to be distributed uniformly throughout the fibre, the counting rate will be proportional to the volume of the outer annulus from which the β-emission is detectable. This volume equals $\pi l(r^2-(r-R)^2)$, or more simply $\pi l(2Rr-R^2)$, where l is the length of the fibre, r is the radius and R is the thickness of the annulus. The extra radioactivity detected at the ends is negligible for fibres more than 500μ long (about 2 days' growth). Therefore the proportion of the total radioactivity that is counted in wool of uniform specific activity will equal the volume of the annulus multiplied by a constant (k) to allow for self-absorption in the annulus, and divided by the total volume of the fibre:

$$\text{Proportion of tritium counted} = \frac{k\pi l(2Rr-R^2)}{\pi r^2 l} = \frac{k(2Rr-R^2)}{r^2} \qquad (1)$$

Since the average range of the β-particles is small by comparison with the radii of the wool fibres, equation (1) may be further simplified:

$$\text{Proportion of tritium counted} \doteqdot \frac{K}{r} \qquad (2)$$

where K is a constant. Thus the counting rate per g of wool will be approximately proportional to the inverse of the average radius of the fibres. More care will obviously be needed in using the direct method for wool labelled with tritium.

The direct counting of wool is much quicker and easier than the methods used previously. It is accurate and, because of the high efficiencies and relatively large sample sizes, is very sensitive. For example, to produce a net counting rate of 30 c.p.m. (that is, equal to the background rate) from 0·5 g of wool a specific activity of 6×10^{-5} μc./g would be required for carbon-14 or sulphur-35, and 3×10^{-3} μc./g for tritium.

DISTANCES OF ATOMS FROM THE 'BEST' PLANES OF CHOLESTERYL IODIDE

By DR. DORITA A. NORTON and JEAN M. OHRT
Biophysics Department, Roswell Park Memorial Institute, Buffalo, New York

THE configuration of the cholesteryl iodide molecule may be quantitatively described by referring its atoms to the series of planes ($A1$, $A2$, $A3$, etc.) illustrated in Fig. 1. The structure of cholesteryl iodide (form B, $P2_1$, a_0 = 12·57 Å, b_0 = 9·04 Å, c_0 = 21·89 Å, β = 149°) was determined by Carlisle and Crowfoot[1]. The fractional monoclinic atomic co-ordinates of Carlisle and Crowfoot (x, y, z) were converted to cartesian atomic co-ordinates in angstroms (p, q, r) as follows: $p = a_0 \sin\beta$, $q = b_0$, and $r = zc_0 + xa_0 \cos\beta$. The p, q, r co-ordinates were afterwards used for calculating the equations ($ax + by + cz = d$) of the best planes of the cholesteryl iodide molecule, the coefficients of which are given in Table 1. The root mean square distances of the atoms from one or several of the best planes have also been calculated and are listed in Table 2. The perpendicular distance of each atom from one or more of the best planes is recorded in Table 3, in which atoms lying between the origin of the unit cell and the plane have a negative value, whereas those lying on the opposite side of the plane from the origin have a positive value.

The best plane through all the carbon atoms of the cholesteryl iodide molecule has the equation $0·08x + 0·99y - 0·03z = 2·22$. The root mean square distance of carbon atoms (C_1–C_{27}) from this plane is 0·58 Å. The root mean square distance of carbons C_1–C_{17} from the best plane ($0·23x + 0·97y - 0·01z = 2·71$) through the steroid nucleus is 0·28 Å. The root mean square distances of the atoms comprising each of the planes which represent

the major subdivisions of the steroid nucleus, all of rings *A*, *B*, *C* and *D* are respectively 0·29 Å, 0·17 Å, 0·26 Å and 0·14 Å. If the ring system is further subdivided, *A*1, *A*2, *A*3, etc., we obtain a series of best plane equations (Table 1) which may be used to describe the intra-ring chair configuration of atoms. When used as references for the calculation of root mean square distances (Table 2), these equations also illustrate the degrees of planarity of the various portions of the intra-nuclear chair configuration. Thus it can be seen that the 'seat' portion of the chairs or partial chairs concerned, namely, *A*2, *B*2, *C*2 and *D*2, exhibit nearly the same degree of planarity with root mean square distances of 0·11 Å, 0·10 Å, 0·07 Å and 0·18 Å.

The angles between the various best planes of the intra-ring components have been calculated and are shown in Table 3. On consideration of these angles, the following steric features of the cholesteryl iodide molecule are evident:

(1) Chair *A* is unsymmetrical with angles of 117° (*A*1 ∧ *A*2) and 137° (*A*2 ∧ *A*3).

(2) Chair *B* is unsymmetrical with angles of 175° (*B*1 ∧ *B*2) and 146° (*B*2 ∧ *B*3), the approach of angle *B*1 ∧ *B*2 to 180° reflecting the presence of the double bond between C_5 and C_6.

(3) Chair *C* is more or less symmetrical with angles of 132° (*C*1 ∧ *C*2) and 129° (*C*2 ∧ *C*3).

(4) The join *B*3*C*1 is essentially planar, as is shown by both the 176° angle *B*3 ∧ *C*1 and the 0·04 Å root mean square distance of atoms C_7, C_8, C_9 and C_{11} from the *B*3*C*1 best plane ($0{\cdot}19x + 0{\cdot}87y + 0{\cdot}45z = 4{\cdot}80$).

(5) The *A*3*B*1 and *C*3*D*1 joins have angles of 134° and 161° respectively.

The root mean square distances of the cholesteryl iodide molecule may be compared with those of 4-bromoœstrone[3] and 4-bromoœstradiol[4]. A surprising similarity exists among the distances of atoms from the steroid nucleus, these being 0·28 Å, 0·26 Å and 0·24 Å respectively. Other similarities are seen where the distances are respectively: (*a*) 0·26 Å, 0·27 Å and 0·26 Å in ring *C*; (*b*) 0·07 Å, 0·00 Å, and 0·04 Å in ring *C*2; and (*c*) 0·14 Å, 0·18 Å, and 0·22 Å in ring *D*. In cholesteryl iodide the root mean square distance of atoms from ring *A* is 0·29 Å, whereas in the two œstrogens the average root mean square distance is 0·025 Å. This dissimiliarity is due to the dissimilarity of the bonding structure of the *A*-ring in the three compounds; in cholesteryl iodide it is saturated, while in the two œstrogens it is aromatic. Root mean square distance dissimilarity due to dissimilar bond distribution is also exemplified by ring *B*, which in cholesteryl iodide

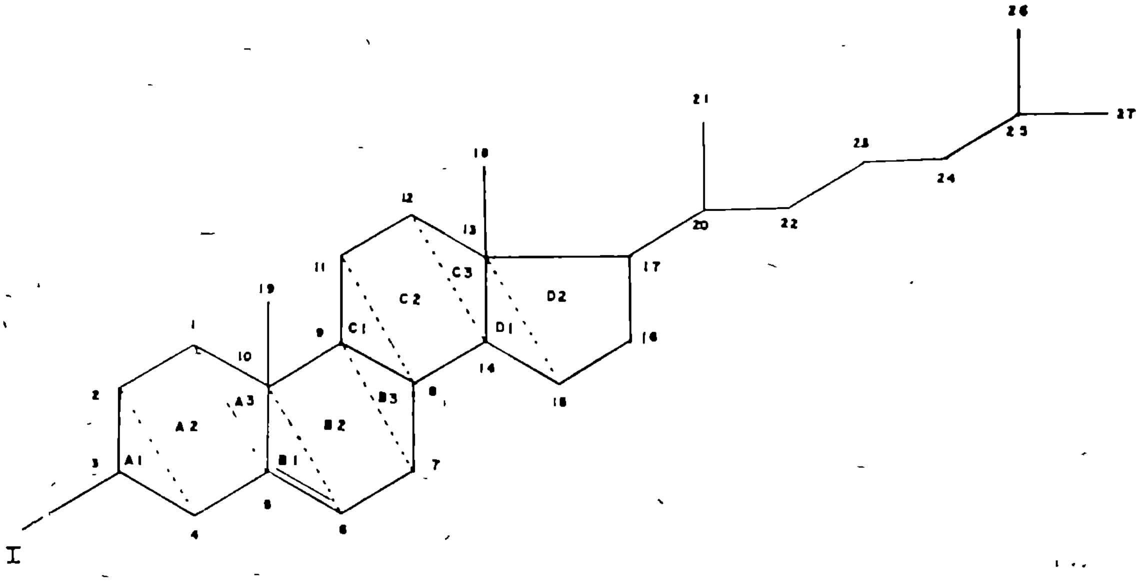

Fig. 1. Cholesteryl iodide

has a distance of 0·17 Å and in 4-bromooestrone and 4-bromooestradiol has distances of 0·29 Å and 0·23 Å respectively. A root mean square dissimilarity, which is effected by changes in side group bonding, is illustrated by ring *D*2, in which the distances are 0·18 Å, 0·01 Å and 0·12 Å respectively.

In view of the evidence presented here, it is clear that the root mean square distances of atoms from the best planes of equivalent portions of the steroid nucleus are approximately equal, except when disrupted by variations in the bonding scheme.

CYTOLOGICAL DEMONSTRATION OF THE CLONAL NATURE OF SPLEEN COLONIES DERIVED FROM TRANSPLANTED MOUSE MARROW CELLS

By DR. A. J. BECKER, E. A. McCULLOCH and J. E. TILL
Department of Medical Biophysics, University of Toronto and Ontario Cancer Institute, Toronto

IN normal mouse hæmatopoietic tissue, there is a class of cells which, on being transplanted into heavily irradiated mice, can proliferate and form macroscopic colonies. In the spleen, the colonies formed in this manner are discrete and easy to count[1,2]. Microscopically, each colony appears as a cluster of hæmatopoietic cells, many of which are dividing; and often, within a given colony, the cells which are observed indicate that differentiation is occurring along three lines, into cells of the erythrocytic, granulocytic and megakaryocytic series, respectively[1].

In vitro techniques, which permit investigations of clonal populations, have greatly advanced the knowledge of the genetic and physiological properties of cells[3]. It was therefore desirable to prove whether or not spleen colonies each develop from single cells and hence are clones; for if they are, it would be possible to study clonal populations of hæmatopoietic cells *in vivo*. Evidence from previous experiments supporting the view that the colonies are clones is as follows: (1) the curve relating the number of nucleated marrow cells that are transplanted to the number of colonies that develop in the spleen is linear, and shows no initial threshold[1,2]; (2) the radiation survival curve of cells that can form colonies closely resembles the survival curves obtained for single cells in cell culture[4] or tumour transplants[5]. These observations provide only indirect evidence that the colonies are clones. It seemed desirable, therefore, to attempt to obtain direct evidence for the unicellular origin of the colonies.

At first glance the easiest way to accomplish this aim would be to make use of marrow cells that have a known chromosome marker, such as that found in *T*6/+ mice[6], and to transplant into irradiated mice a mixture of marrow cells with a marker and marrow cells with no marker. If the colonies that developed in the spleen were always composed of cells with markers or cells without markers it would, of course, suggest the single-cell origin of colonies; but it would not prove the single-cell origin of colonies, because the experiment would not rule out the possibility that the dispersion of donor cells was not complete and that the injected material contained undispersed aggregates of two or more cells which were the units that gave rise to colonies. The procedure used for ruling out this possibility was based on the observation of Barnes *et al.*[7] that the re-population of the hæmatopoietic organs of heavily irradiated mice could be accomplished by a small number of cells, and that the clones originating from these few cells were sometimes characterized by unique abnormal karyotypes. This suggested that if heavily irradiated marrow were utilized for the formation of spleen colonies, some of the cells containing chromosome aberrations, generated at random by radiation, might retain the ability to proliferate and give rise to progeny carrying a recognizable, persistent chromosome abnormality. If a spleen colony develops from one such cell, it would be expected that all the cells of the colony would carry the same abnormality. If, however, a spleen colony derives from an undispersed aggregate of two or more cells, one would not expect all the cells of the colony to have the same abnormal karyotype, since the probability of inducing by radiation the same abnormality in two or more cells of an aggregate is vanishingly small.

The details of the spleen colony technique and the radiation procedures involved have been described elsewhere[1,2]. The particular procedure in the present experiment was to expose recipient Swiss mice of either sex to an initial X-ray dose of 250 rads. Each mouse then received an injection of 10^7 nucleated bone-marrow cells, obtained from the femora of female donors of the same strain. After an interval of 1 h, the host mice, bearing the transplanted cells, were irradiated using a cobalt-60 γ-ray source with two doses of 325 rads each, separated by an interval of 4 h. In this way, the transplanted cells received a total dose of 650 rads *in vivo*, while the host received the larger dose of 900 rads necessary to suppress the proliferation of its own colony-forming cells. As predicted from previous experiments[8], this radiation schedule yielded spleens containing small numbers of discrete colonies.

Eleven days later, all recipient mice were injected intraperitoneally with 'Colcemid' (desacetylmethyl colchicine, Ciba) and killed approximately 1 h afterwards. Their spleens were removed and individual discrete colonies were carefully dissected out. The colonies were then prepared for chromosomal analysis according to a modification of the method of Fox and Zeiss[9].

Each colony was placed in 2 ml. of phosphate-buffered saline which was then diluted in 4 equal steps, with distilled water, to 5 times its original volume. An interval of 10–15 min was allowed to elapse after each dilution step. The colonies were fixed for 1 h in a solution of 3 parts absolute alcohol and 1 part glacial acetic acid at 4° C. They were then transferred into a solution of 40 per cent acetic acid (4° C) where they were kept for a period of 1–2 h. Each colony was afterwards transferred into 0·5 ml. of 60 per cent acetic acid (4° C) in a small plastic cup where it was teased apart by two fine needles and suspended by gentle pipetting. Small drops of this suspension were placed on the surface of a microscopic slide which had been frozen in the manner described by Fox and Zeiss[9]. The slide was immediately heated and dried over a gentle Bunsen flame. Staining was performed under a coverslip with 2 per cent aceto-orcein.

Slides from each colony were systematically scanned under 100 times magnification and every metaphase cell which appeared sufficiently well spread without its cytoplasm being ruptured was carefully searched under oil-immersion, at 1,000 times magnification, for the presence of an abnormal karyotype. If the first 25 meta-

phase cells of any given colony so examined failed to reveal a readily identifiable chromosome aberration, that colony was scored as containing no obvious marker. Since female donor marrow was used, the presence, in the cells of the colonies examined, of the third unpaired small chromosome characteristic of the male karyotype[10] was avoided; this facilitated identifying any odd minute chromosome encountered as a radiation-induced marker.

A total of 42 colonies obtained from 36 animals were examined in the foregoing manner. Of these colonies, 4 contained cells with an obviously abnormal karyotype. Table 1 summarizes the types of chromosome markers encountered and the frequencies of these markers within the cells of each colony. For example, mitotic figures from colony *A* showed three characteristic abnormalities: (1) a modal chromosome number of 39; (2) an abnormally small chromosome; (3) an abnormally long sub-telocentric chromosome (Fig. 1, top). Eighty-one of 100 metaphase cells examined manifested all three abnormalities; and 99 per cent of the cells contained at least one of these distinguishing characteristics. The occasional inability to score one or the other of the two markers is probably the result of the following technical difficulties: (1) cytoplasmic rupture and chromosome loss; or (2) excessive overcrowding and overlapping of chromosomes in less-than-optimally spread metaphase cells. In the latter circumstance, whenever it was impossible to delineate with certainty one or other of the marker chromosomes, the cell was scored as lacking that particular marker. Of the 3 cells from colony *A* which were recorded as containing 40 chromosomes, two were very difficult to count because of overcrowding of the chromosomes, and the chromosome number recorded for them may represent a miscount. Similar considerations are applicable to the interpretation of the data compiled for the other 3 marked colonies. A representative complement from colony *C* is shown in Fig. 1 (bottom). It is characterized by an abnormally small chromosome and a long chromosome which is either a dicentric or has a prominent secondary constriction.

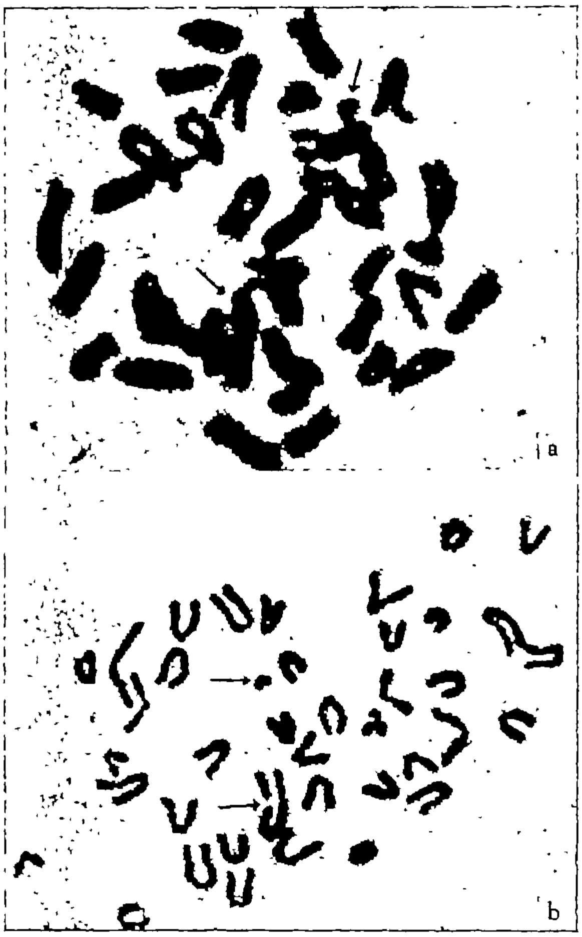

Fig. 1. Representative chromosome complements from two of the colonies listed in Table 1. The abnormal chromosomes are indicated by arrows. (× 1,430)
a, Colony *A*, the chromosome count is 39 instead of the normal 40; *b* colony *C*

Experiments were performed to test for the presence of pre-existing abnormal karyotypes among the colony-forming cells of normal donor marrow. Groups of Swiss mice were exposed to total-body doses of 900 rads; and, following irradiation, each mouse received 5×10^4 nucleated bone-marrow cells from female donors of the same strain. No further irradiation was given. Of 55 colonies examined from these controls, all contained, exclusively, mitoses with the normal female diploid complement of 40 chromosomes. This finding rendered unlikely the existence, within the donor marrow, of uniquely and uniformly marked colony-forming cell aggregates. The 4 abnormal karyotypes were thus the result of chromosome damage by ionizing radiation.

The results given in Table 1 show that when recognizable marker chromosomes are present in the cells of a colony, an overwhelming majority of the cells contain the same markers. Since normal mouse marrow contains no uniquely and uniformly marked colony-forming cell aggregates, and since chromosome breakage by radiation is a random process, rendering highly improbable the generation of an identical abnormality in each of the cells of a hypothetical colony-forming aggregate, it can be concluded that all the cells in these marked colonies were derived from a single cell in which a chromosome aberration was induced by radiation. Thus, in every colony where direct cytological evidence is available this evidence indicates that the colony is a clone. Because the karyotype of the mouse does not permit the identification of individual autosomes, only gross changes in the chromosomes may be identified readily. In the experiments reported here, this was possible for only approximately 10 per cent of the colonies. Nevertheless, if the direct cytological evidence is considered together with the indirect support provided by the dilution and radiation-survival data, the general view that spleen colonies are clones is a most reasonable conclusion. The spleen colony procedure may, therefore, be regarded as an *in vivo* single-cell technique, analogous to the well-known *in vitro* single-cell experimental systems[9]. The advantages inherent in the clonal approach to the study of cell biology are thus available for future investigations on hæmatopoiesis.

We thank Dr. A. A. Axelrad for his advice and Miss R. Wyncoll and Messrs. P. Csordas and J. Hicks for technical assistance. This investigation was supported by the Defence Research Board (grant 9350-14), the National Cancer Institute of Canada, and the Medical Research Council, Canada (grant *MA* 1282). One of us (A. J. B.) is a Fellow of the Medical Research Council, Canada.

Note added in proof. In the four additional marked colonies encountered after the submission of this article, the markers have been unique and present in all the cells.

ELASTASE AND THROMBOGENESIS

By Dr. D. A. HALL and Dr. JEAN E. WILKINSON
Department of Medicine, University of Leeds

DURING the past two decades numerous theories have been developed concerning the various lesions associated with arterial disease. To account for the topographically discrete nature of the mural thrombi implicated by one such hypothesis[1], the suggestion has been made that some fundamental change in the vessel wall must precede fibrin deposition[2]. Although absorption on surfaces such as glass can activate certain of the factors necessary for plasma coagulation[3] *in vitro*, the physical state of the surface of the vessel wall would not appear to determine the site of thrombogenesis since arterial grafts and traumatized regions[4] do not necessarily promote clot formation. The reason for the localization of thrombus formation remains a mystery, and observations which increase the chances of explaining the phenomenon may be of prime importance as starting points for future research and for attempts at therapy.

Since the physical properties of the intimal surface alone cannot explain the vagaries of thrombus production, one must consider the possibility of other changes in the vascular tissue, causing local alterations in the equilibrium between fibrogenesis and fibrinolysis; an equilibrium which under normal conditions would appear to determine the fluidity of the circulating plasma[5]. Activation of the former process or inhibition of the latter could produce the desired effect. We discuss in the present article certain observations which point to the possible existence of localized centres of clotting activation.

The clotting mechanism consists of a complex interplay of factors derived from plasma, platelets and tissue, and activation of the clotting process with the resultant formation of mural thrombi could be due to the localization of one or more of the essential components on the surface of the vascular tissue.

The pancreatic enzyme elastase is not normally considered as a component of the clotting system, but it has been demonstrated that the presence of low concentrations of elastase appreciably shortens the clotting time *in vitro*[6]. The point of intervention of the enzyme has not been proved although Bagdy has shown that it occurs much earlier than the transformation of fibrinogen to fibrin[7]. The results illustrated in Fig. 1 indicate that elastase may in fact act on the platelets, assisting in the release of various platelet factors. Carefully collected platelet-rich plasma responds to the addition of increasing concentrations of elastase over a range of 0–25 μg/ml. to give increasingly shorter recalcification times[8], but this response disappears completely if the platelets are previously degraded by mechanical manipulation.

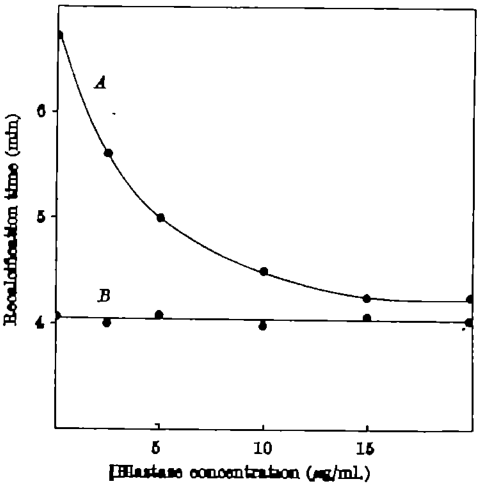

Fig. 1. A typical effect of free elastase on the recalcification time of: *A*, platelet-rich plasma; and *B*, plasma with mechanically degraded platelets. The mixture contained 0·1 ml. 0·2 M sodium chloride, 0·1 0·033 M calcium chloride, 0·1 ml. citrated plasma from a 21-year-old normal male and the appropriate amount of elastase (E_1I^{14}) dissolved in 0·1 m. 0·9 per cent sodium chloride and was incubated at 37° with gentle inversion in a polythene-stoppered tube, following the addition of the plasma

One difficulty which arises in any attempt to associate elastase with systemic activity is the fact that, not only has the enzyme never been identified in plasma but also its acinar origin[9] would appear to preclude a systemic function. Rationalization of these facts with the observations that elastase fed to animals has marked systemic activity[10] may indicate that readsorption through the intestinal mucosa may be possible. The failure to identify elastase in plasma may mean that it is never present at levels high enough for estimation and this may imply that elastase passes rapidly into an immobilized state, possibly by adsorption on to the vascular tissue. Evidence in favour of this hypothesis is already available.

Saxl[11] and Yu and Blumenthal[12] have reported the presence in aortic tissue of a substance variously described as a lipoprotein or mucopolysaccharide but having properties of both and possibly identifiable as a lipomucoprotein. This material, described by Saxl as present throughout the aorta of young subjects, but progressively disappearing from the lumen outwards with age, prevents the dissolution of aortic tissue (frozen sections) under the action of elastase alone. When isolated from aortic tissue[12] it has the power of inhibiting elastolysis *in vitro* by attachment to the substrate rather than to the enzyme. Whether such a complex is still capable of adsorbing elastase is still without proof, but it has been shown[13] that elastin modified by acetylation[14] is capable of adsorbing twice as much enzyme while its susceptibility to elastolysis is reduced by 80 per cent. It may also be significant that the only reported preparation of elastase from mammalian tissue outside the pancreas is that by Gore and Larkey[15] in a crude polysaccharide fraction from aorta. The possibility may exist therefore that elastase becomes adsorbed on to vascular tissue, and evidence is available in support of the concept that in this condition it is capable of intervening in the clotting reaction.

Pancreatic elastase[16] differs from the enzyme derived from bacterial sources in that all attempts to separate elastolytic activity (with solid elastin as substrate) from generalized proteolysis (with soluble proteins such as α-elastin, casein, insulin, etc., as substrates) have been without success[17]. In this enzyme therefore it would appear that both types of activity are essential functions of one molecular species.

The differing rates at which elastase attacks elastin and other proteins[18] may be due to either of two reasons: the physical state of the two types of substrate may affect the rate even if the active centres are identical, or alternatively the enzyme may have two active centres. Recently, evidence has been presented in support of this latter concept[19]. Human plasma inhibits the elastolytic system competitively, whereas its effect on the generalized proteolytic system is non-competitive. From a topographical point of view, this may indicate that whereas the inhibitor attaches itself to the centre through which the enzyme and substrate react in the case of elastolysis, this point of attachment is not the site of enzyme substrate complex formation in the case of generalized proteolysis. The enzyme may therefore be assumed to have two dissimilar active centres.

Because of this property it is theoretically possible for elastase to react simultaneously with two substrates, and if, as suggested here, one of these is solid elastin the proteolytic system will assume the same form as the original elastolytic system but in reverse, the enzyme being solid and the substrate in solution.

Experiments have been carried out to determine whether elastase adsorbed in this fashion on a solid substrate still has the power to take part in the clotting reaction as estimated by the determination of recalcification times[6]. To simplify the system, purified elastin[20] was used rather than whole elastic tissue and this was suitably modified by acetylation[14] to increase the degree of elastase adsorption while suppressing elastolysis. Since the amount of elastase taken up by acetylated elastin (59 per cent of the amount present in the surrounding fluid) is dependent on this latter concentration, it proved impossible to remove excess elastase by washing before the addition of the components of the recalcification system since both the wash water and the plasma and calcium chloride solutions added afterwards would elute elastase from the acetylated elastin. Systems were therefore prepared in the presence and absence of acetylated elastin and measurements of recalcification times made at a variety of enzyme concentrations.

Direct assessment of the effects of acetylated elastin over the range of enzyme concentrations referred to here was rendered difficult on account of a marked prolongation of clotting time, which was apparent in systems in which the modified elastin was added alone to the other components of the recalcification system. This phenomenon was not investigated further, but was presumably brought about by the adsorption of certain unspecified components of the clotting system on the surface of the solid. However, use could be made of a variation in response observed in about 50 per cent of the sera studied. In these cases the decrease in recalcification time over the range of elastase concentrations from 0–15 μg/ml. is followed at higher concentrations of enzyme by an increase and subsequent decrease, giving a region of minimum elastase effect at about 25 μg/ml. Movement of this trough to higher concentrations of elastase in systems containing acetylated elastin would indicate that the effective concentration of enzyme was altered by adsorption on to the solid. The results did not, in fact, show this movement. The curves (Fig. 2) obtained for a group of normal sera were compared and, allowing for the difference due to the basal effect of the solid, could be shown to be statistically identical. It may be assumed therefore that elastase has exactly the same activating effect on the clotting reaction when adsorbed on elastin as when free.

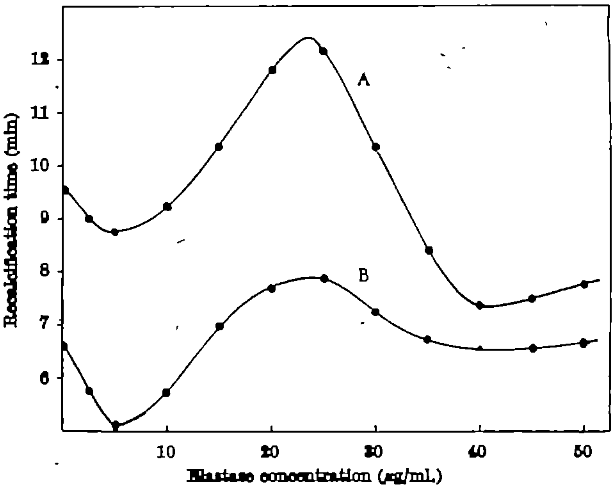

Fig. 2. The effect of elastase in: *A*, the free state; and *B*, adsorbed on acetylated elastin on the recalcification time of a typical plasma from a 19-year-old normal female. Conditions as in Fig. 1

In view of these observations, the suggestion may be made, as a working hypothesis, that elastase, adsorbed on to the lipopolysaccharide rich regions of aortic elastica, revealed following damage to the endothelial lining, may result in the presentation to the surrounding plasma of a proteolytic enzyme system capable of bringing about localized clotting and hence of initiating thrombus formation in these regions.

We thank the Medical Research Council for a grant and Mrs. B. Pearlman for her assistance.

β-HYDROXYASPARTATE PATHWAY: A NEW ROUTE FOR BIOSYNTHESES FROM GLYOXYLATE

By PROF. H. L. KORNBERG and DR. J. G. MORRIS
Department of Biochemistry, University of Leicester

WHEN micro-organisms grow on glycollate as sole source of carbon, reactions ancillary to the tricarboxylic acid cycle must occur to replenish, from the C_2-growth substrate, the intermediates of the cycle which have been removed in the course of cellular syntheses. In micro-organisms such as *E. coli* or *Pseudomonas* sp., the necessary net formation of tricarboxylic acid cycle intermediates is effected via the 'glycerate pathway'[1]. In this pathway, glyoxylate (derived from the oxidation of glycollate) undergoes a condensation reaction in which 2 mol. units of glyoxylate yield 1 mol. unit each of tartronic semi-aldehyde and carbon dioxide[2-4]: the enzyme catalysing this process has been named glyoxylic acid carboligase[3]. The tartronic semi-aldehyde thus formed is afterwards reduced[4-6] to glyceric acid with the aid of tartronic semi-aldehyde reductase. In the presence of adenosine triphosphate and *Pseudomonas* extracts, glyceric acid has been shown[5] to yield pyruvate, this transformation being effected by the well-established Embden–Meyerhof sequence. The net effect of these reactions is to transform 2 mol. units of glycollate to 1 mol. unit of carbon dioxide and 1 of pyruvate which can either be carboxylated to oxaloacetate[3] or, after oxidation to acetyl coenzyme *A*, condense with a third mol. unit of glyoxylate[8] to yield malate[8,9]: in either case, the *de novo* formation of intermediates of the tricarboxylic acid cycle from glycollate has been effected.

Although the reactions of the glycerate pathway have been demonstrated in a wide variety of micro-organisms (for review, see ref. 10), a major problem was posed by the observation that *Micrococcus denitrificans*, which grows readily on glycollate as sole carbon source with either oxygen or nitrate as electron acceptor, is devoid of the key enzymes of this pathway: no glyoxylic acid carboligase and only traces of tartronic semi-aldehyde reductase were detected in extracts of the glycollate-grown organism. The necessary nett formation of tricarboxylic acid cycle intermediates must therefore be achieved by a different route.

An indication of the nature of this route has been obtained from studies with glycollate-grown *M. denitrificans* and with cell-free extracts prepared therefrom. The results obtained are consistent with the view that the growth of *M. denitrificans* on glycollate as sole source of carbon involves a hitherto unknown metabolic route in which *erythro* β-hydroxyaspartate is an intermediate (Scheme 1). The main points of evidence in support of this scheme may be summarized as follows:

(1) When *M. denitrificans*, growing on glycollate, were incubated with [1-^{14}C]glycollate for brief periods, isotope appeared in glycine, malate and aspartate at the earliest times. In contrast to the results obtained with glycollate-grown *Pseudomonas*[5] and *E. coli*[9], no isotope was detected in glycerate or phosphoglycerate.

(2) Extracts of glycollate-grown *M. denitrificans*, prepared either by ultrasonic treatment or by passage through a French press, oxidized glycollate to glyoxylate: this oxidation was greatly stimulated by the addition of phenazine methosulphate.

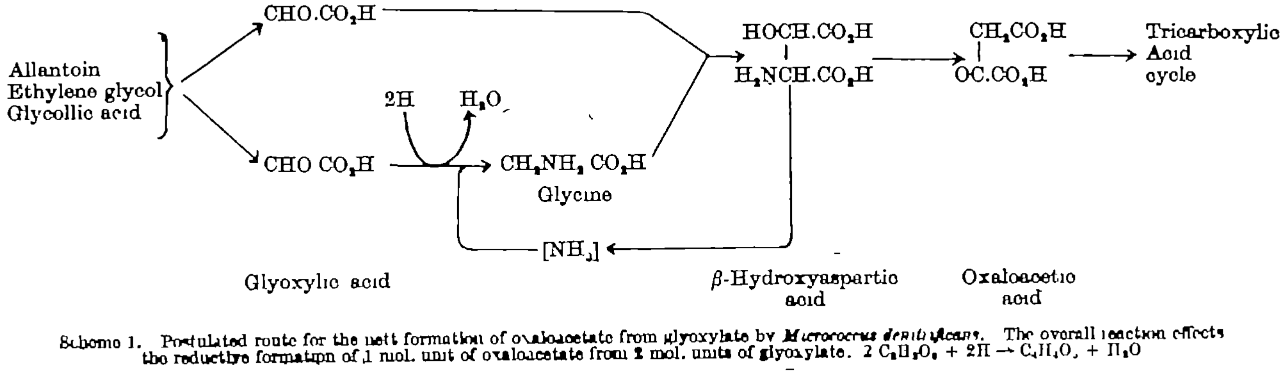
(3) Although *M. denitrificans* grew readily on glycollate, growth on glyoxylate was poor and on glycine, negligible. However, the addition of glycine to a medium, otherwise containing glyoxylate as sole carbon source, stimulated growth.

(4) Sonic extracts of the glycollate-grown organism catalysed the formation of oxaloacetate as measured by the increase in absorbancy at 262 mμ, when both glyoxylate and glycine were added: no such increase in absorbancy was detected if glyoxylate or glycine was added alone. The probable condensation product of glyoxylate and glycine, β-hydroxyaspartate, yielded oxaloacetate in this system at a rate greater than that observed with equimolar concentrations of glyoxylate and glycine.

(5) Sonic extracts, which were rich in a malate dehydrogenase capable of utilizing reduced nicotinamide–adenine dinucleotide phosphate ($NADPH_2$) as electron donor, catalysed the oxidation of $NADPH_2$ when glyoxylate, but not when glycine, was added. However, the rate of $NADPH_2$ oxidation in the presence of glyoxylate was greatly stimulated by the further addition of glycine. Synthetic DL-β-hydroxyaspartate[11] reacted in this system at a rate greater than was found with equimolar concentrations of glyoxylate and glycine: after resolution of the synthetic substrate, it was established[12] that only the *erythro* isomer reacted.

(6) In the presence of $NADPH_2$ or a $NADPH_2$-generating system, the crude extracts catalysed the formation of labelled malate from either [1-^{14}C]glyoxylate and unlabelled glycine or from [1-^{14}C]glycine and unlabelled glyoxylate. The yield of labelled malate was decreased considerably if $NADPH_2$ or the unlabelled substrates were omitted from the incubation mixtures. In these experiments, the formation of labelled β-hydroxyaspartate was also detected.

(7) When extracts were incubated with DL-*erythro* β-hydroxyaspartate and semi-carbazide, at *p*H 6·5, the absorbancy at 252 mμ increased linearly at a rate proportional to the quantities of extract and of substrate added: this indicated the enzymatic formation of the $\rangle C{=}N-$



Scheme 1. Postulated route for the nett formation of oxaloacetate from glyoxylate by *Micrococcus denitrificans*. The overall reaction effects the reductive formation of 1 mol. unit of oxaloacetate from 2 mol. units of glyoxylate. 2 $C_2H_2O_3$ + 2H → $C_4H_4O_5$ + H_2O

linkage of a semi-carbazone. The product of the reaction, converted to the 2,4-dinitrophenylhydrazone and analysed by paper chromatography, was found to be identical with the derivative formed from authentic oxaloacetate[11]. Labelled β-hydroxyaspartate, eluted from chromatograms (see paragraph 6), yielded radioactive oxaloacetic 2,4-dinitrophenylhydrazone in this system.

(8) When extracts of glycollate-grown cells were incubated anaerobically with oxaloacetate, adenosine triphosphate, and cobalt sulphate (under assay conditions similar to those described by Utter and Kurahashi[13]), the rapid evolution of carbon dioxide indicated the presence of phosphopyruvate carboxylase (*E.C.* 4.1.1.32). When [1-^{14}C]glyoxylate and unlabelled glycine were used as enzymatic precursors of oxaloacetate, the carbon dioxide evolved was highly radioactive whereas pyruvate, isolated as the 2,4-dinitrophenylhydrazone, contained only traces of isotope. With unlabelled glyoxylate and [1-^{14}C]glycine, on the other hand, the pyruvate isolated was highly radioactive and the evolved carbon dioxide contained relatively little isotope. Since *erythro* DL-β-hydroxyaspartate also reacted rapidly as enzymatic precursor of pyruvate and carbon dioxide in this system, these findings suggest[12] that β-hydroxyaspartate, formed from glyoxylate and glycine, is transformed to oxaloacetate via a dehydratase similar in action to other dehydratases known to act on α-amino-β-hydroxyacids (*E.C.* 4.2.1.13–4.2.1.16).

(9) The enzyme responsible for the enzymatic formation of oxaloacetate from *erythro* β-hydroxyaspartate, tentatively named 'β-hydroxyaspartate dehydratase'[12] was also present in high activity in extracts prepared from *M. denitrificans* grown on glyoxylate, glyoxylate plus glycine, or substrates known to be catabolized to glyoxylate (such as ethylene glycol or allantoin), as carbon sources. Extracts from cells which had been grown on acetate or succinate were virtually devoid of this enzyme.

(10) Succinate-grown *M. denitrificans*, placed into growth medium containing glycollate as sole carbon source, rapidly formed β-hydroxyaspartate dehydratase during the lag period prior to the onset of growth. When succinate-grown cells continued to grow in a medium containing 5 mM succinate and 25 mM glycollate as carbon source the initial period of logarithmic growth was followed by a stationary phase, which was again followed by renewed growth. During this typical diauxic lag, the low levels of β-hydroxyaspartate dehydratase increased approximately ten-fold and reached a level which was maintained during the subsequent growth on glycollate[14].

The biosynthetic pathway outlined in Scheme I is similar in effect to the glyoxylate cycle[15,16] in which the net formation of C_4-dicarboxylic acids is achieved by the direct condensation of two C_2-units: however, the formation of the C_4-compound (β-hydroxyaspartate) appears to be catalysed by an aldolase-type condensing enzyme which does not necessitate prior activation of one of the C_2-reactants to the coenzyme *A* derivative. The β-hydroxyaspartate pathway differs from other routes of biosynthesis from glyoxylate, such as the glycerate pathway[1] established in other micro-organisms, or the glycollate pathway[17] described in plants, in avoiding the loss of carbon dioxide concomitant with the initial formation from the C_2-substrate of a compound containing more than two carbons.

MANIPULATION OF SALT SOLUTION—FRESH WATER DRINKING REGIMEN AND EATING BEHAVIOUR IN RATS

By HANS KAUNITZ, LESTER M. GELLER and RUTH ELLEN JOHNSON

Department of Pathology and the Division of Neuropathology, College of Physicians and Surgeons,
Columbia University, New York

IN an earlier investigation[1] the effects of marked and moderate food restriction on consumption of freely chosen 1 per cent salt solution, and the possible effects of excessive salt intake on survival, body-weight, reproduction, and the weights of certain organs of the rat were reported in detail. During a three week period of maintenance of reduced weight, free choice (salt solution and water) and control (water only) groups both required the same amounts of food to maintain their weights. Yet the animals in the choice situation increased their consumption of the salt solution to 25 per cent of their body-weight, while the fresh water intake of both groups remained stable. In keeping with Hebb's[2] contention that hunger be considered neither as a particular condition of the body, nor a set of sensations from the stomach, but as an organized neural activity, capable of arousal like any other conceptual process, it was suggested that the intake of water alone failed to provide the animals with an associative link between the consummatory response made (that is, drinking) and appetite, whereas salt did. Put another way, the suggestion was made that fresh water did not serve, as did salt, to arouse a pattern of learned behaviour associated with appetite and/or hunger. The findings were interpreted as lending support to the role of exteroceptive stimuli in activities frequently viewed as responses to internal needs, or as primary biological drives.

The present article is concerned with the eating behaviour, after food deprivation, of rats drinking only water, or water and a 1 per cent salt solution. The experiment seeks to determine whether freely elected alterations in fluid regimen affect the animal's consumption of food. It reflects an interest in the investigation of the role of change in, or manipulation of, external stimuli as a motivator of behaviour.

Adult male albino rats (Sherman strain) were used for these studies. The animals were individually housed on shavings in roomy cages. The rats were raised on a standard ration of 'Rockland *D*-Free' pellets and, at a median age of 135 days (range, 74–162 days), were transferred to a purified diet[3] containing (per cent) 30 lactalbumin, 54 dextrose, 10 lard, 2 cellulose, 0·5 calcium carbonate, and adequate amounts of all known vitamins. To this diet was added 3·5 per cent of *U.S. Pharmacopeia* salt mixture XIII, which allowed a dietary sodium

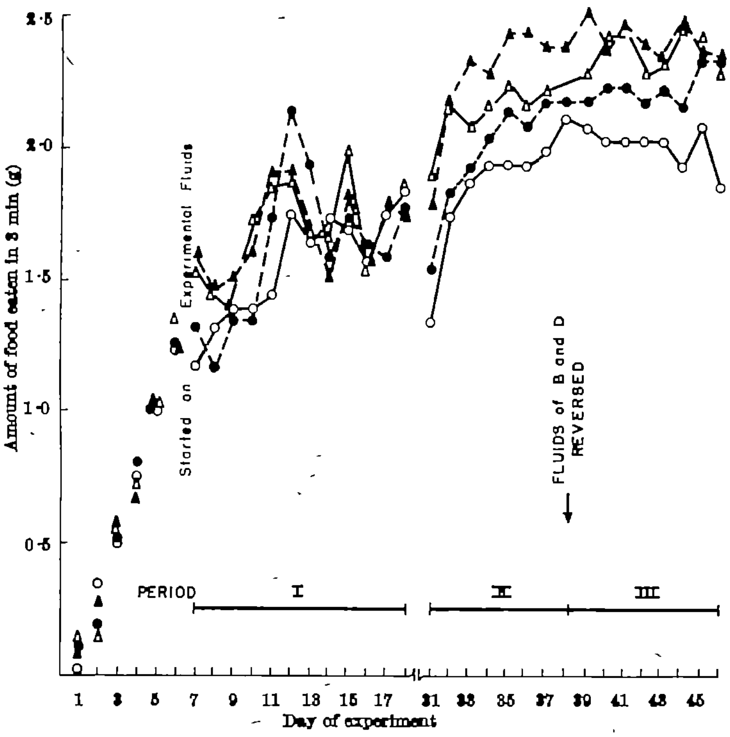

Fig. 1. Amount of food eaten in 3 min by rats drinking water or 1 per cent salt solution and water during each period of the experiment. Each point represents an average determination for 8 animals. The results for the first 5 days of the experiment represent the average daily 3-min amount of food consumed by the groups while they were all drinking water, that is, before the start of the experiment proper. These points have been included only to lend continuity to the graph by showing the gradual increase, with experience, in the quantity of food consumed in a fixed period of time. Group *A* drank water throughout the experiment; *B* was transferred from water to salt solution and water; *C* drank salt solution and water throughout; *D* was switched from salt solution and water to water alone. ○, Group *A*; △, group *B*; ●, group *C*; ▲, group *D*

chloride level of approximately 0·15 per cent. This level had been found to be adequate for growth, survival, and reproduction in our rat colony, and it was our intention to avoid limiting factors in the diet *per se* which might interfere with such functions.

The rats were placed in the experimental room one week before testing so that they might become adjusted to the daily noises around them. Two identical bottles were placed on each cage; both contained water for the water only condition, and one water, and the other a 1 per cent salt solution, for the choice situation. As is well known, rats, when offered this choice, consistently prefer the 1 per cent salt solution. The possibility that specific position preferences among the animals might influence the choice of fluid was controlled by alternating the positions of the bottles on the cages. The feeding tests, which were conducted in a small room built into the larger one, were carried out between 5 a.m. and 8 a.m. in order to minimize possibly distracting noise. The amount of food eaten in 3 min, after 24 h of food deprivation, was measured. The animal was not given any food beyond that eaten in 3 min during the initial series of these determinations. Later, the 3-min measurements were continued, but each rat was given a total of 10 g of food, which it could finish in its cage. The rats were taken for testing alternately from experimental and control groups.

In detail, an eating test was conducted as follows: A glass cup containing food was weighed to 0·05 g and placed in a stainless steel box, 7 × 10 × 6·5 in. The box was evenly illuminated by a fluorescent light six feet above. The rat was carried into the experimental room and placed in the box with its head toward the food, and the stop watch was started. A wire mesh cover was placed very quietly on the box and the experimenter stepped behind a shield to observe and record the behaviour of the animal. At the end of 3 min the watch was stopped (the click stopped the rat from eating), the food cup was taken from the rat, its paws and mouth were dusted into the cup, any spilled diet was replaced, and the cup was reweighed. The rat was returned to its cage together with its food cup during the period when it was being given a fixed amount to eat.

At a median age of 197 days, food was withdrawn, and the animals were weighed. On each of the next five days (days 1–5 of the experiment) they were given 3-min eating tests, but no additional food. On day 5 the animals were distributed into four groups of 8 rats each, matched on the basis of the total amount of food eaten in the five 3-min tests, the amount eaten during the last trial, their body-weight before food deprivation, the percentage of body-weight lost during the trials, and the amount of urination and/or defæcation in the test box. The average weights of the groups at this time were as follows: group *A*, 450 g (range, 399–513 g); *B*, 444 g (348–498 g); *C*, 443 g (359–513 g); *D*, 458 g (403–510 g). Groups *A* and *B* continued to drink water and groups *C* and *D* now were given a choice of drinking water or a 1 per cent salt solution. On day 6, the groups were given another 3-min eating test without additional food. The continuation of the experiment will be discussed in terms of three periods.

Period I. On days 7–18, all animals were given 10 g of food, and the amount eaten in 3 min in the test box was determined. During this period the 3-min food consumptions of the different groups showed no clear or consistent patterns of similarity or difference (Fig. 1). It was thought that more time (that is, a longer habituation period) should be allotted the animals on their basic fluid intakes before any reversal of fluids was carried out, in order to permit some organization of the consummatory response to take place. Accordingly, the rats were given 10 g of food daily, on days 19–30, to be eaten in their cages, and no determinations were made.

Period II. On days 31–38, 3-min eating tests were again carried out, and the rats were permitted to finish their 10 g rations in their cages. After the ingestion of 10 g on day 38, the fluid intake of group *B* was switched from water to a choice of 1 per cent salt solution and water. At the same time group *D* was switched from salt solution and water, to water only. The fluids offered the animals in group *A* (water) and *C* (salt solution and water) remained unchanged.

Period III. On days 39–46, 3-min feeding tests were carried out and the rats were permitted to finish their 10 g rations in their cages.

The average daily amount of food consumed in 3 min by the rats in each group is plotted in Fig. 1. Though the appearance of the curves during periods II and III suggested that differences existed among the groups, a simple analysis of variance of the average 3-min food consumption of the groups, carried out for each of the periods, indicated that these differences were not statistically significant.

The cross-over design of the experiment permitted each animal in groups *B* and *D* to serve as its own control when comparing the amount of food eaten under the different drinking programmes. In periods II and III, 8 rats (group *B*) received water and then water and a 1 per cent salt solution; the 8 animals in group *D* received water and salt solution and then water. In order to minimize residual effects from preceding drinking regimens,

Table 1. AVERAGE QUANTITY OF FOOD (G) CONSUMED IN 3 MIN ON LAST FOUR DAYS OF PERIOD II AND PERIOD III, BY EACH RAT IN GROUPS *B* AND *D* WHEN DRINKING WATER AND WHEN DRINKING SALT SOLUTION AND WATER

The differences (*d*) in food consumption under the two drinking conditions also are included

Rat No.	1% salt solution and water	Water	*d*
Group *B*	Period III	Period II	
35	2·23	2·30	−0·07
30	2·10	2·07	0·03
11	2·82	2·50	0·32
12	2·42	2·12	0·30
18	3·10	2·80	0·30
20	1·60	1·48	0·12
4	2·40	2·15	0·25
56	2·48	2·18	0·30
Group *D*	Period II	Period III	
10	2·87	3·07	−0·20
23	1·50	1·53	−0·03
17	3·20	3·32	−0·12
16	2·45	2·37	0·08
7	2·13	1·90	0·23
42	2·07	2·20	−0·13
29	2·45	2·53	−0·08
8	2·68	2·38	0·30
			$\bar{d} = 0·10$

The cross-over analysis of 3-min food consumptions is based on these results. The standard deviation of $\bar{d}$ (defined below) was calculated by the formula:

$$\sigma d = \sqrt{\frac{\Sigma(d - \bar{d})^2 - \dfrac{(\Sigma \text{period I} - \Sigma \text{period II})^2}{30}}{28}}$$

where d = the difference, for each rat, between the average amount of food eaten in a series of days while drinking water and while drinking salt solution and water; $\bar{d}$ = the mean of the above differences; Σperiod I = the sum of the average consumptions of food of all animals for period I, regardless of their fluid intakes; Σperiod II = the same as above for period II.

This formulation of the standard deviation contains a correction factor which takes into account the control, by the cross-over design, of changes in food consumption due to time, habituation phenomena, and the like.

only the food consumptions on the last 4 days of periods II and III were used for determining the average amounts eaten (Table 1). The average 3-min intake of food (during periods II and III) of each rat (in groups *B* and *D*), while drinking water, was subtracted from its average intake when in the choice situation and the mean and standard deviation of these differences were determined (see foot of Table 1 for procedure followed). The average difference ($\bar{d}$ in Table 1) in the amount of food eaten under the two conditions of fluid intake amounted to 0·10 ± 0·041 g, with the average 3-min consumption of food being significantly higher ($t = 2·41$; $P < 0·05$) when the rats drank salt solution and water than when they drank only water.

The difference between the average daily 3-min food consumption on the last 4 days of period II and of period III was then tabulated for each rat in each of the four groups. A single classification analysis of variance of these data, preceded by a corrected Bartlett's test for homogeneity of variance which failed to reach significance ($\chi^2 = 6·91$; d.f. = 3; $P > 0·05$), demonstrated a significantly higher intergroup than intragroup variance ($F = 3·47$; d.f. = 3·28; $P < 0·05$). To determine which group differences, if any, were responsible for the significant *F* ratio, the intergroup difference significant at the 0·05 level was calculated by the Tukey test[4] and found to be 0·22 g. A significant difference existed between groups *A* and *B*; group *B* increased its 3-min food consumption by 0·19 g when changed to the choice situation, whereas the food consumption of group *A*, which remained on water, decreased by 0·04 g in period III. The significant difference in food consumption noted earlier between groups *B* and *D* did not appear under the more stringent conditions of the analysis of variance, where the combined variance of all groups, rather than the variances of just groups *B* and *D*, were involved in significance testing. Rather than carry out several tests among the different groups, thus increasing the risk of securing significant differences by chance, we chose to use the more penalizing analysis of variance. In either case, the point was established that, following a change in fluid intake, animals ate significantly more food in 3 min when drinking salt solution and water than when drinking only water.

The curves in Fig. 1 resemble those published by others[5-7] who have studied the effects of deprivation on eating behaviour. Ghent[5] plotted the number of seconds spent eating during the first minute of availability of food or water, after deprivation of either, against day of testing. She found, as we also observed, that the animals did not eat immediately when first offered food, but, with continued experience in the testing situation, gradually ate increasingly more during the fixed period of time. This increase in amount eaten was due to more time spent in eating during the fixed time interval, rather than to an increase in the speed with which the animals ate.

The effects of changes in drinking regimen on food consumption were greatest among the animals transferred from water to the choice situation (group *B*). Though this switch was followed by a clear increase in food consumption, the removal of salt solution involved in the transfer in group *D* did not result in a decrease in eating. Conceivably, these findings could be viewed as contradictory. To do so, however, would presuppose a logic in behaviour which, in fact, remains to be demonstrated; moreover, such a view would ignore the obvious possibility of changes in behaviour due to learning. It is not unreasonable to assume that the presence of a particular set of sensory stimuli may lead to a type of behaviour which is sufficiently rewarding so that it is maintained even when these stimuli are removed.

The freely chosen intake of salt solution then, following a change in drinking fluids, was associated with a significant increase in food consumption.

Change or manipulation of external stimuli as a motivator of behaviour has been examined before. Campbell and Sheffield[8] found that rats deprived of food for 24 h showed a marked increase in cage activity when changes in the stimulating conditions in their environment occurred. They suggested that food deprivation reduces the animal's threshold to environmental stimulation, that is, sensitizes it to stimulus change. Similar results were obtained with water deprivation[9]. Teghtsoonian and Campbell[10] observed that food-deprived animals, maintained in a situation where environmental stimulation was markedly restricted, showed a decided reduction in the level of maximum activity during deprivation and in the rate at which this maximum was reached. Another group of food-deprived animals, living in a bustling laboratory environment, showed marked increases in cage activity, ranging to 400 per cent of the pre-deprivation level. These investigations, and others (for example, ref. 11), emphasize the role of exteroceptive stimuli as instigators of behaviour, where sensory stimulation becomes a reinforcer of behaviour in its own right, independently of the part it plays in drive or need reduction[12].

We are indebted to Prof. John W. Fertig and Dr. Khalil El-Kashlan of the Division of Biostatistics of the School of Public Health and Administrative Medicine, Columbia University, for their assistance with the statistical treatment of the data.

PHOTOCHEMISTRY OF A NICOTINAMIDE METABOLITE, N'-METHYL-4-PYRIDONE-3-CARBOXAMIDE

By DENIS ABELSON and A. BOYLE

Department of Medicine, The Graduate Hospital, University of Pennsylvania, Philadelphia, Pennsylvania

IN the course of paper chromatographic investigations of nicotinamide metabolites in human plasma[1,2], it was noted that one of these, later identified[3] as N'-methyl-4-pyridone-3-carboxamide (4-PY), occasionally exhibited a blue fluorescence in ultra-violet light at 360 mμ. Further examination showed that the phenomenon was due to the production of a fluorescent compound or compounds on the paper under the influence of ultra-violet light. Its intermittent occurrence was readily attributable to the varying amounts of ultra-violet radiation to which different chromatograms were exposed for purposes of visual inspection and contact photography. Although the fluorescence was most easily seen on excitation with 360 mμ light, this wave-length had very little photochemical effect. On the other hand, exposure to light from a 254 mμ lamp (the spectral emission of which is shown in Fig. 1) caused a sample of 4-PY spotted on Whatman No. 1 paper to appear to 'melt away' in a few seconds. As the absorption diminished a faint purple glow developed, which in 360 mμ light changed to the characteristic strong whitish-blue fluorescence. The intensity of the fluorescence increased with duration of exposure to radiation until maximum conversion had occurred.

Proof of the formation of at least one new compound was obtained by reversing the chromatogram after irradiation, and running it in the opposite direction (Fig. 2). The unchanged 4-PY ran with its usual velocity, whereas the photoproduct remained at the new origin. A number of different solvent systems, including distilled water, failed to move, and hence to elute, this material from the origin. It was therefore concluded that, under the influence of irradiation at 254 mμ, 4-PY forms a stable fluorescent compound or compounds with cellulose.

Experiments were then carried out to determine whether similar effects could be produced by irradiation of 4-PY in solution. A solution of 4-PY in absolute ethanol at a concentration of 10 μg/ml. was irradiated in a quartz microcuvette situated as close as possible to the 254 mμ hand-lamp. At intervals the cuvette was removed and the absorption spectrum of the solution determined with a Beckman *DU* spectrophotometer. Fig. 3 shows the changes produced. It will be seen that the untreated compound in ethanol exhibits a major peak at 258 mμ and a shoulder at 285 mμ. As irradiation proceeds the 258 mμ maximum diminishes and eventually disappears. The 285 mμ inflection shows little change in intensity but undergoes a bathochromic shift, giving rise to a peak at 305 mμ. In aqueous solution a slight reduction in the intensity of the 258 mμ maximum is the only change observed.

Fig. 2. Chromatogram of 4-PY after running from *A* to *B*, irradiating, and then running from *B* to *A*. (i), Photograph of fluorescing spots, taken at 360 mμ, with filter (ref. 1); (ii), photograph of absorbing spots, taken at 254 mμ

To exclude the possibility that the changes produced on paper were due to heat from the lamp, a sample of 4-PY spotted on Whatman No. 1 paper was heated in an oven at 100° C for periods of up to 30 min. No fluorescence developed. That the changes in ethanol were also not due to heat was shown by the absence of spectral change in a control solution, screened by aluminium foil, which was placed next to the test solution throughout the irradiation period.

When viewed with the 360 mμ lamp, a bluish-green fluorescence is visible in solutions of 4-PY which have previously been exposed to radiation from the 254 mμ lamp. The changes in the intensity of fluorescence with duration of irradiation are shown in Fig. 4. After irradiation for 30 min the solution was taken to dryness and chromatographed on paper in butanol–ammonia. At least two spots showing dark blue fluorescence were seen.

The fluorescence spectra before and after irradiation were determined using an Aminco-Bowman spectrophotofluorometer (Fig. 5). It will be seen that the fluorescence intensity of the irradiated solution is actually less than that of the unirradiated solution. The fact that the former is visible to the naked eye, whereas the latter is

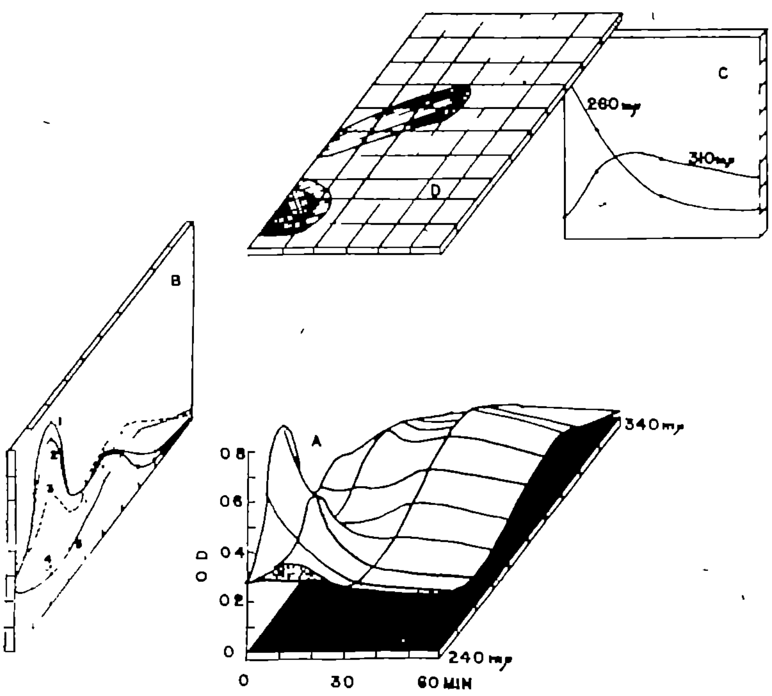

Fig. 3. Absorption stereospectrum of 4-PY in ethanol during ultra-violet irradiation. *A*, Stereospectrum. *B*, (1) spectrum before irradiation; (2) spectrum after 1 min irradiation; (3) spectrum after 8 min irradiation; (4) spectrum after 26 min irradiation; (5) spectrum after 56 min irradiation. *C*, Changes in absorption at 260 mμ and 310 mμ with time. *D*, Areas shaded by parallel lines represent optical density (O D.) greater than 0 3, cross-hatched area O.D. greater than 0 4, and black area O.D. greater than 0 6

not, may be attributed partly to the shift in the fluorescence towards the visible region after irradiation. In addition, it was found that the activation maximum of the unirradiated solution is 300 mμ. compared with 320 mμ for the irradiated solution. (These values are approximate, due to the presence of a scatter peak in the region concerned.) Inspection with the 360-mμ source would therefore excite the fluorescence of the irradiated solution more efficiently For the determination of the emission and activation spectra it is essential to use 'fluorometric grade' absolute ethanol (Hartman-Leddon Co., Philadelphia, Pa.) to eliminate the spurious fluorescence exhibited by reagent grade absolute ethanol in the 400 mμ region.

Although it is known that a number of compounds on paper chromatograms undergo decomposition on prolonged exposure to ultra-violet light[4], the present example is unusual in that it possesses extreme sensitivity to such radiation, and gives rise to a strongly fluorescent photoproduct. This property permits the ready identification of 4-PY among other ultra-violet-absorbing spots. The photoproduct itself displays the distinctive property of being completely immovable in all solvent systems tried, including distilled water. This phenomenon suggests an irreversible association with a constituent of the chromatographic paper, such as hydroxyl or aldehydic groups of cellulose.

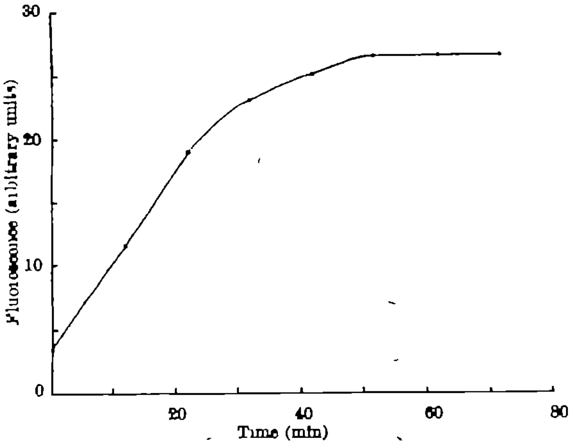

Fig 4 Development of fluorescence with time in irradiated solution of 4-PY in ethanol

The only other comparable situation which we have been able to trace occurs in the field of amino-acid chromatography.

In 1948 Phillips[5] showed that the α-amino-acids and peptides resulting from enzymatic degradation of insulin fluoresced on paper chromatograms. The intensity of fluorescence was greatest when high drying temperatures were used, but some fluorescence developed even when the papers were dried at 37° C. The following year Patton *et al.*[6] showed that this fluorescence remained behind on the paper after washing with water. They demonstrated that the paper was essential for the development of fluorescence, which failed to appear when amino-acids were heated on glass plates. These workers suggested that the fluorescent change is analogous to the browning reaction. Similar results were reported in 1950 by Woiwood[7], who pointed out that most amino-acids fluoresce feebly in the pure crystalline state, although tryptophan, histidine and citrulline fluoresce strongly. When heated with cellulose some twenty amino-acids fluoresced, as did a number of simple peptides and amines. The amino-group alone appeared to be necessary for the reaction which, it was suggested, occurred with aldehydic groups derived from modified or short-chain celluloses present in the paper. We have already indicated that heat does not induce fluorescence in 4-PY on paper.

The effects of ultra-violet radiation on 4-PY in ethanol resemble those obtained on paper chromatograms in that a diminution in light absorption is accompanied by the development of fluorescence. The nature of the fluorophore(s) is unknown. Slomp *et al.*[8] and Taylor *et al.*[9] have proposed a dimeric structure for the product of ultra-violet irradiation of *N*′-methyl-2-pyridone. However, apart from structural differences between this compound and that used in the present investigation, their experi-

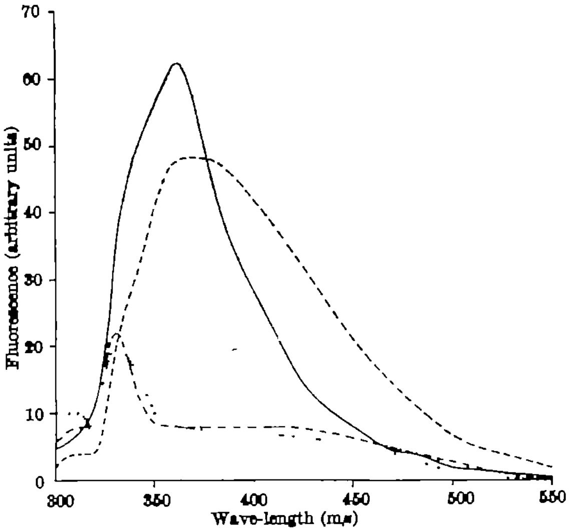

Fig. 5. Fluorescence spectrum of 4-PY in ethanol (10 μg/ml.) before and after 30 min irradiation. Activation monochromator set at 300 mμ ———, 4-PY before irradiation; ----, 4-PY after irradiation; · · ·, absolute ethanol (fluorometric grade) before irradiation, ·– –, absolute ethanol (fluorometric grade) after irradiation

ments were carried out in aqueous solution in which, as we have shown, the spectrum of 4-PY is unchanged. The spectral shift observed in ethanolic solutions of 4-PY suggests reduction of the pyridone with preservation of the quinonoid structure.

INTERPRETATION OF INHIBITION KINETICS OF COENZYME-SUBSTRATE REACTIONS, AND THE ROLE OF ZINC IN ALCOHOL DEHYDROGENASES

By Dr. K. DALZIEL*

Department of Biochemistry, University of Sheffield, Sheffield, 10

SEVERAL types of inhibition are distinguished experimentally by the effects of a fixed inhibitor concentration on the slopes and intercepts of plots of initial rate data according to Lineweaver and Burk[1], or by the point of intersection when plots in presence and absence of inhibitor are extrapolated. They receive theoretical interpretation by the inclusion of compounds *EI* and *ESI*, with dissociation constants K_{EI} and K_{ESI} respectively, in the reaction scheme proposed by Michaelis and Menten[2] for a single substrate reaction. The general relation between initial rate in the steady state, v_0, the enzyme concentration e, the substrate concentration s, and the inhibitor concentration i, takes the form:

$$1/v_0 = (1 + i/K_{ESI})/V + (1 + i/K_{EI})K_m/Vs$$

or:

$$e/v_0 = \varphi_0(1 + i/K_{ESI}) + \varphi_1(1 + i/K_{EI})/s$$

The parameters V and K_m, or φ_0 and φ_1, and K_{EI} and K_{ESI} can be determined experimentally from plots of e/v_0 against $1/s$. Increased slope with unchanged intercept, or intersection on the abscissa, indicates competitive inhibition ($K_{ESI} = \infty$). Increased intercept with unchanged slope, that is, parallel plots, has been designated uncompetitive inhibition ($K_{EI} = \infty$). Equal proportionate increase of slope and intercept, or intersection on the ordinate, denotes non-competitive inhibition ($K_{EI} = K_{ESI}$). 'Mixed' types are competitive–non-competitive, with greater proportionate increase of slope than intercept and intersection above the ordinate ($K_{EI} < K_{ESI}$), and non-competitive–uncompetitive, with greater proportionate increase of intercept than slope and intersection below the ordinate ($K_{EI} > K_{ESI}$).

The behaviour of inhibitors in coenzyme-substrate reactions has also been described in these terms, both with reference to the coenzyme, from initial rate measurements with constant substrate concentration, and with reference to the substrate, by experiments with constant coenzyme concentration. The underlying assumption appears to be that if the concentration of either the substrate or the coenzyme is maintained at a level much greater than its Michaelis constant, the reaction will be kinetically equivalent to a single substrate reaction. This is not necessarily so[3], and it cannot be assumed[4] that inhibition equations deduced for a single substrate reaction are applicable to coenzyme-substrate reactions.

The main purpose of this article is to show that on the basis of a compulsory order mechanism, by which the coenzyme is bound to the enzyme first, it is to be expected that an inhibitor which competes with the coenzyme only will in general exhibit different 'types' of behaviour with reference to the substrates for the forward and reverse reactions. Experimental observations of this kind with the zinc-binding inhibitor *ortho*phenanthroline and liver alcohol dehydrogenase have been considered[5] inconsistent with a compulsory order mechanism, and have invoked conclusions regarding the binding of the substrates which appear to be unjustified[5-7].

Such a mechanism is represented by the following reactions:

$$\begin{aligned}
&E + I \rightleftharpoons E.I\\
&E + C \rightleftharpoons E.C\\
&E.C + S \rightleftharpoons E.C.S \rightleftharpoons E.C'.S' \rightleftharpoons E.C' + S' \qquad (1)\\
&E.C' \rightleftharpoons E + C'
\end{aligned}$$

The initial rate equation in the steady state, whether or not the ternary complexes $E.C.S$ and $E.C'.S'$ are included, takes the form[8,9]:

$$e/v_0 = \varphi_0 + \varphi_1\,(1 + i/K_{EI})/c + \varphi_2/s + \varphi_{12}\,(1 + i/K_{EI})/cs$$

With the reciprocal of the coenzyme concentration, $1/c$, as variable:

$$e/v_0 = (\varphi_0 + \varphi_2/s) + (\varphi_1 + \varphi_{12}/s)(1 + i/K_{EI})/c \qquad (2)$$

and with any constant values of substrate and inhibitor concentration, s and i, the effect of the inhibitor will be to increase the slope by the factor $(1 + i/K_{EI})$, from which K_{EI} may be calculated, while the intercept will be unchanged, that is, competitive behaviour, as expected.

With $1/s$ as variable:

$$e/v_0 = [\varphi_0 + \varphi_1(1 + i/K_{EI})/c] + [\varphi_2 + \varphi_{12}(1 + i/K_{EI})/c]/s \qquad (3)$$

The effect of the inhibitor will be to increase both slope and intercept, but not necessarily in the same proportion. The relative increases will be determined by the relative values of φ_0, φ_1, φ_2 and φ_{12}, initial rate parameters which may be estimated experimentally in absence of inhibitor. Re-arranging equation (3):

$$e/v_0 = \varphi_0\left[1 + \frac{\varphi_1}{\varphi_0}\left(\frac{1 + i/K_{EI}}{c}\right)\right] + \varphi_2\left[1 + \frac{\varphi_{12}}{\varphi_2}\left(\frac{1 + i/K_{EI}}{c}\right)\right]\frac{1}{s} \qquad (4)$$

or in alternative symbols[9,10]:

$$1/v_0 = \frac{1}{V}\left[1 + K_{m1}\left(\frac{1 + i/K_{EI}}{c}\right)\right] + \frac{K_{m2}}{V}\left[1 + K_{EC}\left(\frac{1 + i/K_{EI}}{c}\right)\right]\frac{1}{s}$$

V is the maximum rate; $\varphi_1/\varphi_0 = K_{m1}$, the Michaelis constant for the coenzyme; $\varphi_2/\varphi_0 = K_{m2}$, the Michaelis constant for the substrate; and $\varphi_{12}/\varphi_2 = K_{EC}$, the dissociation constant of the enzyme–coenzyme compound.

The 'type' of behaviour of the inhibitor towards the substrate will therefore depend on the relative values of K_{m1} and K_{EC}. Only if these two quantities are equal will the slope and intercept be increased by the same proportion, indicating 'non-competitive inhibition'. If $K_{m1} < K_{EC}$, the inhibition will be 'competitive–non-competitive', or if the inequality is large, almost 'purely competitive'. If $K_{m1} > K_{EC}$, the inhibition will be 'uncompetitive' or 'non-competitive–uncompetitive'.

* Sorby Research Fellow of the Royal Society.

A Michaelis constant may be greater or smaller than the true dissociation constant[3]. For a number of dehydrogenases that use the coenzyme nicotinamide–adenine dinucleotide (NAD+), including lactate dehydrogenase[11], yeast[12] and liver[13,14] alcohol dehydrogenases and malic dehydrogenase[15], for which initial rate data at pH 6–8 are available, it is found[16] that for the reduced coenzyme, NADH, $K_{m1} > K_{EC}$ (that is, $\varphi_1/\varphi_0 > \varphi_{12}/\varphi_2$), while in the reverse reaction for NAD+, $K'_{m1} < K_{EC}'$. These complementary relations for the oxidized and reduced coenzymes are to be expected theoretically[8] for a compulsory order mechanism. (For the special case that ternary complexes $E.C.S$ and $E.C'.S'$ are not kinetically significant (that is, the Theorell–Chance[17] mechanism) it can be shown[16] that $K_{m1}/K_{EC} = K_{EC'}/K'_{m1}$.) It follows from equation (4) that an inhibitor that competes with the coenzyme should in general show different 'types' of behaviour towards the substrate in the forward and reverse reaction. Moreover, since the relative values of K_{m1} and K_{EC} may vary with pH, so also may the 'type' of inhibition.

Hoch, Williams and Vallee[6] interpreted experimental data for the inhibition of yeast alcohol dehydrogenase by *ortho*phenanthroline on the basis of mechanism (1), except that the ternary complexes were omitted. They concluded that the inhibitor showed non-competitive behaviour towards both ethanol and acetaldehyde, which they considered, mistakenly as has been shown, to be required by this mechanism[5]. Their data with the highest inhibitor concentration indicate that the inhibition is in fact competitive–non-competitive towards ethanol and non-competitive–uncompetitive towards acetaldehyde, in accordance with the preceding discussion.

With liver alcohol dehydrogenase, more marked differences between the apparent behaviour of *ortho*phenanthroline towards the two substrates have been detected and variously interpreted. It is of some interest, therefore, to show that as with the yeast enzyme the experimental data are in accordance with mechanism (1), and the fact that for this enzyme, in neutral solution, the values of K_{m1}/K_{EC} for NADH, and K_{EC}'/K'_{m1} for NAD+, are large. This can be done by substitution in equations (2) and (4) of experimental values for the initial rate parameters reported by me[13]. Equation (4) then becomes, for the reaction of ethanol and NAD+:

$$e/v_0 = 0{\cdot}37\left[1 + \frac{3{\cdot}0(1 + i/K_{EI})}{[\mathrm{NAD^+}]}\right] + 110\left[1 + \frac{65(1 + i/K_{EI})}{[\mathrm{NAD^+}]}\right]\frac{1}{[\mathrm{C_2H_5OH}]}$$

and for the reaction of acetaldehyde and NADH:

$$e/v_0 = 0{\cdot}0075\left[1 + \frac{13(1 + i/K_{EI})}{[\mathrm{NADH}]}\right] + 3{\cdot}3\left[1 + \frac{0{\cdot}42(1 + i/K_{EI})}{[\mathrm{NADH}]}\right]\frac{1}{[\mathrm{CH_3CHO}]}$$

The Lineweaver–Burk plots in Figs. 1*c* and *d* were calculated from these equations with $i = 120$ μM and $K_{EI} = 2{\cdot}5$ μM, and the fixed concentrations of coenzymes indicated. Figs. 1*a* and *b* were obtained by similar substitutions in equation (2). It should be added that larger values for the fixed concentrations would merely require a greater inhibitor concentration to produce comparable effects, and would not alter their nature; and also that if the initial rate parameters reported by Theorell and McKee[18] are used, the same types of plot are obtained.

It is evident that the 'partially competitive' type of inhibition towards ethanol and the 'non-competitive–uncompetitive' behaviour towards acetaldehyde are predicted by mechanism (1), and provide no grounds for earlier conclusions that the two substrates are bound at different sites on the enzyme, and that the ethanol-binding site interacts with, or is adjacent to, that responsible for coenzyme and *ortho*phenanthroline binding[7]; or that the substrates must have an effect on the binding of *ortho*phenanthroline to liver alcohol dehydrogenase, and that the mechanism may be different to that for the yeast enzyme[6].

All workers agree that *ortho*phenanthroline is strictly competitive towards the coenzymes, but there are discrepancies between the values obtained for K_{EI}. Plane and Theorell[6] did not interpret their data in terms of a compulsory order mechanism, however, but considered that binary complexes of enzyme and substrate are formed. With this assumption, they calculated values for K_{EI} of 3·0, 0·013 and 11 μM from data corresponding to Figs. 1*a*, *b* and *c* respectively. To account for these apparent discrepancies, they postulated ternary complexes of enzyme, inhibitor and substrate, and estimated their dissociation constants. There are no such discrepancies, however, if their data are interpreted in terms of mechanism (1). By means of equations (2) and (4), values close to 2·5 μM for K_{EI} are obtained from all three plots; the close agreement between the slopes of the competitive plots against the two coenzymes is apparent on inspection. The theoretical plots in Fig. 1 are in fact calculated for the same concentrations of inhibitor, coenzymes and substrates as those used by Plane and Theorell, and resemble their experimental plots closely. The value of 2·5 μM is also in reasonable agreement with 4 μM calculated in a similar manner by Vallee, Williams and Hoch[5] from competition with NADH under slightly different conditions. These workers obtained a much higher value from competition with NAD+, but this may arise from the high ethanol concentration

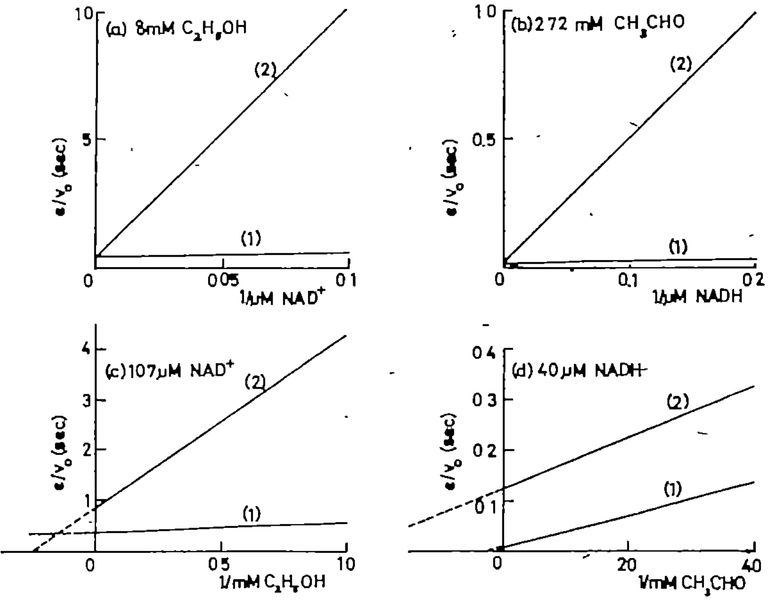

Fig. 1. Effects of an inhibitor which competes with the coenzyme on the initial rate of the liver alcohol dehydrogenase reaction at pH 7·1 and 23·5°, on the assumption of a compulsory order mechanism. The reciprocals of specific initial rates e/v_0 are plotted against the reciprocals of the coenzyme (*a*, *b*) and substrate (*c*, *d*) concentrations. The plots (1) for the uninhibited reaction were calculated from experimental values for the initial rate parameters (ref. 13), and the plots (2) showing the theoretical effects of 120 μM inhibitor, with $K_{EI} = 2{\cdot}5$ μM, by equations (2) and (4) in the text

PHYSICS DEPARTMENT LIBRARY

used, which causes substrate inhibition and renders equation (2) inapplicable. It appears that the kinetic data for the inhibition of liver alcohol dehydrogenase are consistent with mechanism (1) and a value of about 2·5 μM for K_{EI} at pH 7 and 23·5°. A discrepancy remains, however, between this value and that obtained by spectrophotometric measurements[19].

Vallee *et al.*[5,9] conclude from the absence of strictly competitive behaviour of *ortho*phenanthroline towards the substrates that the latter cannot be bound to zinc in ternary complexes of yeast and liver alcohol dehydrogenases. If the substrate were so bound it might be expected that competition between *ortho*phenanthroline and substrate for $E.C$ in mechanism (1) would occur with formation of $E.C.I$. This would introduce the inhibition factor $(1 + i/K_{ECI})$ in the term φ_1/s in the initial rate equation. It may also imply the formation of the product complex $E.C.'I$, which would give $\varphi_0(1 + i/K_{EC'I})$ as the maximum rate, and the compound EI_2 also. In any event, there is no evidence of such effects in the experimental data.

Theorell *et al.* assume a random order mechanism for liver alcohol dehydrogenase[6,18,20], with kinetically significant binary enzyme-substrate complexes. If the substrates were bound to zinc, competition from *ortho*phenanthroline would again be expected, in this case for the free enzyme also. Theorell and McKee[20] explain the absence of strict competition by assuming that of the three available bonds of octahedral zinc, the inhibitor can only utilize the same two co-ordination sites as the coenzyme, and cannot compete for the third substrate site. The evidence for ternary complexes of enzyme, *ortho*phenanthroline and substrate adduced by Plane and Theorell[6] is taken to support this explanation. The 'partially competitive' behaviour towards ethanol, but not acetaldehyde, is attributed to a stabilizing effect of ethanol on the binding of NAD+.

The compulsory order mechanism (1) seems to provide a simpler explanation of the experimental data which, contrary to the conclusions of Vallee *et al.*[5,9], does not preclude the binding of substrate to zinc in the ternary complex, as suggested by Theorell and McKee[20]. If the metal were the centre of an octahedral ternary complex, with three bonds to the protein, and two to the bidentate coenzyme, the absence of competition between the bidentate *ortho*phenanthroline and substrate for the remaining co-ordination site of the enzyme–coenzyme complex would be understandable. Thus if binary enzyme-substrate complexes are not assumed, no further assumptions are needed to explain the behaviour of the *ortho*phenanthroline towards the substrates. Indeed, the conformity of the inhibition data to the initial rate equation derived from a compulsory-order mechanism and the absence of competitive behaviour towards both substrates, might be construed as evidence against the view that such complexes are kinetically significant. Unlike the coenzymes, *ortho*phenanthroline would not be expected to have binding sites on the enzyme other than those to zinc, as Theorell and McKee[20] remark; it seems improbable, therefore, that of the three co-ordination sites of the free enzyme, only the two utilized by the coenzyme are available to the *ortho*phenanthroline, as they suggest.

It may be concluded that inhibition kinetics with *ortho*phenanthroline provide valid evidence that the coenzymes are bound to zinc in the enzyme–coenzyme complexes of yeast and liver alcohol dehydrogenases, and are consistent with, but do not prove, the binding of substrates to zinc in the reactive ternary complex in a compulsory order mechanism. It may also be concluded that in kinetic studies of inhibition of coenzyme-substrate reactions, it is desirable that measurements be made with simultaneous variation of both coenzyme and substrate concentrations, so that the effects of the inhibitor on all the terms in the initial rate equation may be evaluated and used to assess the mechanism.

FORMATION AND DISTRIBUTION OF AMYLOSE AND AMYLOPECTIN IN THE STARCH GRANULE*

By Prof. N. P. BADENHUIZEN
Department of Botany, University of Toronto

STARCH granules are biological objects and as such closely linked to the genotype and the physiology of the plant which produces them. Although most starch granules contain linear and branched molecules of the α-1,4-glucosidic type, with α-1.6 linkages at the branching points, there is much heterogeneity in these two fractions. There is also an enormous variation in their ratio and in their packing to a paracrystalline pattern. It is well known that there is a different shape of starch granule for every plant species.

This variability in properties is surprising when we consider that the basic chemistry is the same for all starches and that all plastids have the fundamental ability to make starch in their ground substance[1]. It suggests the presence of a complex of interfering factors which makes the production of starch in plants an extremely variable process.

We will limit the discussion to the plastids of higher plants, and we ask: How are starch granules formed, what enzymes play a part in their synthesis, how can modifying factors influence the deposition of a mixture of linear and branched molecules and their relative amounts? If one could give detailed answers to all these questions, the fine structure of the different types of starch granules would be clear. Unfortunately, this is not yet possible and much has still to be done.

(1) *The plastid and starch formation.* Chlorophyll-containing plastids (chloroplasts) have been most extensively studied because they form the photosynthetic apparatus and are available in quantity. We will deal

---

* Substance of an address given on September 12, 1962, to the one hundred and forty-second meeting of the American Chemical Society in Atlantic City.

only with the amyloplast, which forms the storage-type of starch granule. Only in exceptional cases is the amyloplast coloured (as in *Pellionia*). When examined with the electron microscope[2] it appears to be a vesicle surrounded by a double membrane, with few, if any, membranous structures inside. Nevertheless, amyloplasts from various plants show typical structural characteristics which must have a genetical origin and which are associated with the chemical composition of the plastid. The influence of genetical factors has been clearly demonstrated in the shape and composition of starch granules from various corn varieties. (I have summarized these aspects elsewhere[3].)

At the time of starch formation, potassium permanganate causes the production of a fine homogeneous precipitate in the plastid. This precipitate disappears when the first starch deposit is formed and may therefore represent an accumulation of precursor substance with reducing properties. With a new supply of carbohydrate similar particles, also visible after potassium permanganate treatment, appear; electron pictures suggest that again they represent precursor material which is added to the starch granule. The particles range in size from 250–300 Å, and the smallness of the droplets they represent explains an earlier observation that starch may be deposited in extremely thin layers[4]. Growth of starch granules by apposition has been fully demonstrated, but so far we did not know how it actually occurs. Lengthening of molecules at the periphery of the granule was thought to be the mechanism by which growth takes place. However, this theory does not take into account the inability of retrograded molecules to act as primers. The electron picture may give a better representation of the real situation.

The possibility that starch crystallizes out from a coacervate was suggested in 1946 by MacMasters *et al.*[5]. If it is true that tiny coacervate droplets carry fresh material towards the periphery of the starch granule, then a new approach to our understanding of the composition of the granule is possible. To appreciate this we have now to consider the enzyme systems involved in starch synthesis.

(2) *Starch synthesizing enzymes.* Phosphorylase has been thought to be responsible for starch synthesis (in collaboration with the *Q*-enzyme, which has branching action), since it was found in those parts of plants where starch accumulates and because of its location inside the plastids. Doubts about its function have been expressed before (see my summary elsewhere), but more recently it was even rejected as a starch synthesizing enzyme *in vivo*. The reasons for this rejection can be read in an article by Whelan[6]. A new enzyme proposed is one that uses uridine diphosphoglucose (UDPG) as a glucose donor[7]. Other possible systems, suggested by Whelan and by Erlander, have been discussed earlier[3,6].

The implication is that an enzyme may be present, but that it has no physiological function. Such instances can actually be found. In the plant epidermis, for example, plastids contain phosphorylase, although under natural conditions they never form starch[8]. It is possible that the function was lost during the process of evolution; such loss in the epidermis would not discredit the enzyme as a starch synthesizer in other tissues. In addition, it becomes more and more clear that organisms are versatile and can adapt their metabolic pathways to varying conditions. We know as yet very little about the co-ordination between enzyme systems which may be involved in the production of starch. It is reasonable to assume that they all play their part at times.

The enzyme discovered by Leloir *et al.*[7] needs preformed starch to make more starch. Since the enzyme could not be extracted from the starch granules, it is probably located inside the granules and provides for some addition to existing molecules *in situ*. Such growth by intussusception will be limited in extent. This mechanism does not explain how the starch was formed in the first instance, or how there can be linear and branched molecules. As Porter[10] rightly remarks, *de novo* synthesis of starch may yet depend on the presence of phosphorylase.

What more does the Leloir enzyme do? It makes oligosaccharides (up to 6 units) from maltose and maltotriose in the presence of UDPG, but it was found that these oligosaccharides cannot act as intermediates in starch synthesis. They could, of course, act as primers for phosphorylase.

Turner *et al.*[11,12] have shown that UDPG is an excellent source of glucose-1-phosphate (G-1-P), the substrate for phosphorylase, from which this enzyme may make starch even without primers being present[13]. This G-1-P is produced from sucrose, the main sugar of transport in plants. In potato plants which had assimilated $^{14}CO_2$, sucrose was found to be transported down the stem and to spread evenly throughout the tuber, where it appeared in the cytoplasm of the cells. From there radioactivity entered the plastids, the membranes of which must have some regulatory function. Finally, the starch granules become radioactive, in the first instance in those parts of the tuber where phosphorylase activity was highest[4].

Our conclusion must be that phosphorylase is the predominant starch synthesizing enzyme and that it can be excellently co-ordinated with a UDPG or related system. Further discussion in this article will be based on this conclusion.

At this junction I wish to stress again that studies of tissue homogenates cannot give a proper insight into the processes inside the plastid. As Krech[9] has pointed out, in such homogenates various substances come together which would never meet in the intact cell. This is one reason why the ratio inorganic/organic phosphate, as observed in tissues, is not so important as was thought before. We have to study the plastids themselves in undamaged, healthy cells, in order to discover their mechanism.

(3) *The general distribution pattern of amylose and amylopectin.* One of the most difficult problems facing starch chemistry is to explain why there are linear molecules at all, when we know that a mixture of phosphorylase and branching enzyme (often indicated respectively as *P*- and *Q*-enzyme) always gives only a branched product in a solution containing G-1-P and primer molecules. Both enzymes have been found in normal corn endosperm (containing starch with about 25 per cent amylose), waxy corn (1 per cent amylose) and wrinkled pea (65 per cent amylose and more). Assuming a different *P*/*Q*-ratio for these plants does not help in elucidating the differences between their starches.

Both *P*- and *Q*-enzymes must be present with their substrates in the plastid, because that is the place where the starch granule is formed. Phosphorylase has been repeatedly detected histochemically inside the plastid, but we have to confirm the localization of *Q*-enzyme and the other substances involved. Since G-1-P penetrates only very slowly into the cells[9] and a UDPG-enzyme system was found in association with the starch[7], it is likely that sucrose is admitted to the plastid and converted while inside. The mechanism by which this could happen has to be investigated. We also do not know how the enzymes (and other proteins) become included.

Now the stage is set for the production of starch. In principle we may expect the same reactions to happen as are demonstrated in the test tube, and the question therefore arises: what are the factors that can modify this standard pattern? In other words, How is the hereditary chemical composition of the plastid reflected in the structure of the starch granule it produces?

One of the effects appears to be that for most starches crystallization from a coacervate takes place before all the linear molecules have become branched. We may assume that the amylopectin is formed rapidly, but that the *Q*-enzyme will reach entangled linear molecules with increasing difficulty. This would explain the presence of an intermediary fraction and slight branching in longer molecules[14,21] when crystallization takes place at this stage in the tiny coacervate droplets. In waxy starch *Q*-enzyme appears to be able to branch completely the original linear molecules before crystallization starts.

Since each coacervate droplet produces a mixture of linear and branched molecules in ordinary starch, and an immense number are required to build up a new shell, we do not expect *a priori* a difference in location between the two fractions. They must show an even distribution throughout the granule in the form of mixed crystals, which is in agreement with the results of microscopic investigations[3].

Only 1/5 to 1/3 of the total chain-length in the starch granule shows orderly arrangement in crystalline patterns[14]. Amorphous regions are therefore found both within and in between the shells, those in between forming the so-called amorphous layers[3]. Permutoid reactions will occur in the more accessible amorphous regions in the first instance, and this is the reason why amylase action spreads tangentially from the corrosion canals in cereal starches, and why treatment with dilute acid (lintnerization) causes separation of layers in practically all starches. During these processes amylopectin is degraded by preference[15–18], and this result indicates that both amylose and amylopectin are also present in the amorphous regions. We conclude with Hess[19] that the only difference between the shells and the amorphous layers is in their water content, and this must be related to a periodic supply of carbohydrate. When there are no layers present, as in cereal starches which were produced under conditions of constant illumination, there is an uninterrupted addition of coacervate droplets. The fundamental process remains the same and therefore we do not expect chemical differences between granules with or without layers (when studied in the same species of plant).

It will scarcely be necessary to stress again[20] that there is no layer with special chemical properties surrounding the starch granule.

The assumption that the concentration of amylopectin increases towards the outside of the granule was based on an incorrect interpretation of the swelling phenomena (for a discussion see my earlier work[21]). Recently, Samotus and Schwimmer[22] demonstrated an increase in esterified phosphate during the development of the potato starch granule. Combining this result with growth by apposition only and the assumption that esterified phosphate is located at the branching points[23] could lead to the conclusion that there is an increase in the degree of branching in a centrifugal direction (in the potato starch granule).

The potato starch granule shows unique behaviour in many respects. I have given arguments which could support an increase of amylopectin content within one layer of the potato starch granule[21] (separation of layers after leaching out the longest molecules). It is, admittedly, very difficult to demonstrate such fine differences in structure with certainty. On no account, however, should one use specific observations, made on potato starch granules, to draw general conclusions about the cereal starches[21].

Finally, there are the waxy types to be considered. These starch granules consist mainly of amylopectin, so that obviously there is no chemical difference between the layers. Many of them contain a low percentage of amylose, which is located in the centre of the starch granule[3]. These cores can easily be isolated and consist of a globular particle, often surrounded by one or two layers. They were well known in waxy corn starch, but I found them also in grenadilla and waxy sorghum starch. Since a 'blue core' cannot be detected in the earliest starch deposit, one wonders whether they are caused by an after-production of linear molecules (which may become slightly branched as they grow longer); this would be a possible conclusion on the basis of recent chemical results[24]. A similar explanation might be given to the increase in linear component observed in all cereal starches[3] and wrinkled pea starch[24] during their development. I have always maintained that, while growth is by apposition, some intussusception could easily occur, especially since parts of the plastid matrix may become included as the starch granule grows[3]. The peculiarities mentioned deserve intensive study.

(4) *Factors which can influence starch deposition in the plastid.* We assume that: (1) the chemical composition of the plastid is genetically fixed; (2) phosphorylase is the initial starch synthesizing enzyme; (3) amylose is formed first and then transformed into amylopectin by *Q*-enzyme; (4) starch crystallizes out in microcoacervate droplets before branching is complete (ordinary starches) or after it has been completed (waxy varieties).

Some of the factors that may have an influence on this process are listed here; they may differ between species and between organs of one plant.

(*a*) The quantity of water available for hydration is known to influence the type of crystallization: less water available causes a tendency towards the *A*-spectrum[3].

(*b*) Higher temperature also brings about stronger molecule association; both *in vivo*[25] and *in vitro*[3] the X-ray spectrum is shifted towards the *A*-type. Higher temperature can have the effect of producing amylose chains of shorter length[26].

(*c*) Fatty acids and phospholipids cause stronger retrogradation, especially of the linear fraction.

(*d*) Inorganic phosphate limits the chain-length of amylose by suppressing its formation[27]. Esterified phosphate increases swelling power (as in the potato starch granule).

(*e*) Many salts retard retrogradation[28], and some influence the crystallization pattern[29]. In this connexion it may be significant that potato starch has the highest ash content of all[30], with potassium as the main cation.

(*f*) Glucose may inhibit amylose formation[27].

(*g*) Sucrose competes successfully for hydration water[3]. This may be an important factor in all seeds where high sucrose concentration is associated with decreased starch production. Such seeds shrink when they are dried; their starch has low swelling power and high amylose content. Examples are: wrinkled pea, sweet corn, and corn with the gene *sh*-2.

(*h*) Proteins can form complexes with the starch molecules[3]. Interaction with enzymes like amylases may shorten the chain-length of the linear fraction[24].

(*i*) The type and quantity of primer has a great influence; the concentration of G-1-P may be equally significant[3].

I consider the factors last mentioned under (*i*) to be of prime importance, because they initiate starch formation. There may be factors other than the few enumerated, but it will be clear from the examples cited that starch formation in the plastid is a very complex process. At present it is impossible to correlate the factors with known starch properties, but there is a wide field open for research in this direction. All we can say now is that variations in starch granule structure are probably associated with the complexity of the plastid.

Substances like saponins and chlorogenic acid, which are known to have an inhibitory action on starch formation, occur in the vacuoles and not in the plastids; they are of little interest in this connexion.

In coacervate droplets linear molecules will be continuously formed and gradually subjected to the branching action of *Q*-enzyme. During their formation the molecules are subjected to the influence of substances in the plastid. Crystallization brings an abrupt end to this process, and could leave a minority of molecules unbranched, some slightly branched[21], and others unfinished on their way to amylopectin. A good approach for further research would be the study of plastid models in which various factors are allowed to act under controlled conditions, to test the validity of the foregoing concept.

FUNGAL DISEASE IN MALAYAN TOADS: AN ACUTE LETHAL INFLAMMATORY REACTION

By Dr. S. S. DHALIWAL
Department of Zoology
AND
Dr. D. A. GRIFFITHS
Department of Botany University of Malaya, Kuala Lumpur

Bufo melanostictus collected around Kuala Lumpur for laboratory class dissection work showed a high incidence of tumour-like structures on the skin (Fig. 1). Out of 471 toads examined to date, 218 were infected externally. No difference in the percentage of infected animals was found between males and females, and random samples collected at different periods over a year showed no seasonal variation. The commonest sites of infection were the ventral and dorsal surfaces and the hind limbs, the incidence being higher on the ventral surface. Of the 218 infected toads 76 were infected internally and the organs commonly infected were the liver and kidney, but the spleen, ovary, heart (ventricle) and the lung were occasionally involved. No toads were found to be infected internally unless at least one external lesion was also present.

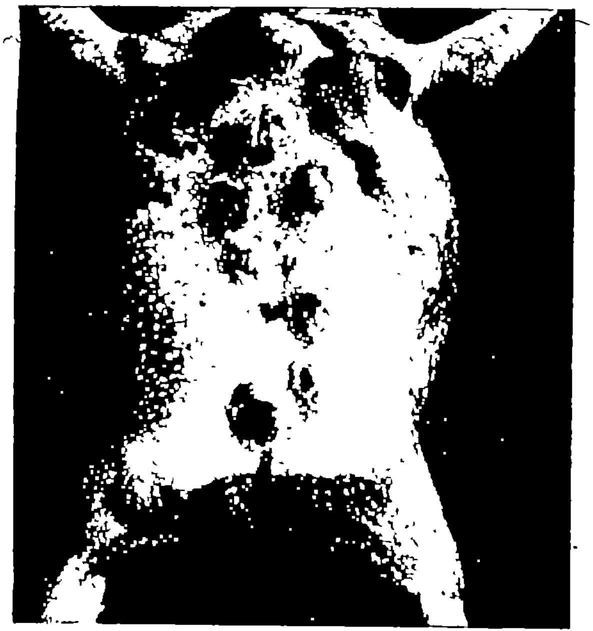

Fig. 1. Ventral view of a toad showing external lesions. Note the large lesion at the top of the sternum

Gross appearance of lesions. The external lesions appeared as pale red or whitish tumour-like structures which varied in size from small nodules to structures of 10–20 mm in diameter. The smaller nodules were hard, whitish and fibrous, while the larger and older lesions tended to be soft and reddish and were frequently ulcerated. The internal lesions were usually whitish and varied in size from small nodules to large structures, sometimes 2–3 times the size of the kidneys.

Histopathology of the lesions. The lesions from the skin and internal organs were almost identical in histology, that is, between the cellular elements were found fungal hyphæ consisting of dark-staining, separate hyphæ frequently composed of globular segments (Fig. 2). Fruiting bodies were never present in the tissues. The individual segments of the hyphæ were usually widely separated by large masses of inflammatory tissue, a condition which contrasts with that reported by Elkan[1] in *Bufo bufo*, where large masses of mycelium had induced inflammatory reaction in the epidermis and the renal tissues.

The inflammatory tissue surrounding the fungal hyphæ consisted mainly of monocytes interspersed with fibrocytes. Foreign-body giant cells with 5–100 or more nuclei were seen in various regions of the sections, usually surrounding part of a fungal hypha. The number and size of giant cells varied according to the site of infection and in the skin lesions they frequently contained 25–50 nuclei. In the liver 100 nuclei could be counted in some of the giant cells but in the kidney, heart and lung lesions they usually had only 5–10 nuclei.

Lesions on the skin consisted of inflammatory tissue which completely replaced the connective and muscular layers in the dermis. The blood vessels in this region were dilated to 10–20 times the size of normal blood vessels in the dermis (Fig. 3). The epidermal layer above the infected region was invariably thickened except in advanced lesions where ulceration had occurred and no epidermal layer was present. A few mitotic cells could be seen among the inflammatory tissue, but these

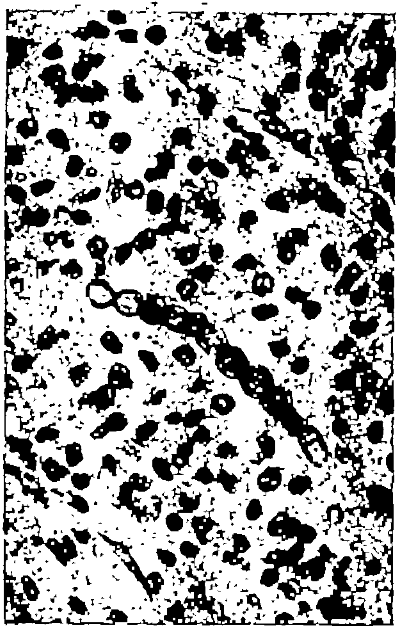

Fig. 2. Photomicrograph of fungal mycelium surrounded by fibrocytes and monocytes

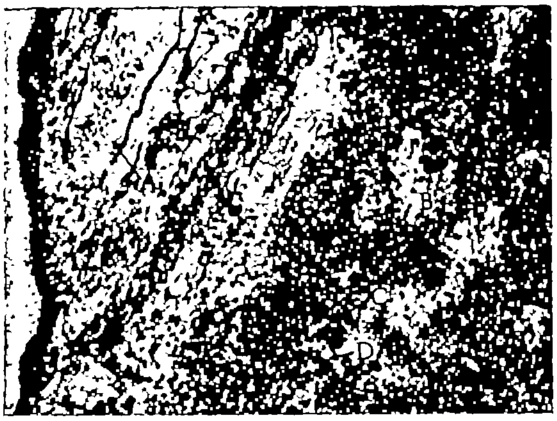

Fig. 3. Photomicrograph of a surface lesion showing dilated blood vessels (*A*), and inflammatory tissue with giant cells, *B*, *C* and *D*

were especially common in and below the hyperplastic epidermis. In one experiment (see further on) the most pronounced effect of strapping the fungus on the back of the toad was the enlargement of poison glands and accumulation of monocytes along their ducts. Study of small young lesions showed that the primary sites of infection are the poison glands. The poison glands have openings to the exterior, and presumably the fungus enters the poison gland through the duct.

The internal lesions on the liver and kidney were histologically similar to the external lesions. There was an accumulation of monocytes and fibrocytes. Giant cells were common in the liver tissue, although only a few were found in the kidney tissue. The blood vessels in the lesions were enlarged. In liver and kidneys with advanced lesions, inflammatory tissue completely replaced the liver lobules and kidney tubules. In the periphery of the lesions the tubules were intact and bits of hyphæ associated with the inflammatory tissue occurred in between the tubules. Only three cases of infection were found in the heart. All these were heavily infected and generally very little cardiac tissue was left intact.

Transplantation of inflammatory tissue. Inflammatory tissue was transplanted subcutaneously with a trocar and cannula after mincing with a fine pair of scissors. The transplanted tissue grew to 20–30 mm in about 10 days, killing all the toads within three weeks. On dissection the tissue was found to be heavily vascularized, and infective centres occurred on the liver and kidney in a majority of toads. Presumably the fungus was carried from the primary site of inoculation to these secondary sites of infection.

The severe reaction produced in such a short time indicates that the fungus is highly toxic and lethal to the toads.

Inoculation of crude extract. Crude extracts of inflammatory tissue were prepared by mincing the tissue in sterile water in glass homogenizers. The cellular elements were removed by centrifuging at 1,200*g* and the extract inoculated subcutaneously and intraperitoneally. Toads injected developed the disease at the sites of inoculation and died within two months. Histological examination of sections of the infected tissue again showed the presence of fungal hyphæ. This indicates that some hyphæ were present in the extract.

Isolation of fungus. Freshly caught toads bearing severe external lesions were anæsthetized, surface washed with mercuric chloride and dissected under sterile conditions. Small nodules on the liver were removed and macerated in sterile saline solution. The macerate was suspended in sterile distilled water and a dilution series made in malt agar, containing 100 units penicillin and 50 μg streptomycin mixture/ml. After 4 days incubation at 25° C, hyphæ growing from segments of liver tissue were removed and sub-cultured on to nutrient agar containing no antibiotics to test for contamination by bacteria. Pure cultures of the fungus were transferred to liquid Czapek-Dox solution supplemented with autoclaved, bacterially filtered toad-liver extract.

Inoculation of fungus. After three weeks' growth in liquid culture the mycelium was removed and macerated in sterile distilled water. This macerated fungal material was inoculated subcutaneously and intraperitoneally into healthy toads with a trocar and cannula. The animals were kept in large aquaria and after 10 days were anæsthetized and dissected.

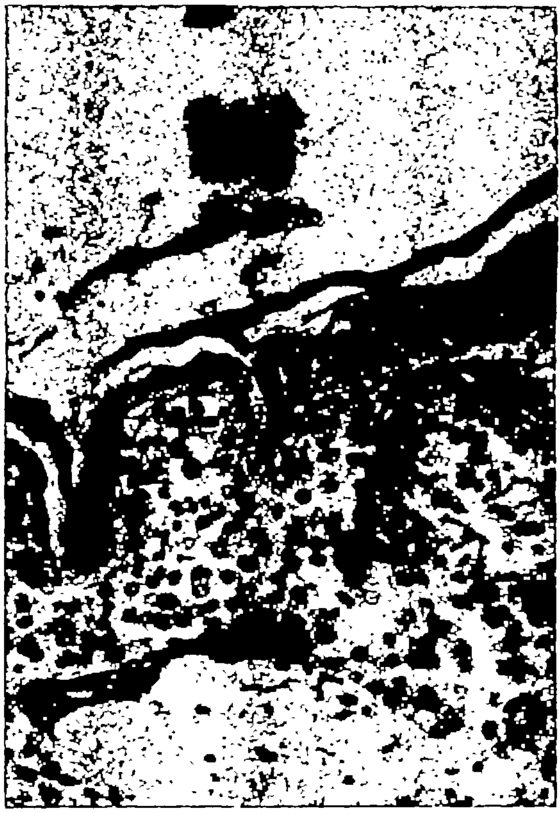

Fig. 4. Photomicrograph of the abdominal wall showing emergence of fungal hyphæ

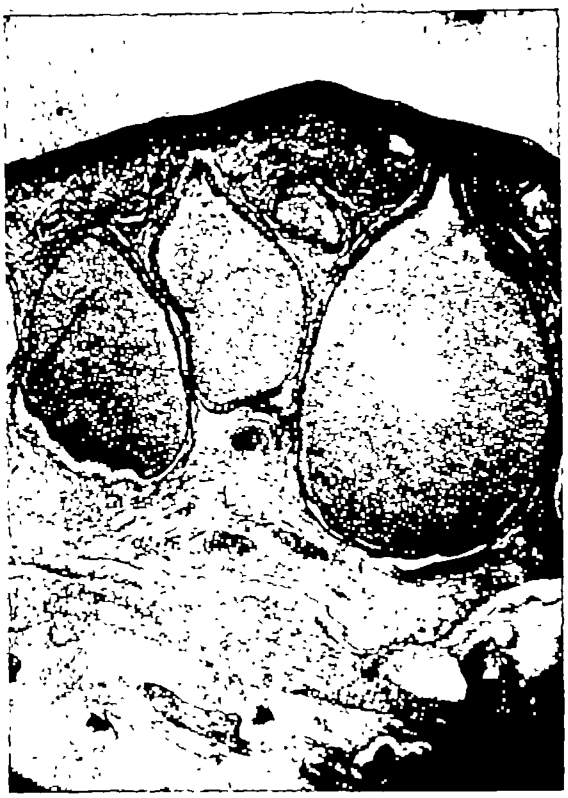

Fig. 5. Photomicrograph of the epidermal and sub-epidermal layer showing gross enlargement of poison glands and hyperplasia of epidermal layer

Series I: Subcutaneous inoculation. Macroscopically, the only observable symptom was the development of small nodular structures in the sub-epidermal connective tissues. In section these were seen to consist entirely of inflammatory tissue containing intercellular fungal hyphæ.

Series II: Intra-abdominal inoculation. The most obvious macroscopic symptom was the marked inflammatory reaction at the site of abdominal puncture. At this point the abdominal wall became greatly thickened and nodulated. The inflammatory tissue was seen to be composed of monocytes and fibrocytes arranged in whorls, that is, each piece of hypha became the locus of cellular accumulation. The muscular layers of the outer abdominal wall consisted of normal fibrillar layers between which were developed masses of small nucleated cells similar to those making up the inflammatory tissue. In many instances the muscular layers had been completely destroyed by the inflammatory tissue. Where this had occurred hyphæ had grown through the abdominal wall and penetrated the sub-epidermal layers resulting in the development of hyphæ on the outer surface of the animal (Fig. 4), thus facilitating dissemination of the fungus. In some sections the fungal hyphæ had migrated towards the epidermal layer and entered the poison glands from the inside, together with an accumulation of phagocytic monocytes. Associated with inflammation of the abdominal wall, organs within the abdominal cavity invariably developed small white nodules similar to those found in naturally infected toads. Sections of the liver, kidney and lungs showed marked inflammation at the site of infection and the development of migratory hyphæ and inflammatory tissue between the tubules at the periphery of the lesions.

Attempts to establish infection via the epidermis failed due to the difficulty of maintaining a skin/fungus contact over a period of several days' incubation. In cases where contact had been established for 5 days the most obvious histological feature was the increase in thickness of the dermal layers due to the enlargement of the poison glands beneath the epidermis and hyperplasia of the epidermal cells (Fig. 5).

We thank Dr. E. Elkan of the Group 9 Pathological Laboratory, Watford, England, for his advice throughout the investigation and to Prof. J. R. Hendrickson and Prof. M. E. D. Poore for help in the preparation of the manuscript.

'WASTING DISEASE' FOLLOWING THYMECTOMY IN THE HAMSTER

By Dr. JOSEPH D. SHERMAN and Dr. WILLIAM DAMESHEK

Blood Research Laboratory, Pratt Clinic—New England Center Hospital and the Department of Medicine, Tufts University School of Medicine, Boston

SINCE thymectomy has been shown to impair the immune response in rats[1], mice[2], chickens[3] and rabbits[4], this procedure was undertaken in the golden hamster (*Mesocricetus auratus*), in an attempt to develop a group of animals which might be tolerant to transplanted human leukæmia and lymphoma. Male and female hamsters were thymectomized 1–4 weeks following birth, and in addition, some animals were partially thymectomized and sham operated. It was soon apparent that total thymectomy in male (but not in female) hamsters 1–4 weeks of age resulted in the development of a disease which had many of the gross and clinical features of runt disease[5]. Histologically, there was a marked generalized reduction in lymphoid tissue.

Eighty-four nursing hamsters 1–4 weeks of age were totally thymectomized. The animals were anæsthetized with intraperitoneal pentobarbital sodium. A midline incision was made through the skin and superficial fascia from the mid-cervical area to the level of the sixth rib and then extended down to the deep fascia. A longitudinal incision was then made through the middle of the sternum and extended to the level of the fourth rib exposing the bilobed thymus. The gland was freed from the surrounding structures by blunt dissection. All bleeding was easily controlled with a cotton-tipped applicator stick. After removal of the thymus, interrupted sutures were placed in the pectoralis muscles, and the skin was closed by continuous sutures. There was a 5 per cent mortality due to respiratory arrest, overdosage of anæsthesia and cannibalism.

The total removal of the thymus gland was followed by the rapid development (4–14 days) of a severe, progressive, fatal disease, characterized by weight loss, wasting, lethargy, dorsal kyphosis, periorbital and facial œdema, rough, unkempt fur and posterior cervical alopecia, unsteady gait and diarrhœa or constipation (Figs. 1 and 2). Anæmia, slight reticulocytosis, thrombocytopænia, mild leukopænia and an absolute reduction in circulating lymphocytes were also found. Only males were affected: thus of 44 males thymectomized, 28 developed the wasting syndrome; however, of 36 females thymectomized, none showed any indications of the disorder.

Post-mortem examination of the affected animals revealed no gross evidence of sepsis and cultures of the surgical site and heart blood were negative. There was a striking depletion of body fat, no evidence of residual

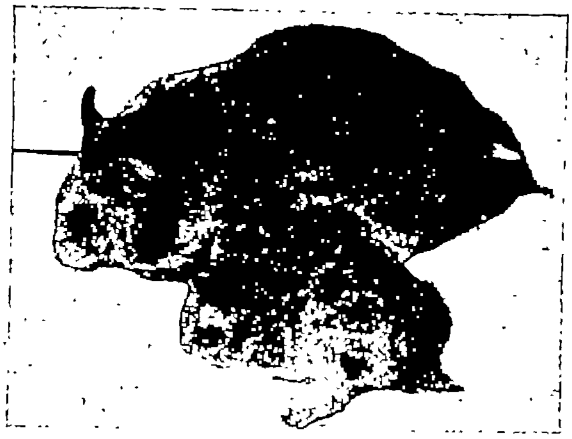

Fig. 1. Sham-thymectomized and thymectomized hamsters, 4 weeks after birth. The smaller thymectomized animal shows loss of weight wasting, unkempt fur, dorsal kyphosis and periorbital œdema

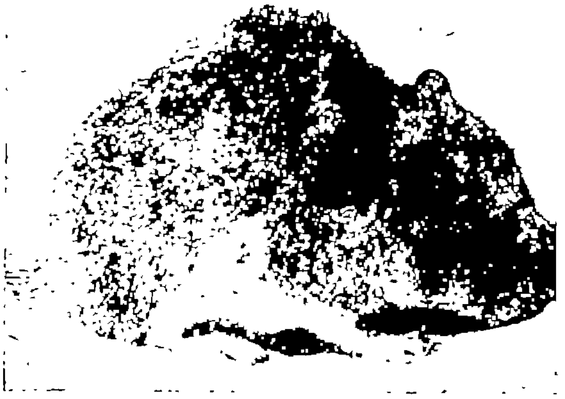

Fig. 2. Close-up of thymectomized hamster of Fig. 1 showing in more detail the features of 'wasting disease' and having the general appearance of runt disease (homologous or secondary disease)

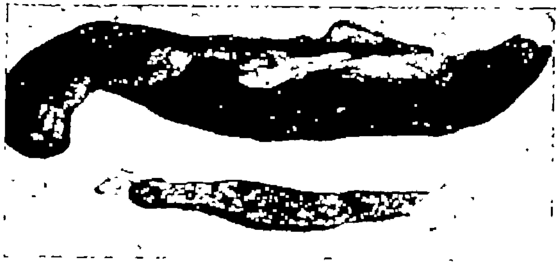

Fig. 3. Marked reduction in spleen size in a thymectomized hamster compared with its litter mate, sham-thymectomized, control

thymic tissue, a marked reduction in spleen size (Fig. 3) and an almost complete absence of Malpighian corpuscles in the spleen (Fig. 4); Peyer's patches were similarly reduced. These gross and histological changes were not observed in sham-thymectomized, partially thymectomized or control hamsters (Fig. 5).

It is obvious that thymectomy induced a state of what might be called wasting, cachexia, or runting. Was the condition observed 'runt disease' or did it merely simulate it more or less closely? Runt disease (homologous or secondary disease) is almost universally conceded to be a graft versus host reaction produced by the administration of immunologically competent cells to an immunologically neutral recipient. The various immunological reactions of the genetically different grafted tissue against the recipient's cells and tissues are thought to induce this experimental disorder[4–7]. Runt disease produced by the injection of parental strain spleen cells into normal adult F_1 hybrid mice is characterized by hæmolytic anæmia with a positive antiglobulin test, leukopænia, thrombocytopænia, splenomegaly, loss of weight, lethargy, hunched appearance, rough unkempt fur with partial alopecia in the posterior cervical area, facial and periorbital œdema and hypothermia[8].

There is a striking similarity between the various clinical features of the 'wasting disease' produced in thymectomized hamsters and the changes produced in mice injected with parental strain spleen cells. The hæmatological features, that is, anæmia, mild reticulocytosis, leukopænia and thrombocytopænia, are perhaps similar although a positive Coombs' antiglobulin test has not been demonstrated. Pathologically, the 'wasting disease' of the hamster differs from runt disease of the mouse in that the former does not have splenomegaly, but on the contrary is characterized by a generalized depletion of lymphoid tissue, with a reduction of Malpighian corpuscles, Peyer's patches and peripheral blood lymphocytes. The histology of runt disease is variable,

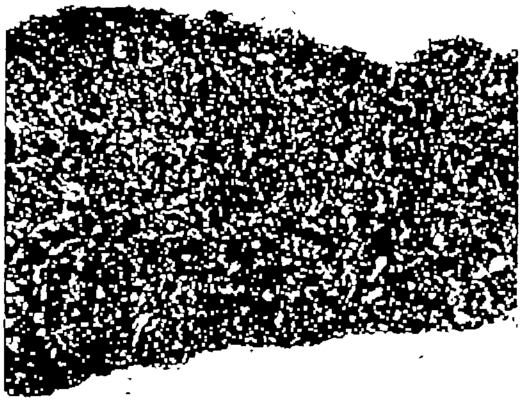

Fig. 4. Section of small spleen in Fig. 3 (thymectomized hamster) showing absence of Malpighian corpuscles (× 350)

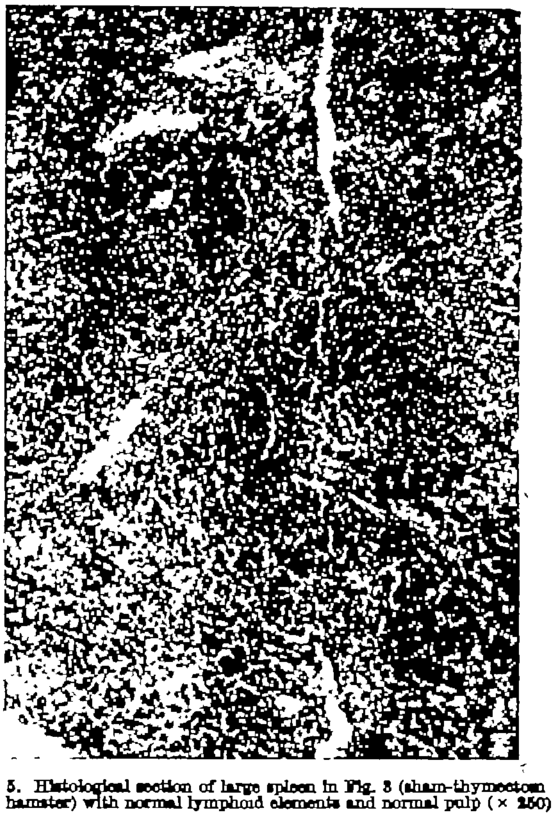

Fig. 5. Histological section of large spleen in Fig. 3 (sham-thymectomized hamster) with normal lymphoid elements and normal pulp (× 250)

although some observers allude to a great reduction in lymphoid elements in the spleen and lymph nodes[8].

In view of the many striking similarities between runt disease and the 'wasting disease' which was induced in new-born hamsters by thymectomy, one may speculate that they are either similar 'end-products' of different mechanisms or that the fundamental mechanism may be the same in both instances. A graft-versus-host phenomenon can be ruled out in the thymectomized animals. There is a possibility that the depleted lymphoid tissue might lead to an unbalanced state of antigen excess to antibody production, which could in some manner lead to runting. Or perhaps the thymus is involved in runt disease, a subject not discussed in the literature of that disorder until very recently. Thus, Billingham *et al.*[9] recently noted that injection of thymic tissue failed to induce runt disease in F_1 hybrid rats and thymic atrophy occurred in runted rats. We have noted thymic atrophy in runted male F_1 hybrid LAF_1 mice injected with parental strain spleen cells.

It is noteworthy that depletion of lymphoid tissue has been considered to be an important factor in the production of runt disease[4]. Mueller *et al.*[3] made chickens lymphoid deficient by 19-nortestosterone, and noted signs of a disease that was similar to that seen in our thymectomized hamsters. It should be noted that splenectomy of the hamster has not resulted in any disease.

A condition which has been called 'thymic cachexia' has been observed by other investigators in other species[10–12] and the various features as described are comparable with those noted in the hamster. Similarities between post-thymectomy wasting and runt disease have not been previously mentioned. The failure of females to develop the wasting syndrome following thymectomy is of considerable interest and requires further study. This and other observations are at present under way to define more clearly the role of the thymus gland in the gross reduction of lymphoid tissue that follows total thymectomy of the new-born hamster, and its relation to the wasting disorder.

This work was supported by grant No. *CY*–4168 from the U.S. Public Health Service and during the tenure of a special fellowship *CF*–3237 from the National Cancer Institute, U.S. Public Health Service (J. D. S.).

ANTIGENIC RELATIONSHIP BETWEEN HOST AND PARASITE

By Dr. J. K. DINEEN

C.S.I.R.O., Division of Animal Health, McMaster Laboratory, New South Wales, Australia

IT has been suggested that the immune response of the host may exert selective pressure on 'fitness' for survival of many parasitic species. In those situations where the effect of the immune response is contemporary with the development of the parasite within the host, it is expected that selection for survival may only favour variants of the parasite which display reduced antigenic disparity with the host[1]. It was also suggested that for the evolution of the host/parasite relationship a reduction of disparity would only be necessary with those antigenic characters of the parasite, which stimulate immune responses which adversely affect survival of the parasitic species. It seems likely that many other antigenic characters stimulate a variety of immunological responses in the host; but if these in no way influence 'fitness' of the parasitic species then a progressive change in the causal antigens would not be a requirement for evolution of the host/parasite relationship. Such characters which do not stimulate the mechanism of resistance of the host may undergo mutation in a random fashion, and this genetic change may be expressed without progressive drift for reduction of antigenic disparity with the natural host.

The experiment described in this article was designed to seek evidence of reduction of antigenic disparity associated with selection for 'fitness' characters[1]. It is based on a comparison of the serological responses evoked by larval and adult antigens of the parasite *Haemonchus contortus* in the natural host (sheep) with those evoked in the rabbit. It is deduced, as an *a priori* consequence of hypothesis, that the natural host will fail to recognize 'fitness' antigens, or will show relatively little immunological responsiveness to them while reacting with normal vigour to those antigens of the parasite which do not influence 'fitness' of the organism. Conversely, it is expected that with the rabbit, which is not a natural host for this parasite, there will be serological responses to a greater range of antigens because there has not been the same reduction in disparity due to selection of 'fitness' antigens during an evolutionary period. By the use of the Ouchterlony gel-diffusion technique, evidence was obtained which supports the thesis that certain antigens of the parasite show reduced disparity with the natural host (sheep), and that these relevant antigens are shared by the larval and adult stages of development of the parasite.

For the experiments, antigens were prepared by homogenizing the infective larvae and adult worms of *Haemonchus contortus* in physiological saline. The larval and adult-worm homogenates were then fractionated by differential centrifugation. The crude particulate material of the homogenates was sedimented by centrifugation at 4,000 r.p.m. for 1 h at 2°–4° C in an angle-head centrifuge. The supernatant fluids were then centrifuged at 144,000*g* for 1 h in a Spinco model *L* ultra-centrifuge. The clear gelatinous pellet sedimented by ultra-centrifugation was redissolved in physiological saline. The crude particulate material, and the sediment and clear supernatant obtained after ultra-centrifugation, were used for the production of antisera in sheep and rabbits. The soluble antigenic fractions, that is, the redissolved gelatinous pellets and supernatant fluids of both larval and adult-worm preparations, were used in the Ouchterlony-plate technique to characterize the antibodies in the rabbit and sheep sera and to assess their specificity.

Eight rabbits and eight sheep, born and reared worm-free, received the larval and adult-worm antigens by four intraperitoneal injections of the fractions spaced at 3-weekly intervals. Blood for serum samples was collected from the marginal ear vein of the rabbits and from the jugular vein of the sheep ten days after the fourth injection of the antigen.

Gel-diffusion plates were prepared from 1 per cent Oxoid 'Ionagar No. 2' in physiological saline with merthiolate added as preservative to a concentration of 1 in 10,000 parts. Agar plates were poured to a depth of 7 mm and five symmetrically placed wells, 8 mm in diameter, were cut with a cork borer and centred 16 mm from a central well also 8 mm in diameter. Each central well was charged with one of the soluble larval or adult-worm antigenic fractions and the peripheral wells with the appropriate undiluted antisera. The plates were incubated at 30° C and bands of antigen/antibody precipitate were usually fully developed in five to six days.

The results of the gel-diffusion studies have been consistent. In comparison with the antisera produced in rabbits, larval and adult-worm antisera produced in the natural host (sheep) showed a relatively high degree of specificity of reaction with antigens from the corresponding developmental stage of the parasite.

With sheep antisera, multiple antigen/antibody bands were formed during the course of double diffusion of the larval antisera with the larval fraction used for immunization. Furthermore, tests with each of these larval antisera and the other soluble larval fraction produced cross-reactions. This finding was expected because of the crude nature of the antigenic fractions. However, none of the four larval antisera reacted with the crude antigenic fractions similarly prepared from adult worms. The four sheep-antisera to adult-worm fractions showed a similar degree of immunological specificity but in the reverse direction. These sera precipitated with the adult-worm fraction used for immunization and cross-reactions with the other adult-worm fractions were also observed. Thus the specificity of antisera prepared in the sheep was demonstrated by the failure of the larval antisera to react with the adult-worm antigens and vice versa.

The larval and adult-worm antisera produced in rabbits precipitated with the injected antigenic fractions, and cross-reactions were observed with larval or adult-worm fractions other than the particular fraction used for immunization. In addition to the cross-reaction with fractions from the corresponding developmental stage of the parasite, the rabbit antisera also reacted with the other category of antigenic fractions, that is, the rabbit larval antisera reacted with the adult-worm fractions and the adult-worm antisera reacted with larval antigens. These cross-reactions were in sharp contrast with the results obtained with sheep antisera.

The relative unresponsiveness of the natural host (sheep) to those antigens which are common to the larval and adult stage of development of the parasite suggests that such antigens constitute 'fitness characters'. It is relevant in this context that infecting parasites, when superimposed on an existing infection, may not develop beyond the larval stage. Roberts and Keith[2] have extended this finding by showing that, after the differential removal of adult worms by treatment of a *Haemonchus placei* infection of cattle with phenothiazine, the remaining larvæ that had been arrested in their growth may then complete their development. If, as Roberts and Keith have suggested, this phenomenon of arrested growth in larvæ is based on an immunological response of the host to the infection, then the results of the experiments just described indicate that the control exercised by the host on larval development could be stimulated not only by antigens in larvæ but also by certain antigens in adults which are common to both stages of development.

It is interesting to note that Michel[3] has recently suggested that resistance to *Dictyocaulus viviparus* in cattle is also a reaction to antigens produced by both early parasitic stages of the organism and by mature adults. The observations described in the present study are consistent with these views.

Further work on the relationship of antigens from host and parasite is being undertaken with the aid of the more refined technique of immune electrophoresis.

GROSS STRUCTURE OF HÆMOGLOBIN A_3 AND THE NATURE OF ITS BINDING TO CHROMIUM-51

By H. A. PEARSON*, M. T. VAN METRE and K. M. VERTREES

U.S. Naval Hospital and Radiation Exposure Evaluation Laboratory,
National Naval Medical Center, Bethesda

HÆMOGLOBIN from the red cells of normal persons when separated by electrophoresis at alkaline *p*H is not homogeneous. Rather, it consists of three components: the major fraction, hæmoglobin A_1, constituting about 90 per cent; the slow minor component, hæmoglobin A_2, constituting 2–3 per cent; finally, the fast minor component, hæmoglobin A_3, ranging in quantity from 3 to 10 per cent of the total hæmoglobin. Synthesis of hæmoglobin A_1 and A_2 is under direct genetic control. The nature of hæmoglobin A_3 is less clear, and it has been postulated that it is a senescent form or breakdown product of hæmoglobin A_1 (ref. 1).

One of the most striking characteristics of hæmoglobin A_3 concerns its properties with respect to tagging with chromium-51. Metrakis, in 1957[2], and afterwards Malcolm and Ranney[3] and Ebaugh *et al.*[4] have noted that when hæmoglobin labelled with chromium-51, obtained from normal red cells, is electrophoresed at alkaline *p*H, the hæmoglobin A_3 fraction contains disproportionately large amounts of radioactivity. Using starch block electrophoresis at *p*H 8·6, we also have noted that although hæmoglobin A_3 constitutes only 5–10 per cent of the total hæmoglobin, 32–60 per cent of the total chromium-51 radioactivity is associated with the hæmoglobin A_3 fraction.

Investigations previously reported from our laboratory indicated that chromium-51 binding to hæmoglobin was largely a function of the β-polypeptide chains[5]. This conclusion was based first on the finding that hæmoglobin H (β_4^A) had approximately twice the specific activity per unit of hæmoglobin as did hæmoglobin A_1 ($\alpha_2^A\beta_2^A$). This observation has been confirmed and extended by Rigas[6]. Secondly, when hæmoglobin A_1 labelled with chromium-51 was mixed with non-radioactive hæmoglobin C ($\alpha_2^A\beta_2^C$) and the mixture then subjected to acid dissociation and recombination, only a 2–3 per cent increase in the radioactivity associated with the hæmoglobin C fraction was observed. This would indicate β-chain binding in the order of 95+ per cent. Schneiderman has repeated similar recombination studies and confirmed these findings[7].

Ebaugh *et al.*[4] studied polypeptide chain binding of chromium-51 by means of the Wilson and Smith technique of gradient elution with acid urea from a weak cationic resin column[8]. Under the condition used by Ebaugh, chromium-51 activity was found to be largely associated with the β-chain fractions. However, Chernoff, using a similar technique, observed what was interpreted as α chain binding[9].

Since hæmoglobin A_3 has such unusual chromium-51 binding properties, it was decided to investigate the pattern of chromium-51 activity and gross polypeptide chain composition of hæmoglobin A_2. Hæmoglobin A_1 and hæmoglobin A_2 were obtained by multiple starch block electrophoretic separations in veronal buffer *p*H 8·6. Approximately 200 mg of hæmoglobin A_2 and 500 mg of hæmoglobin A_1 were collected. The hæmoglobin solutions were dialysed free of buffer. Tagging was then accomplished by the addition of approximately 25μ of chromium-51 (as $Na_2{}^{51}CrO_4$) per gramme of hæmoglobin, and incubation of the mixture at room temperature for 4 h. The radioactive hæmoglobin solutions were then dialysed against 11·7 per cent formic acid before adsorption on 25 g of washed 'Amberlite *CG*-50' type II resin. The resin with adsorbed hæmoglobin was then added to the top of a column containing 75 g of wet resin. 1 l. of 2 M urea, *p*H 1·9, was passed through the column before starting the continuous molarity gradient from 2 to 8 M with acid urea. Three hundred, 12–15 ml. fractions of eluate were collected. The optical density at 280 M μ of the even-numbered fractions was read in the Beckman *DU* spectrophotometer. The corrected counts/min/ml. eluate of the odd-numbered fractions were determined in a scintillation counter with a 3-in. well-type sodium iodide crystal.

* Present address: Department of Pediatrics, University of Florida School of Medicine, J. Hillis Miller Health Center, Gainesville.

The results of the separation of radioactive hæmoglobin A_1 are depicted in Fig. 1. The first protein peak separated by this method consists largely of α-chains, while the second peak contains predominantly β-chains[8]. More than 95 per cent of the total radioactivity that was associated with protein-containing fractions was found in the β-chain region, confirming Ebaugh's results.

In addition, in agreement with Ebaugh, we observed a large initial loss of radioactivity long before the first protein peak. Chernoff apparently did not encounter such an initial loss, perhaps because of his modifications of the chromatographic technique[9], in which 3 M urea is used initially and a discontinuous acid urea gradient is used.

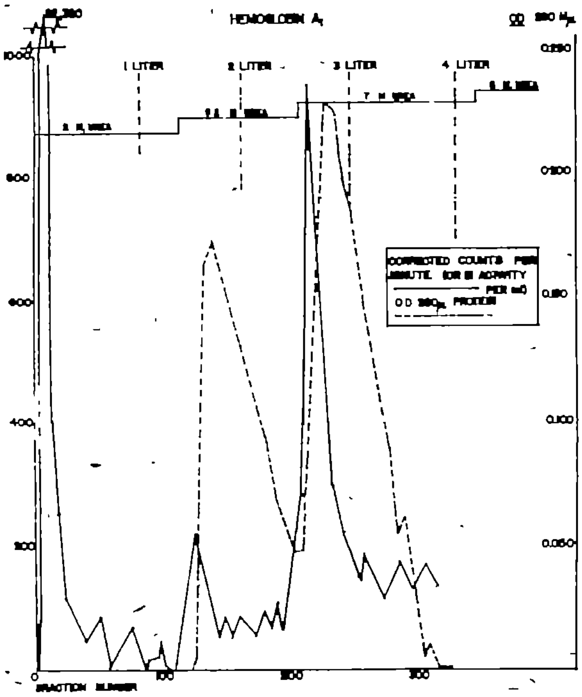

Fig. 1

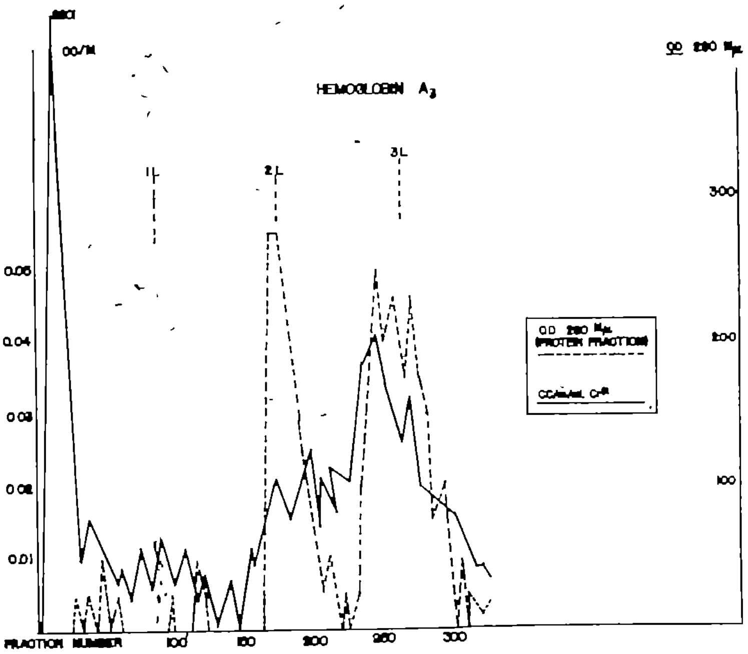

Fig. 2

When hæmoglobin A_2 labelled with chromium-51 was separated in the same way, the patterns for both protein and chromium-51 activity were similar to those obtained with hæmoglobin A_1 (Fig. 2). Because of the lesser amount of hæmoglobin A_2 used, both protein and chromium-51 curves were of less magnitude. However, the ratio of optical density to corrected counts per minute for the β-chain fraction of hæmoglobin A_1 and hæmoglobin A_2 were similar.

The observation of a similar pattern of the protein peaks obtained with hæmoglobin A_2 and A_1 indicates that there is no gross molecular alteration of hæmoglobin A_2, and that α- and β-chains are present in roughly equal proportions in hæmoglobin A_2.

1 per cent solutions of hæmoglobin A_1 and A_2 were placed in separate bags and dialysed for 24 h in a single container against an aqueous solution containing 100 μc. of $Na_2{}^{51}CrO_4$. After tagging had been thus accomplished, the hæmoglobins were dialysed against distilled water for 12 h to eliminate all unbound isotope. The specific radioactivity for hæmoglobin A_1 and A_2 was found to be the same. This suggests that, under these experimental conditions, there is no significant difference in binding capacity of hæmoglobins A_1 and A_2.

These studies suggest that the increased activity of chromium-51 observed in the hæmoglobin A_2 fraction after electrophoresis at alkaline *p*H is not due to some peculiar polypeptide configuration of hæmoglobin A_2. Rather, it is likely that since the chromium-51–hæmoglobin A_1 complex is more electronegatively charged than hæmoglobin A_1 alone, the complex has a more rapid anodal migration. Hence, after electrophoresis, the hæmoglobin molecules tagged with chromium-51 may become concentrated in the hæmoglobin A_2 fraction, producing the very high specific activity which has been repeatedly observed.

LETTERS TO THE EDITOR

ASTROPHYSICS

A New Method of directly measuring the Galactic Magnetic Field

WITH the announcement of the existence of polarization in the Crab Nebula at a wave-length of 21 cm[1], a new method of determining the galactic magnetic field becomes available—the measurement of the Faraday rotation of the plane of polarization due to the presence of anomalous dispersion in the neighbourhood of the 21-cm line of neutral hydrogen. This may be calculated as follows:

The index of refraction due to hydrogen atoms at frequency ν_s is given by:

$$n = 1 + \frac{e^2 N(\nu_0) f}{4\pi m \nu} \; \frac{\nu_s - \nu}{(\nu_0 - \nu)^2 + \left(\frac{\Gamma}{4\pi}\right)^2} \cdot \frac{1}{4}$$

where f is the Ladenburg f for the transition, $3 \cdot 8 \times 10^{-12}$. The factor 1/4 appears because only the atoms in the lower state cause a phase shift. Summing over all hydrogen atoms:

$$n - 1 = \frac{e^2 f}{16\pi m \nu} \int_{-\infty}^{\infty} \frac{(\nu_s - \nu) N(\nu_s)}{(\nu_s - \nu)^2 + \left(\frac{\Gamma}{4\pi}\right)^2} \, d\nu_s$$

When $\Gamma \rightarrow 0$ this integral becomes a Cauchy principal value.

$$n - 1 = \frac{e^2 f}{16\pi m \nu} \text{ c.p.v.} \int_{-\infty}^{\infty} \frac{N(\nu_s)}{\nu_0 - \nu} \, d\nu_s$$

A ray is thus delayed beyond a ray *in vacuo* by:

$$\Delta t = \int \frac{n - 1}{c} \, ds = \frac{ef}{16\pi m\nu c} \text{ c.p.v.} \int_{-\infty}^{\infty} \frac{\int N(\nu_s) ds}{\nu_s - \nu} \, d\nu_s$$

which corresponds to a phase lag of:

$$\Delta\varphi = \omega \Delta t = \frac{e^2 f}{8mc} \text{ c.p.v.} \int_{-\infty}^{\infty} \frac{\int N(\nu_s) ds}{\nu_s - \nu} \, d\nu_0$$

The optical depth $\tau(\nu_s)$ is given by:

$$\tau(\nu_0) = \frac{\nu}{c} \beta \int \frac{N(\nu_s)}{T_s} \, ds$$

where $\beta = 5 \cdot 45 \times 10^{-14}$ cm^3 sec^{-1} deg. K, and T_s is the spin temperature.

If we assume T_s constant:

$$\Delta\varphi = \frac{e^2 f}{8m\beta\nu} T_s \text{ c.p.v.} \int_{-\infty}^{\infty} \frac{\tau(\nu_s)}{\nu_s - \nu} \, d\nu_0$$

The Faraday rotation ψ is the change in phase between the right and left circularly polarized components. If they are separated in resonant frequency by:

$$\Delta\nu = 2 \cdot 8 \times 10^6 B \text{ c.p.s.}$$

then

$$\psi = \frac{e^2 f}{8m\beta\nu} \mathrm{T}_s \frac{d}{d\nu} \left(\text{c.p.v.} \int_{-\infty}^{\infty} \frac{\tau(\nu_s) d\nu_s}{\nu_0 - \nu} \right) \Delta\nu$$

numerically:

$$\psi = 6 \cdot 22 \, T_s \frac{d}{d\nu} \left(\text{c.p.v.} \int_{-\infty}^{\infty} \frac{\tau(\nu_s) d\nu_s}{\nu_s - \nu} \right) \Delta\nu$$

The absorption profile observed with a single paraboloid has been taken from Clark, Radhakrishnan and Wilson[2] to derive the frequency-dependent part of this expression. The resultant for a field of 10^{-6} gauss and $T_s = 100°$ K is plotted in Fig. 1. Some smoothing has inadvertently been introduced in the process of numerical integration. Since ψ is essentially dependent on the second derivative of optical depth with respect to frequency, the estimated rotation is somewhat sensitive to the band-width and saturation corrections to the measured absorption profile.

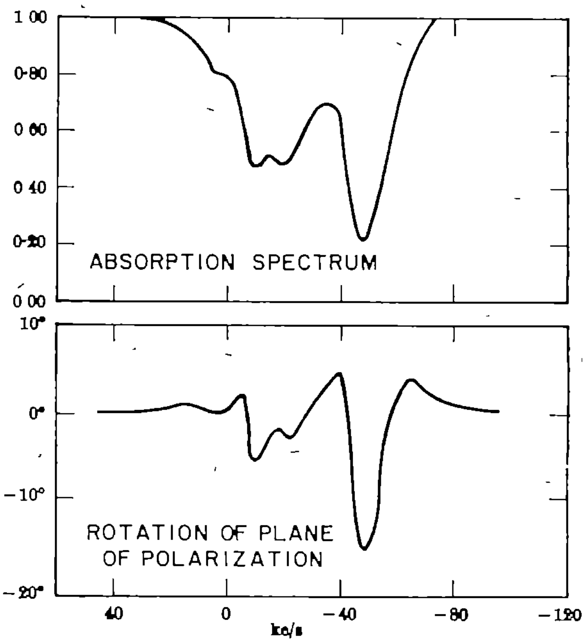

Fig. 1. Absorption profile and Faraday rotation in the Crab Nebula

The measurement of this rotation is in some ways not as difficult as an absolute measurement of the angle and amount of the polarization since instrumental polarization effects need not be considered in finding the frequency dependence of the polarization. Thus the question again reverts to having a sufficiently good signal to noise ratio to detect the polarization. For small magnetic fields the method is comparable in sensitivity with the more conventional measurement of Zeeman splitting in right and left circular polarizations.

RADIOPHYSICS

Radio Observations of Jupiter during 1962

IT has been suggested by Barrow[1] that a rigorous comparison of solar, geomagnetic and Jupiter activity in radio emission cannot be made until continuous observation of Jupiter is possible throughout an apparition. The results summarized in this communication will, it is hoped, help to fill some gaps in the available figures for the 1962 apparition.

Standard communications receivers, suitably modified, were used in conjunction with single folded dipole aerials

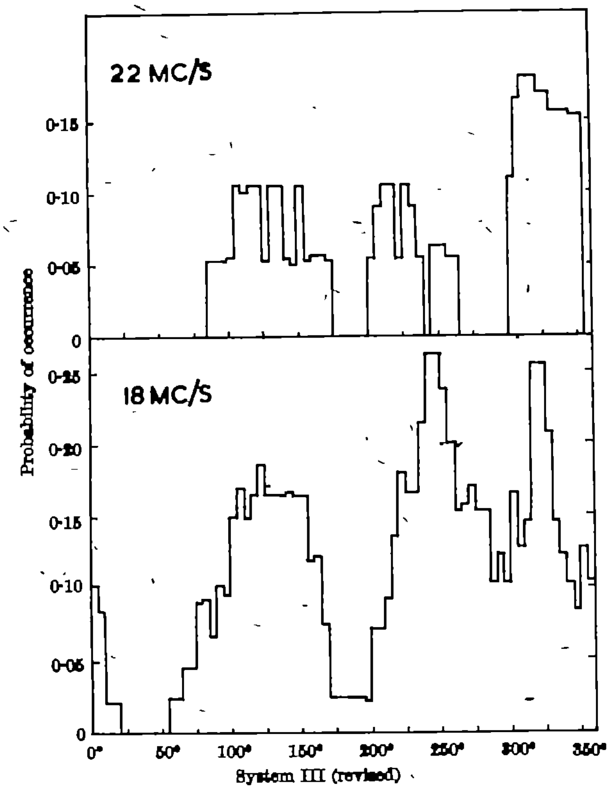

Fig. 1. Occurrence probabilities of radio noise from Jupiter at 18 and 22 Mc/s, July–October 1962

to record signals at frequencies close to 18 and 22 Mc/s, at a site (*A*) near Grahamstown, South Africa. Another standard communications receiver, with an eight-dipole broadside array, was operated at a frequency close to 18 Mc/s to record the noise at a site (*B*) near East London. Observations were made at site *A* each night from July 16–17 until October 15–16, that is, on 92 nights. Jupiter was observable by the equipment from about 2200 h to 0300 h U.T. at the beginning of the period of observation and from 1800 h to 2300 h at the end of it. Observations at site *B* were more irregular but results for 26 nights are available. Recordings were continually monitored aurally at site *B*, but only occasionally at site *A*. Identification of Jupiter noise was made by comparison of records from the two sites, where available, and otherwise by the characteristics of the recorded trace.

Signals identified as coming from Jupiter were observed on 38 nights at site *A* and 14 nights at site *B*. Interference from thunderstorms, apparatus failure, etc., prevented useful recordings on 32 nights at site *A* and from August 29 onwards at site *B*.

The histograms in Fig. 1 show the occurrence probability for each 5° interval of central-meridian longitude on Jupiter, in terms of the revised system III co-ordinates[1]. The occurrence probability is defined as the ratio of the number of events occurring while the central meridian lay in the 5° interval concerned to the total number of times during which that interval was under observation in interference-free conditions. Three sources, at longitudes of about 120°, 240° and 320°, are clearly shown, in agreement with the observations previously reported by other workers[1,2]. The maximum signal strength was of the order of 10^{-20} W/m^2 c/s.

We wish to point out that any investigation of the relationship between solar phenomena and Jupiter's activity must be complicated by the fact that Jupiter's orbital period of 11·9 years almost coincides with the length of the sunspot cycle. It is worthy of note that during the period of minimum activity found by Carr *et al.*[2] the south pole of Jupiter was inclined towards the Earth. The minimum would therefore be consistent with the theory that the radio noise may be produced by particles trapped in Jupiter's magnetic field interacting with the Jovian atmosphere in a possible magnetic anomaly in the vicinity of the north pole.

It is planned to extend observations to a wider frequency band during the 1963 apparition.

We wish to thank the South African Council for Scientific and Industrial Research for a grant for apparatus, the Council of Rhodes University for a grant in aid of transport expenses and the Grahamstown City Council for permission to set up the receiving station on municipal land. We also thank Mr. S. F. H. J. Archer, who suggested the problem and collaborated with us in the early stages.

High-resolution Observations of the Galactic Radiation at 4·7 Mc/s

As part of a programme of radio astronomical measurements at wave frequencies less than 10 Mc/s, observations of the distribution of sky brightness at 4·7 Mc/s were made in Tasmania during the winter of 1962.

The antenna system was a filled-in array 4,000 ft. east–west by 1,000 ft. north–south. It was connected to receivers in which the signals were added in six independent phase arrangements in such a way that the intensity of the cosmic noise at six declinations could be recorded simultaneously. The antenna beam-width was 3° × 11°. The band-width of the receivers was 4 kc/s and minimum reading recorders were used to reduce interference from atmospherics and transmitting stations.

During the nights of May, June, July and August, the ionospheric critical penetration frequency f_0F_2 was normally less than 3 Mc/s for 12–14 h each night. On most nights it was less than 2 Mc/s for lesser periods, and on some less than 1 Mc/s. As a result it was possible to obtain many observations which covered a range of southern declinations of 50°.

Fig. 1 shows examples of records for five declinations. Four of these were recorded on the same night. A notable feature of those for declinations −27° to −47° is the pronounced absorption trough between 1600 *R.A.* and 1900 *R.A.* A peak in the intensity is visible through this trough at declination −27°, that is, in the direction of the galactic centre. This absorption is consistent with a layer of ionized hydrogen in the plane of the galaxy, several hundred parsecs in thickness[1–3].

Two external galaxies *NGC* 5128 and *NGC* 1316 were recorded. The record of Fig. 1 shows *NGC* 5128. These sources had previously been detected with an interferometer at 4·8 Mc/s[4]. In addition, fine detail was observed in the absorption trough as indicated in Fig. 1. This appeared to be due to bright objects of angular size less than the beam-width of the antenna. It was very weak and requires higher angular resolution for further investigation.

The main conclusion to be drawn from this preliminary report is that high-resolution radio astronomy is possible at frequencies less than 5 Mc/s using ground-based receivers in suitable locations. The sky appears to contain as much interesting detail as at higher frequencies. Because of the strong absorption, objects seen near the

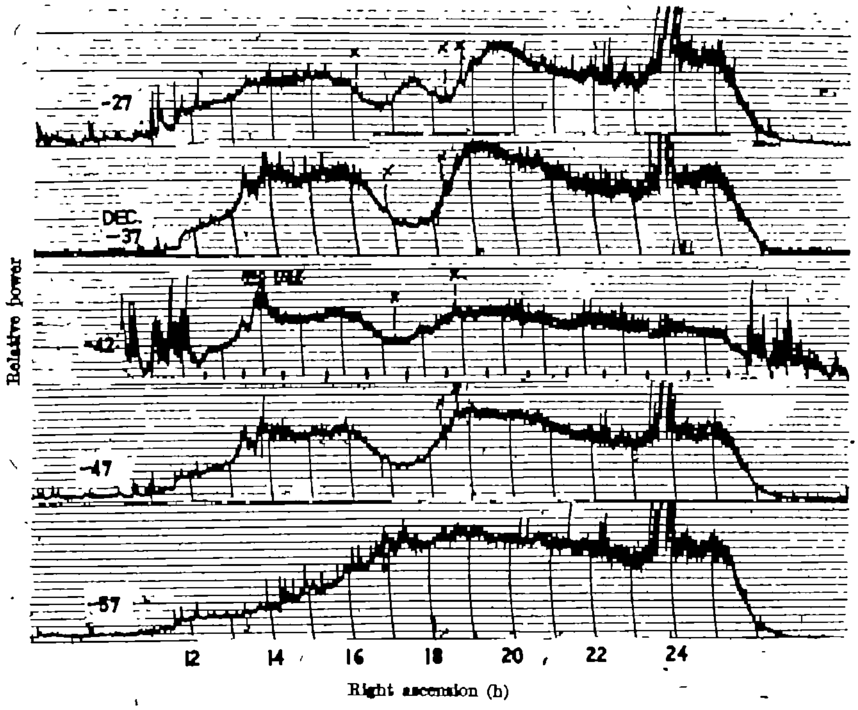

Fig. 1. Records of cosmic radio noise at 4·7 Mc/s. Antenna beam width, 3° × 11°. Discrete detail between 1600 *R.A.* and 1900 *R.A.* is indicated thus *I*

plane of the Milky Way are likely to be located within a few kiloparsecs of the Sun and there would seem to be a possibility of establishing a distance scale for such objects by observations in the 1–10 Mc/s band. Since the optical depth of the interstellar medium varies as the square of the wave frequency, progressive reduction in the frequency rapidly reduces the radial limits of observation. At the same time, the study of the absorption provides a sensitive way of investigating the interstellar medium.

GEOLOGY

Thermo-chemical Remanent Magnetization of Rocks

When titanomagnetites, $x\mathrm{Fe_2TiO_4}\cdot(1-x)\mathrm{Fe_3O_4}$, are heated in the atmosphere at a certain high temperature, they are oxidized, becoming solid solutions of titanomagnetites and titanomaghaemites, $y\mathrm{FeTiO_3}\cdot(1-y)\mathrm{Fe_2O_3}$ having a spinal crystal structure[1-4].

The oxidation process is proved[1-4] to be represented simply by $\mathrm{Fe^{2+}}\rightarrow\mathrm{Fe^{3+}}$, a ratio (Fe + Ti)/Fe, being kept invariant per unit molecule. This results in a certain amount of vacancies in the crystal lattice, accompanied by a decrease in lattice constant (a) of the cubic crystal and an increase in Curie temperature (Tc).

For example, a titanomagnetite of 40 mol per cent $\mathrm{Fe_2TiO_4}\cdot$60 mol per cent $\mathrm{Fe_3O_4}$ ($\mathrm{FeO} : \mathrm{Fe_2O_3} : \mathrm{TiO_2}$ = 58 : 25 : 17 in mol per cent), having a = 8·440 Å and Tc = 365° C, becomes a solid solution of titanomagnetite and titanomaghaemite, with a composition of $\mathrm{FeO} : \mathrm{Fe_2O_3} : \mathrm{TiO_2}$ = 38 : 44 : 18. a = 8·407 Å and Tc = 560° C, after the original specimen has been heated about 2 h at 470° C in the atmosphere.

In other words, the original titanomagnetite is paramagnetic at 470° C at the initial instant of the oxidation procedure, whereas the oxidized specimen is ferrimagnetic at the same temperature.

If the oxidation procedure is performed in a magnetic field, H, the oxidized titanomaghaemite–titanomagnetite acquires a fairly stable remanent magnetization the direction of which is the same as that of H and the intensity of which depends on the intensity of H.

The remanent magnetization mentioned here is different from the chemical remanent magnetization in that this new process occurs only at high temperatures whereas the ordinary chemical remanent magnetization involving a change from a non-magnetic to a ferri- (or ferro-) magnetic state occurs at atmospheric temperature[5-7].

Verhoogen[8] also has suggested a possibility of this kind of remanent magnetization based on his studies on oxidation of iron–titanium oxides in igneous rocks. The new type of remanent magnetization may be called thermo-chemical remanent magnetization (TCRM).

Fig. 1 illustrates a process of development of thermo-chemical remanent magnetization (Jr) with time of oxidation for an initial constituent of x = 40 per cent titanomagnetite in H = 41·0 oe at temperature T = 470° C. Development with time of intensity of magnetization, $J = Jr + \chi H$, at 470° C is also shown in Fig. 1.

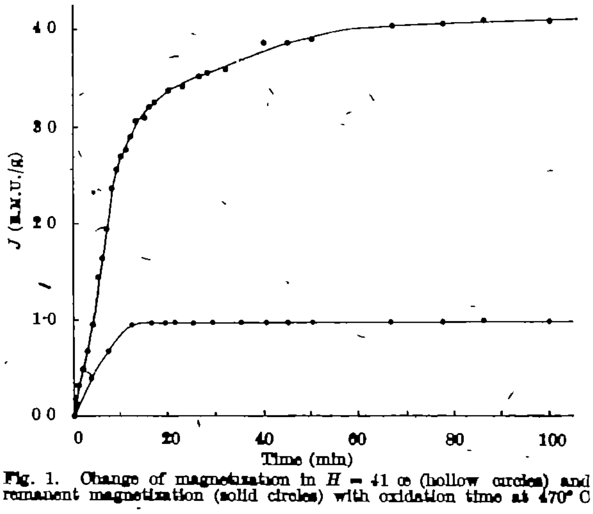

Fig. 1. Change of magnetization in H = 41 oe (hollow circles) and remanent magnetization (solid circles) with oxidation time at 470° C

The intensity of thermo-chemical remanent magnetization, $Jr(T)$, thus acquired at T = 470° C increases, due to an increase in the spontaneous magnetization, when the specimen is cooled to atmospheric temperature in non-magnetic space.

Fig. 2 illustrates the a.c.-demagnetization curve of the thermo-chemical remanent magnetization together with the a.c.-demagnetization curves of isothermal remanent magnetization and thermo-remanent magnetization of the same oxidized specimen. It is shown in Fig. 1 that the thermo-chemical remanent magnetization is as stable as the thermo-remanent magnetization and is much more stable than the isothermal remanent magnetization

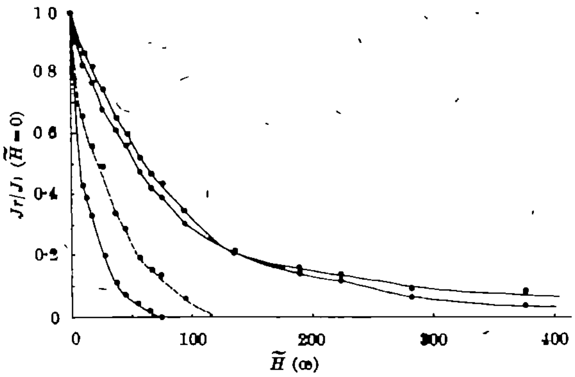

Fig. 2. Demagnetization by alternating magnetic field of various types of remanent magnetization of titanomaghemite (size *B*). —○—, TCRM (H = 41 oe); —○—, TRM (H = 20·5 oe); – – – ○ – – –, IRM produced at 470° C by 41 oe, —●—, IRM produced at 30° C by 100 oe

against the a.c.-demagnetization. The stability of the thermo-chemical remanent magnetization is, therefore, quite similar to that of the ordinary chemical remanent magnetization.

The results of preliminary studies on the thermo-chemical remanent magnetization during a thermo-chemical change from titanomagnetites to titanomaghemites are summarized in Table 1.

Table 1. Original sample, 40 per cent Fe_2TiO_4·60 per cent Fe_3O_4. Heat treatment, 2 h at 470° C in air

0·0	0·00	0·00	0·00	0·00
20·5	1·18	0·73	—	0·143
41·0	1·77	0·97	1·19	0·445

Although the intensity of isothermal remanent magnetization is very sensitive to the grain size of the ferrimagnetics, that of the thermo-chemical remanent magnetization is not sensitive. As already reported[1], the degree of oxidation of titanomagnetites can be primarily controlled by the heating temperature, so long as the heating time ranges from an hour to days. The development of thermo-chemical remanent magnetization dealt with here may be interpreted as due to an increase of the total volume of the oxidized parts within the specimen while individual oxidized parts can attain almost finally oxidized states rather quickly, say within 10 min. This interpretation seems to be supported by a fact that a ratio $Jr/J = Jr/(Jr + xH)$ is kept nearly constant, being about 0·3, throughout the entire time of the oxidation process.

Some remanent magnetization of oxidized natural rocks can be attributed to the thermo-chemical remanent magnetization described here. Results of detailed studies will be published elsewhere.

Replacement in the Octahedral and Interlayer Positions in Micas

IN a paper read at the eleventh National Clay Conference, Ottawa, 1962[1], one of us (I. Th. R.) presented results of a radioactive tracer technique and infra-red spectroscopy applied to dioctahedral and trioctahedral micas. The mineral powders had been pre-treated with deuterium oxide and tritium-bearing water. The results indicated that dioctahedral hydrous micas contained water molecules in interlayer positions substituting some of the K^+ ions of the ideal end member. The necessary charge balance in the crystal model was achieved by substituting some of the apical O's by OH (or by filling in H^+ in vacant positions of the octahedral layer).

The communication by White *et al.*[2] strongly indicates that lithium may enter vacant positions of dioctahedral micas, expelling potassium from the interlayer position. In continuation of the work reported we have treated muscovite from Bjortjenn, Aust-Agder. and phlogopite from Skåtøy, south-eastern Norway (Table 1), with tritium-bearing water and tritium-water containing 1·2 m lithium chloride and 1·1 m rubidium chloride.

1 g of mineral powder (D_e < 5μ) was heated for 6 days to 125° C in quartz tubes together with the reagents mentioned. Afterwards the samples were washed with distilled water to remove all solved alkali, and afterwards the samples were heated at a rate of 100° C/h in a tube furnace. The water phase given off was collected, and the

Table 2. ALKALIS SOLVED AFTER SIX DAYS AT 125° C AS PERCENTAGE OF ALKALI CONTENT OF THE MINERAL POWDERS

		H_2O	1·2 m LiCl	1·1 m RbCl
Muscovite	Na	7·2	16·5	12·7
	K	0·8	5·6	2·9
Phlogopite	Na	13·8	11·5	11·5
	K	1·7	2·7	1·9

amount of tritium oxide therein determined for each 100° C in the interval from 100° to 1,200° C. The results for tritium are given in Figs. 1 and 2. The amount of alkali solved from the mineral by the different treatments is given in Table 2.

The results support the concept that water molecules are present in the interlayer position of hydro-muscovites. Further, it is shown that by treatment with lithium chloride considerably more alkali is liberated from the di-octahedral micas than by the other treatments. Further, the maximum amount of tritium enters the lattice by this treatment. The replacement $Li^+ + H_2O$ against K^+ supports the opinion by White *et al.* that lithium enters into the octahedral position in the dioctahedral micas expelling a potassium from the interlayer sheet. The hole left gives place to a water molecule.

By the trioctahedral phlogopite no such replacement in the octahedral layer is possible. Consequently no significant difference is seen by the various treatments.

By treatment with lithium chloride we seem to obtain mixed crystals between $KAl_2(Si_3Al)O_{10}(OH)_2$ and $H_2O(Al_2Li)(Si_3Al)O_{10}(OH)_2$ compared to our concept of hydro-muscovite as mixed crystal between $KAl_2(Si_3Al)O_{10}$-$(OH)_2$ and $H_2O(Al_2H)(Si_3Al)O_{10}(OH)_2$ or $H_2OAl_2(Si_3Al)O_9$-$(OH)_3$.

PHYSICS

Electron Microscopic Examination of Highly Radioactive Fall-Out Particles

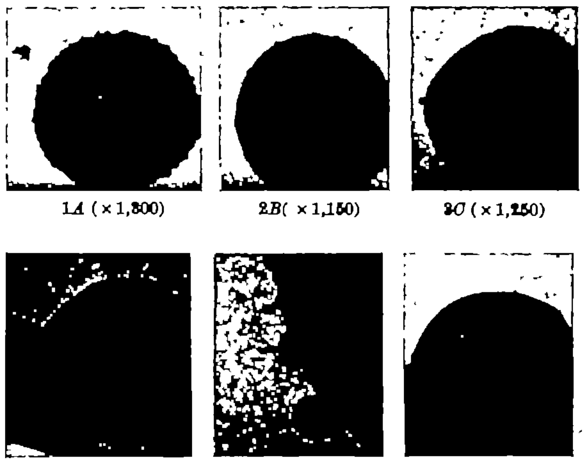
MICROSCOPIC examination of highly radioactive fall-out particles, produced by the series of large-scale nuclear test explosions carried out during September and October 1961, revealed that although they were quite or nearly spherical, their surface states were different from particle to particle and some of them were much creased or had small spherical particles attached to their surface[1]. Electron microscopic examination followed by electron photomicrography has been carried out to examine their surface state in detail. A vacuum-evaporated silica film backed with evaporated carbon film was used for holding a sample particle. A small drop of benzene was put on the silica film which was supported on a 150 sheet mesh, then a sample particle which had been picked up by the tip of a fine needle was transferred into the drop seen under a microscope. The sample particle was left on the film after the drop evaporated out. Electron photomicrographs of four particles, *A*, *B*, *C* and *D*, were taken. In Table 1 are given their diameters, radioactivities and fractionation factors for $^{141}Ce + ^{144}Ce$ (ref. 2). Fig. 1 (1,2,3) gives electron photomicrographs of particles *A*, *B* and *C*, respectively. Small particles adhered to the surface are thought to be fine fall-out particles which are micron size or smaller[3]. Fig. 1 (5) is a close-up of a part of particle *C*. The diameter of this small particle is about 1·4μ.

Table 1

	Mean diam. (μ)	Estimated β-activity at the beginning of November 1961 when the particle fell on the ground surface (mμc.)	Fractionation factor for $^{141}Ce + ^{144}Ce$
Particle *A*	16·3	26·6	0·21
Particle *B*	18·9	50·2	0·36
Particle *C*	17·2	57·5	0·21
Particle *D*	17·5	29·9	0·29

During electron microscopic examination, it was experienced that the particle surface became smooth and small particles adhered to the surface disappeared by the evaporation caused by too intense electron beam. Fig. 1 (4) shows the smooth surface, and the broken silica film thus occurred during examination of particle *C*. The same situation observed on particle *D* is shown in Fig. 6, in which a more smooth surface formed by a more intense electron beam is seen.

As already reported[4–6], the uptake of radioactive substance through the leaf surface was confirmed to take place at the point where a highly radioactive fall-out particle was located. This fact suggests that a highly radioactive fall-out particle has easily soluble components.



1*A* (×1,300) 2*B* (×1,150) 3*C* (×1,250)
4*C* (×4,600) 5*C* (×1,250) 6*D* (×1,200)

Fig. 1. Radioactive fall-out particles

On the other hand, it has been confirmed by the aid of an autoradiographic technique that some fall-out particles are impossible to be dissolved even in hot aqua regia.

The surface of a highly radioactive fall-out particle is assumed to be as follows. The main part of the particle was produced by condensation followed by solidification of explosion products at relatively high temperature immediately after explosion. On the surface of the particle thus produced, volatile elements such as ^{131}I and ^{106}Ru condensed to form a film at relatively low temperature and at the same time submicron size particles happened to be attached through collision.

Activation Analysis of Particulate Air Contaminants

Typical air samples contain particulate air contaminants in concentration of 100–2,000 μg/m^3. Standard methods for analysing the composition of these contaminants are tedious and often insensitive[1]. The application of activation analysis for the inorganic elements appears to be attractive as a fast, sensitive and highly specific method. Preliminary irradiations of samples collected on filter paper have been performed and have shown that the method is feasible. Identification of several radioactive species has been accomplished, and quantitative estimates have been made. One problem has been that the filter paper as well as the contaminants activate, necessitating the irradiation of a control sample to correct for the effect.

The airborne particulate material was collected using Whatman No. 41 filter paper. Collection efficiency was approximately 99 per cent for particles greater than 0·1μ in diameter. The filter paper containing the sample, together with a filter paper control, were then irradiated in the University of Florida training reactor. β-activities were measured with a 2π proportional counter and γ-activities were measured with a single-channel pulse height analyser equipped with a well-type sodium iodide (Tl) crystal. In addition, one sample was studied with a multichannel analyser used in conjunction with a sodium iodide (Tl) crystal.

A description of the activation samples and irradiation histories is given in Table 1. As indicated there, several of the samples were collected in environments containing a very high particulate concentration.

Typical decay curves of the β-activity of several samples are shown in Fig. 1. Also shown there is the activity of the filter paper control which was irradiated at the same time as one of the samples. After subtracting the activity of the filter paper control, the decay curves were analysed for the half-life of the various components. Results of these analyses are shown in Table 2 together with tentative identification of the isotopic species responsible for the activities. The presence of barium in sample Nos. 2 and 6 is attributed to the fact that these samples were collected during an operation which involved barytes concrete dust.

	12·0 min		Magnesium-27
	3 3 min		Aluminium-28

* Typical estimated *S.D.* of half-life: 9 per cent

In order to investigate the γ-spectrum from the activated contaminants, sample No. 3 was irradiated for 100 min together with a filter paper control. Following the irradiation the γ-spectra of the sample and the control were measured with a 256-channel analyser. The results of this measurement are shown in Fig. 2. The principal activities in the corrected spectrum appear to be due to sodium-24 and manganese-56.

An obvious need in improving the sensitivity of the method is to use filter paper having the lowest possible content of constituents which activate and interfere with the sample determination. Accordingly, samples of Whatman No. 41 (0·00009 g of ash per piece), Whatman No. 42 (0·00006 g of ash per piece) and 'Millipore' were irradiated. The results indicated that Whatman No. 41 and 'Millipore' contained approximately equal constituents, while Whatman No. 42 contained only about 10 per cent equivalent constituents (in terms of the activation cross-section, $V\Sigma_{act}$). On this basis Whatman No. 42 would have been a better choice than Whatman No. 41 filter paper. The 'Millipore' paper has the advantage that it can be dried to a constant weight, thus permitting a quantitative correction for the activities due to the filter paper.

If one assumes the contaminant in sample No. 5 is concrete dust (1·80 weight per cent magnesium), then the observed 8-min activity may be attributed to 266 μg of magnesium. This value agrees very well with the value of 271 μg calculated from the observed activity after corrections are made for sample decay and counter efficiency. Similarly, for sample No. 2 one obtains 254 μg of magnesium (14·1 mg total × 1·80 weight per cent magnesium) as compared with 245 μg calculated from the measured activity.

We plan to improve the precision of the method as follows: (1) use radiochemical separation to aid in identification of specific elements; (2) use standards and standard carriers to ensure reproducible quantitative data.

Bath-tub Vortex

With reference to Prof. A. H. Shapiro's recent communication[1] on the above subject, I venture to call attention to the fact that in 1908 the Austrian physicist, O. Turmlitz, described careful and effective experiments which demonstrated the effect of the rotation of the Earth on the outflow of water through a central aperture, in a paper entitled "Ein neuer physikalischer Beweis der Achsendrehung der Erde"[2].

I dealt at some length with the whole question of rotation at outflow in a lecture on "Whirlpools and Vortices"[3] given in 1938.

CERAMICS

High-pressure Densification of Glass and the Effects of Shear

When certain oxide glasses are temporarily compressed at high pressures, a large 'permanent' increase of density may occur when the pressure is released. For example, Bridgman and Simon[1] reported that the density of vitreous silica was increased 7 per cent after room temperature compression at 200 kilobars; below an apparent threshold pressure of about 100 kilobars, however, no densification was possible at room temperature. Roy and Cohen[2] afterwards reported that a density increase of 7 per cent was achieved at only 55 kilobars, and that from 20 to 160 kilobars densification of silica glass at room temperature was a linear function of pressure. Despite the unexplained large disparity between these results, it was proposed[2] that silica glass be used as a pressure calibrant for the range 10–200 kilobars. More recently, Christiansen, Kistler and Gogarty[3] furnished yet another different set of results. These and some results of the present work at room temperature are shown in Fig. 1. The results of Roy and Cohen which were presented as changes of refractive index have been converted to changes of density from a calibration obtained by us. The results of curves *A*, *B*, and *C* were all obtained on the opposed-anvil apparatus. Whereas Roy and Cohen used powdered glass, the samples of the other workers were in the form of thin glass disks. The results reported here were obtained on solid cylinders about 2 mm in diameter and 2 mm in height with a pyrophyllite–alumina cell in a 'belt' apparatus[4].

Bridgman[5] had questioned whether densification of glass was possible under pure hydrostatic condition without the co-operation of shear. In one experiment on soda glass in which densification of several per cent was first observed, this large increase was no longer possible after the cell design was altered to decrease shearing forces during compression. Christiansen *et al.*[3] have suggested that a larger degree of shear was possibly present in their experiment resulting in the disagreement with Bridgman's results. The very much higher densification reported by Roy and Cohen[2] is understandable in view of the powdered samples used. A greater degree of shear is expected when irregular particles in contact with one another undergo sliding motion on compression. A further cause may be due to localized heating arising from friction, since densification increases with increasing temperature at constant pressure.

In the present work, large differences are found in the densification of silica glass dependent on the degree of shear present. Thus, with an alumina container, the densification at 60 kilobars and 400° C for 2 min is 14 per

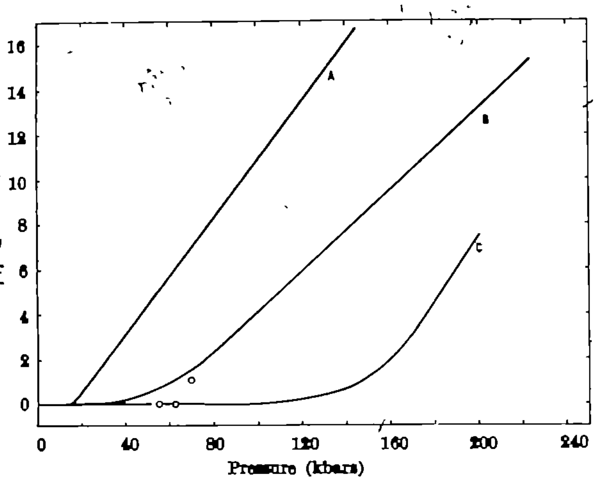

Fig. 1. Increase of density with applied pressure at room temperature for silica glass. *A*, Roy and Cohen (ref. 2); *B*, Christiansen *et al.* (ref. 3); *C*, Bridgman and Simon (ref. 1); O, present work, alumina cell

cent. When the container is silver chloride, it is only 4 per cent. Cohen and Roy[6] reported that, at 40 kilobars, densification of approximately 4 and 10 per cent was achieved at 300° and 500° C, respectively. When a solid piece of silica glass was embedded in silver chloride, we found the corresponding results to be 0 and 1·5 per cent.

Roy and Cohen[2] suggested that "for each pressure and temperature there is a pseudo-equilibrium volume for silica glass" and that this volume is attained in less than 15 sec in their experiment. Since densification increases with shear, the effect of time on the comparatively less dense glass must be considered. Christiansen *et al.*[3] found that at about 100 kilobars the observed densification of about 4 per cent is unchanged from 1 min to more than 2 h. The corresponding value of Roy and Cohen is 11 per cent. At 400° C and 60 kilobars, we have found that no further densification was observed from 4 min to 1 h in a silver chloride cell. The apparent final value of 7 per cent is still far less than that of 14 per cent attained in the alumina cell in 2 min. It appears, then, the final volume attainable is dependent not only on pressure, temperature, and time, but on the degree of shear as well.

The use of glass as a pressure calibrant is further complicated by the high annealing rates at atmospheric pressure. Some typical results are shown in Fig. 2. If densification had occurred at elevated temperatures and pressures, and the pressure is decreased prior to cooling, the significance of the density of the cooled glass must be dependent on the cooling rate.

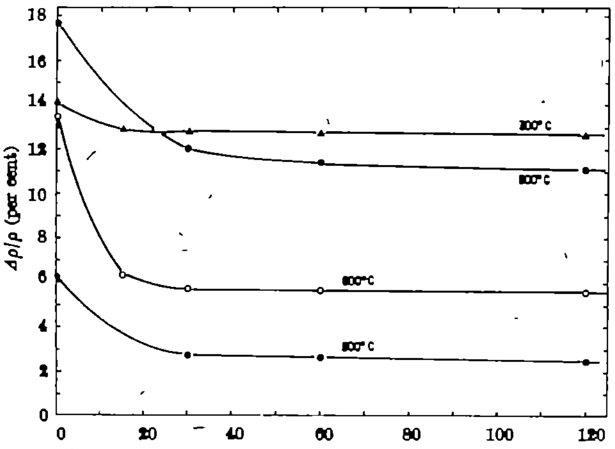

Fig. 2. Decrease of density of densified silica glass as a function of time by annealing at various temperatures and atmospheric pressure

Details of both the densification and annealing studies will be published elsewhere. We thank Dr. W. F. Claussen for the high-pressure facilities made available.

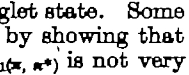
RADIATION CHEMISTRY

Origin of the Phosphorescence Radiation in Aromatic Hydrocarbons

WHEREAS the triplet nature of the (π, π^*) phosphorescent state of aromatic hydrocarbons has been definitely proved by the electron spin resonance investigations[1], the origin of the phosphorescence radiation is far from being understood.

Pure triplet–singlet transitions are forbidden according to the electric dipole selection rules. Phosphorescence in fluorescein is found experimentally[2] to be an electric dipole radiation. Perturbation theory is thus applied to mix the emitting triplet state (T_1) with some singlet character, or the ground state (S_0) with some triplet character (because of energy separation arguments the latter mixing was unjustifiably neglected). Whereas different workers use the spin orbit interaction for the perturbation operator, they differ on the type of the mixing singlet state. Some workers[3,4] can explain the long lifetime by showing that the mixing between $S_{(\pi,\pi^*)}$ states and $T_{1(\pi,\pi^*)}$ is not very strong because the one and two centre integrals of the spin orbit matrix elements vanish[3] if the molecule has a plane of symmetry in the molecular plane and across the bonds. Other workers[5] use the (σ, π^*) singlet states and can also account for the observed lifetime. None of these calculations is accurate or strong enough to support or reject one or the other mechanism. Thus, theoretically, this is still an unsolved problem.

Experiments were designed to gain more insight about the radiation source of the phosphorescence process. Two different independent types of experiments were carried out. The first experiment was meant to examine the effect of bending the aromatic ring on the $T_1 \rightarrow S_0$ transition probability. Because of the nature of the (π, π^*) states and the form of the spin orbit Hamiltonian for these molecules, such mixing should be very sensitive to the degree of molecular planarity. Bending the aromatic ring would bring in contributions from the one and two centre integrals, which do not contribute[3] in the planar molecules. This should greatly decrease the natural lifetime of the phosphorescence if these were the mixing states. Theoretical analysis on the (σ, π^*) states has not yet been made. The phosphorescence characteristics of [2·2] para*cyclo*phane[6], with the structure



is studied. X-ray examination of this molecule showed[7] that each carbon atom in the ring goes through ~12° of non-planarity. The observed lifetime of its blue phosphorescence was found to be 3·3 sec, compared with 7 sec in benzene. The difference might very well be due to slightly more radiationless processes in the para*cyclo*phane molecule. It therefore seems that bending does not have any effect on the phosphorescence lifetime.

The polarization of the phosphorescence spectrum of these molecules is very valuable in determining the symmetry properties of the perturbing state. The method of photoselection[8] was used where the molecules studied are embedded in a plastic medium[9], and the polarization measurements were carried out at room and liquid nitrogen temperatures. The molecules chosen were naphthalene (D_{2h}), phenanthrene (C_{2v}), chrysene (C_{2h}), and coronene (D_{6h}). The results on the polarization of these molecules strongly indicate that the whole spectrum is polarized similarly and perpendicular to the $S_{(\pi,\ \pi^*)} \leftrightarrow S_0$ transitions; that is, the emission shows a great amount of out-of-plane polarization (the results on phenanthrene are shown in Fig. 1). The great variations in the electronic structure of the molecules examined in this work suggest that such results are general for aromatic hydrocarbons. Therefore, it can be concluded that in aromatic hydrocarbons the (π, π*) singlet states are not very important in mixing with the emitting (π, π*) triplet state. The important singlet (or triplet) state could be a (σ, π*), (π, σ*), or Rydberg (or ionization) state to which the transition from the ground (or the emitting triplet) state is polarized perpendicular to the molecular plane. It is further concluded that the polarization results are independent of the symmetry of the aromatic molecule.

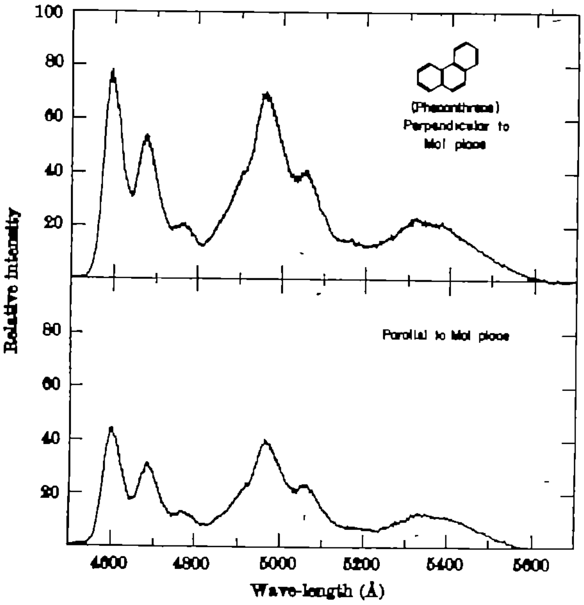


Fig. 1. Results on the polarization of the phosphorescence spectrum of phenanthrene using the method of photoselection. Excitation in the two perpendicularly polarized π, π* singlet states gave similar results and indicated that the phosphorescence is polarized perpendicular to the molecular plane

When corrected for the radiationless processes, it was found[10] that many of these hydrocarbons possess the same natural phosphorescence lifetime. It was also found[11] that many of the benzene derivatives have a phosphorescence spectrum with the same polarization characteristics as benzene. These results, together with those found in this work, indicate that the phosphorescence mechanism is insensitive to the symmetry, the planarity or to the details of the fine structure of these molecules. This is a rather strange result for a phenomenon which originates, according to our present understanding, from molecular perturbation effects. It might mean that the effect is mainly due to a one-centre interaction on the carbon atom or else the perturbing state is a high-energy one with mixed nature and so far separated from the molecule that it is insensitive to the finer details of its structure (for example, high-energy Rydberg or σ, π* states).

I thank Prof. D. J. Cram and his co-workers for providing me with the paracyclophane sample, Dr. W. Melhuish for providing the plastic samples, and the U.S. Atomic Energy Commission for its support of the research under contract No. AT(11-1)-34, Project No. 91.

BIOPHYSICS

Thermochemiluminescence of Chlorophyll–Carotene Mixtures

ARNOLD[1] has measured the emission of light from chloroplasts on illumination and subsequent heating in air. Litvin *et al.*[2] established that oxidation of photoreduced chlorophyll is accompanied by chemiluminescence. Goedheer and Vegt[3] have oxidized chlorophyll in methanol solution with ferric ion and observed chemiluminescence on reducing with ferrous ion.

We have observed chemiluminescence on heating in air mixtures of chlorophyll *a* and all-*trans*-β-carotene which had been deposited from benzene solution on stainless steel disks.

Chlorophyll *a* was prepared according to a modification of the method of Jacobs[4], and the all-*trans*-β-carotene (obtained from Nutritional Biochemicals and from Mann Biochemicals) was examined spectroscopically to determ-

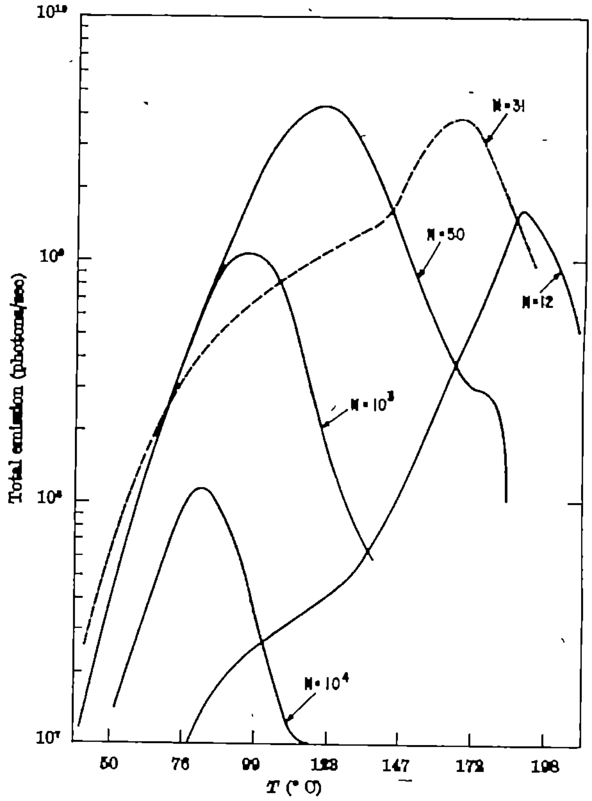

Fig. 1. Concentration dependence of the thermochemiluminescence of chlorophyll–β-carotene mixtures. β-Carotene: 1 mg/disk (~ 0·04 mg/cm²). *N*, Molar ratio of β-carotene/chlorophyll. Disks prepared and heated as described in text

ine its purity. No difference was observed between the behaviour of the carotene from the two sources. The deposited mixture was checked spectroscopically and found to be of uniform composition. Heating was done at 13° C/min, and detection was with a cooled R.C.A. No. 7102 photomultiplier isolated by a Corning No. 4600 filter and calibrated against a radiation thermocouple. Absolute calibration is conservatively estimated to be accurate to ± 50 per cent.

Table 1. TRANSMISSION BY CORNING FILTERS OF LIGHT EMITTED FROM CHLOROPHYLL a–β-CAROTENE MIXTURES

Filter No.	Transmission
2404	0·90
2418	0·93
2030	0·80
5850	0·25
5031	0·125
2550	0·03
2540	0

Fig. 1 shows typical data for the thermochemiluminescence of samples of 1 mg β-carotene with varying amounts of chlorophyll. (We have adopted this terminology as descriptive of the fact that the light is emitted during a chemical reaction which was catalysed by heating in the manner conventionally used in thermoluminescence work.) Self-absorption of the emitted light is not a problem at these low chlorophyll concentrations. Height of the lower temperature peak increases approximately linearly with increasing chlorophyll concentration until a carotene/chlorophyll molar ratio of 50 (0·037 mg carotene + 0·0031 mg chlorophyll/cm²) is reached. Beyond that the lower temperature peak is quenched very sharply with increasing chlorophyll content in the film, while the higher temperature peak comes up rapidly. Samples prepared in very dim light and samples illuminated for 5 min with a 500-W projection lamp prior to heating gave substantially the same results. We have measured the spectral distribution of the emitted light with a series of Corning graded filters. The results are given in Table 1. They are consistent with two peaks in emitted intensity, one centred at 6950 Å and the other, with relative intensity 0·6 as great, at 7450 Å. The results have been corrected for the response of the S–1 photosurface plus No. 4600 filter combination.

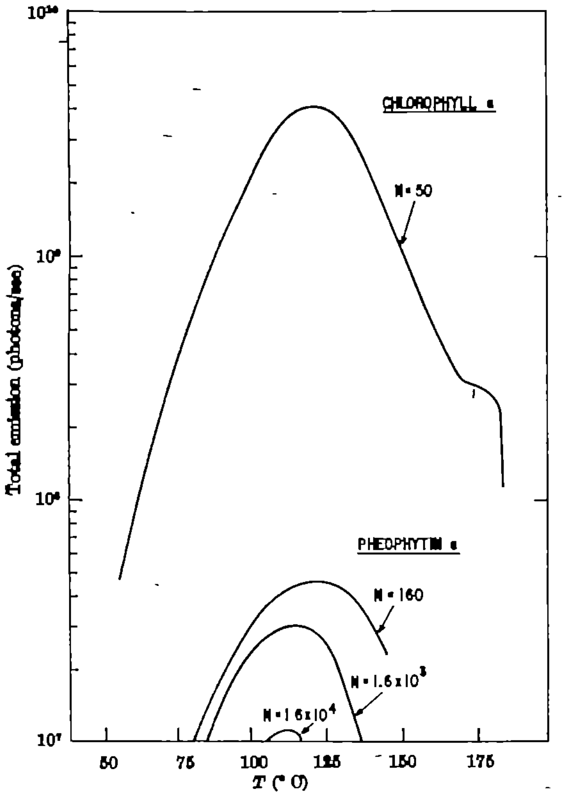

Fig. 2. Thermochemiluminescence of pheophytin–β-carotene mixtures. Concentrations and notations as in Fig. 1

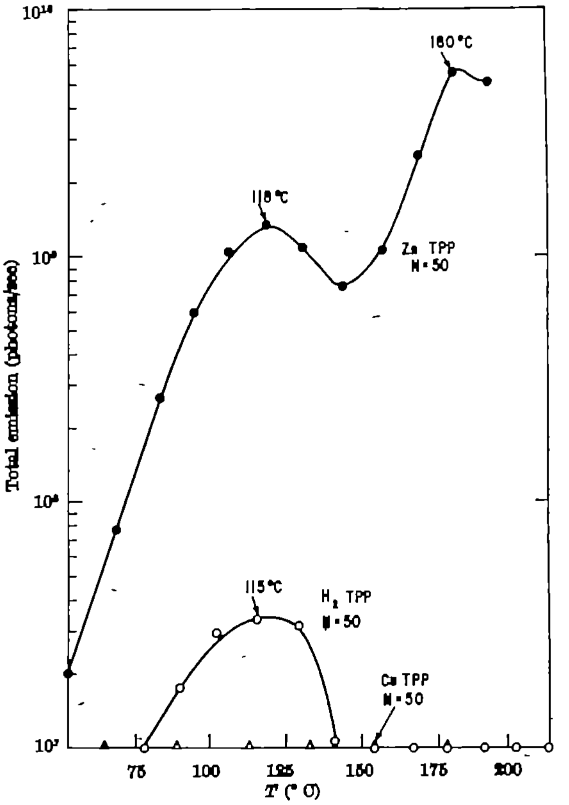

Fig. 3. Thermochemiluminescence of tetraphenyl porphin–β-carotene mixtures. ZnTPP, Zinc tetraphenyl porphin; CuTPP, copper tetraphenyl porphin; H_2TPP, free base tetraphenyl porphin. Concentrations and notations as in Fig. 1

We have measured the thermochemiluminescence of mixtures of carotene with an allomerized chlorophyll a prepared according to Gilman's method[5]. There appears to be very little difference between the results for chlorophyll a and allomerized chlorophyll a.

Mixtures of β-carotene and pheophytin a were examined with the results shown in Fig. 2. The striking decrease in emission may be noted by comparison with the curve reproduced from Fig. 1 for a carotene/chlorophyll ratio of 50. The decrease in luminescence accompanying removal of the magnesium from the chlorophyll is related to the interaction between the β-carotene and the porphyrin and is not a trivial effect due to loss of oscillator strength in the pheophytin red luminescence. This was established by measurement of the fluorescence yields of chlorophyll and pheophytin a and of allomerized chlorophyll a in benzene solution when excited by 400 and 430 mμ light. They were observed to differ by less than a factor of two. (We thank Dr. Charles Hurwitz of the Medical Research Laboratory, Veterans Administration Hospital, Albany, New York, for the opportunity to use his spectrofluorometer to make these measurements.)

Linschitz[6] has measured the chemiluminescence of tetralin–tetraphenylporphine (TPP) mixtures. He found that ZnTPP catalysed the chemiluminescent decomposition of tetralin hydroperoxide, and was itself gradually consumed in the process. The metal-free TPP did not interact to decompose the tetralin hydroperoxide.

We have measured the thermochemiluminescence of mixtures of ZnTPP, CuTPP, and H_2TPP (we thank Prof. H. Linschitz, Brandeis University, for the gift of samples of these materials) with β-carotene by dissolving the porphyrins in benzene and following the procedures described here. The results are shown in Fig. 3. The complete absence of chemiluminescence for the carotene–CuTPP mixture is not surprising in view of the fact that CuTPP is non-fluorescent. The fluorescence yields of ZnTPP and H_2TPP in benzene at 1 × 10^{-6} M, however, do not appear to differ by more than a factor of two, and, as in the case of the chlorophyll–pheophytin system, the decrease in luminescence upon removing the complexed metal from the porphyrin ring appears to stem from the change in porphyrin–carotene interactions.

Photochemistry of Thymine

In spite of intensive work, much concerning the primary physical and chemical processes in the effects of radiation in DNA and its constituents remains obscure. Stimulated by the reported ultra-violet dimerization of thymine[1] and the peroxidation induced by ionizing radiations[2], we have re-investigated the photochemistry of thymine.

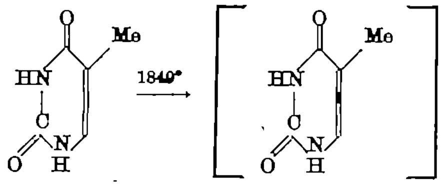
Thymine in aqueous solution has generally been supposed to be resistant to ultra-violet radiation, for example, Wierzchowski and Shugar[3], quoting a quantum yield for destruction of thymine of 4 × 10^{-4}. Using a 'Mineralight *R*-51' low-pressure mercury lamp in conjunction with a 1·5-mm Corning 7–54 filter to give pure 2537 Å radiation, we have re-determined this quantum yield at 4·3 × 10^{-4}. Oxygen seems to have no effect at the wave-length and no hydrogen peroxide was found. On removing the filter the rate of thymine has increased 80-fold while the intensity of 2537 Å radiation only increased by a factor of 3·8. However, it is known that this type of lamp, especially with the newer quartz envelopes, can emit an appreciable amount of radiation at 1849 Å (manufacturer's estimate ~5 per cent of total energy).

Accordingly, we suggest that the rapid photolysis of thymine is due to 1849 Å radiation and we estimate for this a quantum yield ~ 0·2.

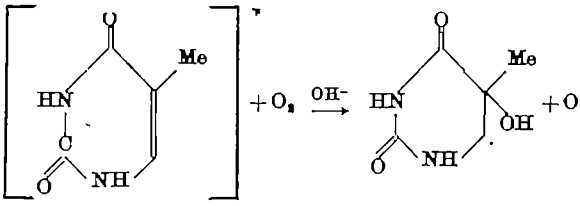
We have further investigated the nature of the primary chemical reaction. Using a high-intensity flash discharge (measurements made at Illinois Institute of Technology on the apparatus of Dr. L. Grossweiner, whose co-operation and assistance are gratefully acknowledged) (8 kV, 22 μF) known to form small amounts of hydrogen peroxide in water (and hence emitting radiation in far ultra-violet) it was found that repeated flashing caused no loss of thymine in oxygen-free solution, whereas in air-equilibrated solution it caused a 25 per cent loss at 2·5 × 10^{-5} M and 14 per cent loss at 1 × 10^{-4} M. It is concluded that oxygen is necessary for the primary photochemical process at 1849 Å.

The nature of the photoproducts has been investigated. Reaction with I^- reagent at *p*H 4 (ref. 4) shows the presence of hydrogen peroxide (confirmed by reaction with titanium reagent[5]) and a hydroperoxide. Preliminary indications from the rate of reaction are that the hydroperoxide is 4-hydroperoxy-5-hydroxythymine, which is the opposite order of addition to that formed, presumably by free radical attack, on X-irradiation[6]. Further product identification is in progress.

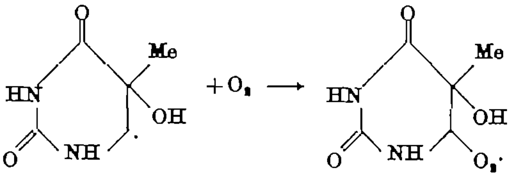
Kinetic investigations show both the hydroperoxide and hydrogen peroxide to be major initial photolysis products and it is suggested that this behaviour can be understood in terms of the following reactions, in which the critical step is the electron transfer to oxygen from O_4 position of the excited state of thymine[2], followed by further reaction of thymine radical with oxygen[3].



(1)



(2)



(3)

The O_2^- ion can give rise to hydrogen peroxide and the peroxy radical to the hydroperoxide.

It should be emphasized, however, that the nature of the absorption process at 1849 Å and of the excited state remain to be determined.

This investigation was supported in part by U.S. Public Health Service research grant *AM* 06420–01 from the National Institute of Arthritis and Metabolic Diseases.

CHEMISTRY

Analysis of Partial Glyceride Mixtures

It has been emphasized by Hartman[1] that the computation of diglycerides and triglycerides in technical monoglyceride mixtures merely from the free hydroxyl content and amount of monoglyceride (both 1- and 2-forms) is liable to serious error. He suggested that a direct estimation of mono-, di-, and tri-glycerides was required particularly in view of the anomalies which appear to arise in attempting to assign a random distribution to the results.

Some years ago[2] a full analysis was carried out at this Station of the products arising from the alcoholysis at 240° C of linseed oil with glycerol (essentially an equilibrium mixture of glycerides) in the following manner:

(*a*) *Glycerol.* This was obtained from the hydroxyl values of the glyceride mixture before and after washing away the glycerol with water. Good agreement was found with the direct periodic acid oxidation method[3]. The hydroxyl value before washing was also taken as a measure of the glycerol/linseed oil proportions, thus correcting for any losses of glycerol that might have occurred during heating.

(*b*) 1- *and* 2-*monoglycerides*. Analysis for 1-monoglyceride was carried out on the washed sample (glycerol free) using a standard periodic acid oxidation procedure[4], the 2-monoglyceride content being obtained by a similar technique after isomerization of the sample with perchloric acid[5,6].

(*c*) 1,2-, 1,3- *and tri-glycerides*. The original glyceride mixture (including glycerol) was treated with methyl iodide and excess silver oxide to convert the hydroxyl groups to the corresponding methyl ethers. As a result of this methylation procedure the system no longer underwent isomerization and the tri-methoxy-propane (from the glycerol) and the 1,2- and 1,3-dimethoxy glycerides (from the 1- and 2-monoglycerides) could be removed by distillation without affecting the distribution of fatty acid radicals.

The residue after distillation consisted of 1- and 2-methoxy diglycerides and triglycerides from which, after saponification and acidification, 1- and 2-methoxy glycerol and free glycerol were obtained in aqueous solution. The free glycerol was then determined by a modification of the periodate technique[7] (liberation of formic acid) and the 1-methoxy glycerol by difference from the total consumption of periodate[8] and that consumed by the glycerol as determined here. The results could then be recalculated in terms of 1,2-diglyceride and triglyceride in the original reaction product. Thus, only the 1,3-diglyceride content need be calculated by difference.

The results of this analysis are shown in Table 1.

Table 1. ANALYSIS OF PARTIAL GLYCERIDES OBTAINED FROM 1 MOLE LINSEED OIL : 1·85 MOLE GLYCEROL AFTER HEATING FOR 2 H AT 240° C (WITH 0·1 PER CENT TRISODIUM PHOSPHATE CATALYST)

Component	Experimental analysis (% by weight)	Theoretical distributions (% by weight) (1) Assuming different 'reactivities' for 1- and 2-hydroxyl groups	(2) Assuming randomization of fatty acid radicals
Glycerol	6·5	6·5	6·5
1-Monoglycerides	36·5	39·5	28·3
2-Monoglycerides	4·4	5·1	14·2
1,2-Diglycerides	15·6	14·1	27·0
1,3-Diglycerides	32·7*	26·9	13·5
Triglycerides	4·3	7·9	10·5

* Calculated by difference.

Possible theoretical distributions are also included for comparison, calculations of the proportions of the various glycerides being made on a weight basis by:

(1) Assuming that the hydroxyl groups of glycerol have different 'reactivities' related to the ratio of 2-monoglyceride to 1-monoglyceride determined experimentally, namely, 0·13. This figure was the average found for several systems of varying linseed oil/glycerol proportions and also the ratio of 2- to 1- monostearin found on heating either pure 1- or pure 2-monostearin until equilibrium was established[2].

(2) Assuming equal 'reactivity' of all hydroxyl groups, that is, complete randomization of fatty acid radicals occurs.

The results in Table 1 show that the relative proportions of 1,2- and 1,3-diglycerides found are in good agreement with the theoretical distribution derived by assuming different reactivities for 1- and 2-hydroxyl groups. In fact almost an inverse ratio to that found would be required if the distribution were on a random basis.

Confusion in the literature has surely arisen from the use of the term 'random distribution' to describe experimental results when only the total monoglycerides present have been determined—the total diglycerides being obtained by difference, for example, in an early paper by Feuge and Bailey[9]. Clearly a true random distribution of acyl radicals cannot occur unless the ratio of 1- to 2-monoglycerides in the final equilibrium mixture is 2 : 1 by weight (experimental figures are normally closer to 8 : 1) and the ratio of 1,2- to 1,3-diglyceride is also 2 : 1 by weight.

I am not aware of any published figures for the individual diglyceride isomers of mixed glycerides and I have therefore directed attention to the work of the Paint Research Station in this field.

In more recent work at this Station the use of thin layer chromatography for the analysis of partial glyceride mixtures has been examined[10].

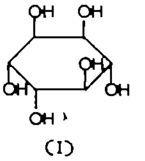
Occurrence of Configurational Inversion during Tritiation by the Wilzbach Method

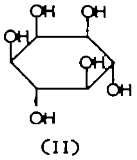
LABELLING of organic molecules with tritium by the Wilzbach method[1] — exposure to tritium gas for a prolonged period—has become widely used, particularly for biochemical investigations. A considerable amount of decomposition always accompanies the formation of labelled material which, therefore, has to be very carefully purified. It is important to know whether replacement of hydrogen atoms on asymmetric carbon atoms may occur with inversion of configuration: if it does, diastereomers of the original compound will be formed, which may not be readily separated by recrystallization or other methods of purification. Absence of diastereomers has been reported in one case, that of 1,2,3,5-tetra-*O*-acetyl-D-ribofuranose[2], whereas 30 per cent racemization occurred on labelling of (–)-mandelic acid[3].

We have chosen (–)-inositol (I) for an investigation of the stereochemistry of Wilzbach labelling, because in this compound replacement of any hydrogen atom attached to carbon by tritium with inversion will result in the formation of a different isomer: myo- (II), allo- (III), or muco-inositol (IV)[4]. Inversion on any carbon can therefore readily be detected.

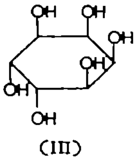
(–)-Inositol was exposed to tritium gas for eight weeks; equal amounts of each of myo-, allo-, and muco-inositol were then added, and the isomers were separated and purified by chromatography and chemical reactions. Each of the isomers was found to contain tritium, the ratio of specific activities being: (–)-inositol 1·0; myo-0·09, allo- 0·06, muco-inositol 0·03. Some inversion of every carbon atom has therefore occurred during the introduction of tritium.



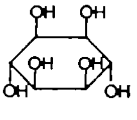
(I)



(II)



(III)



(IV)

Extensive intermolecular hydrogen bonding in a crystalline inositol would be expected to favour retention of configuration during tritiation. A non-crystalline derivative, hexa-*O*-methyl-(−)-inositol, was therefore submitted to Wilzbach tritiation, and it was found that inversion occurred to a far greater extent than in (−)-inositol, the ratios of specific activities being: (−)-inositol 1·0, myo-0·65, allo- 0·47, muco-inositol 0·33. In fact, since labelled (−)-inositol is produced by tritiation with retention at any one of the six carbon atoms, whereas each other inositol is formed by tritiation with inversion at either of two out of six carbon atoms, inversion is more extensive, on the average, than retention.

This example should serve as a warning that diastereomers may be encountered, after Wilzbach tritiation, in any compound containing asymmetric carbon atoms.

Hypercritical Aerosol

THE inhomogeneity of fluids at close proximity to their critical point has long been known[1,2], well examined[3,4] and theoretically explained[5,6]. The 'critical opalescence' is in fact a two-phase system in the state of fine division, one of the phases being a gas; thus this state may be looked on as an aerosol. This point of view was expressed sixty years ago[7]. As an aerosol, the near-critical state is a very peculiar one: the specific gravity of the dispersed phase is but slightly different from that of the dispersing medium; the viscosity of the latter is considerably above the usual values for gases.

The purpose of the investigation reported here was to prepare and investigate the 'hypercritical aerosol' in a two-component system. Solutions of comparatively non-volatile substances, such as camphor and boric acid in liquid carbon dioxide, were examined in a cylindrical pressure cell 2 cm in diameter and 2 cm long, closed at both ends by appropriate transparent windows. By raising the temperature of the cell very slowly (so that the whole cell interior was at the same temperature), the transition in the gaseous state occurs homogeneously (Cagniard-Latour phenomenon), but, differently from the single component systems or the two-component ones with a common critical point, a cloud of particles persists above the critical point of the carbon dioxide. The cloud disappears slowly by sedimentation. The mean particle diameter for camphor, estimated from the sedimentation time—on the assumption that the gas is pure carbon dioxide at the measured temperature (32° C) and pressure (90 kg/cm^2) and the dispersed phase is pure camphor—is slightly less than 3μ. The persistence of an 'aerosol' of that size in a volume of only few cm^3 for several minutes is rather remarkable, but easily explained by the differences of the present experimental conditions from those to be found in the more familiar aerosols.

If the temperature of the cell is not rigorously uniform with a temperature gradient of a few tenths of a degree C, the bottom being warmer and below the critical temperature, a cloud above the liquid phase can be maintained indefinitely. In this event, boiling of the liquid occurs and the splashed droplets replenish the sedimentating cloud permanently. This kind of cloudiness, while being an aerosol near the critical point, is not a hypercritical aerosol, because of the presence of the liquid. This is a near-critical aerosol, which, in a homogeneous system, had been already prepared, not as described previously, by the use of a temperature gradient, but by exposing the liquid carbon dioxide, slightly below its critical point, to mechanical vibrations[8].

At the start of the experiments, 'Plexiglas' windows 2 cm thick were used. Carbon dioxide under 70 or more kg/cm^2 pressure is soluble in 'Plexiglas' and after releasing the pressure, gaseous bubbles, accompanied by the deformation of the surface, appear near the inner surface of the window. This effect is reversible, and does not weaken the window noticeably. But at 40° C and 100 kg/cm^2 pressure, camphor in the presence of liquid carbon dioxide enters instantly into solid solution in 'Plexiglas'. The resulting solid solution is pale yellow, opaque and with a mechanical strength much below that of 'Plexiglas'. That was in one case responsible for the failure of the window—somewhat hazardous at the working pressure.

Constituents of Dental Calculus from Sheep

WHILE the crystalline composition of dental calculus in man is well elucidated, very little is known about such calculus in animals. We have had the opportunity of comparing the results of X-ray diffraction examinations of samples of dental calculus from sheep from Dundee, Scotland, and from Greenland. Powder diagrams were taken with copper *K*α-radiation in cameras of the Guinier type.

The two Danish samples, both from the same sheep, and one of the three Scottish samples exhibited a lustrous pigmentation. The material responsible for the pigmentation did not, however, show up in any of the diagrams. The results of X-ray analysis of the samples are shown in Table 1.

Table 1

	Danish samples		Scottish samples		
	1	2	1	2	3
	Pigmented	Pigmented			Pigmented
Major constituents	Brushite	Whitlockite	Apatite	Whitlockite and apatite	
Minor constituents	Whitlockite	Weddellite	—	Weddellite	

Diffraction lines due to brushite ($CaHPO_4,2H_2O$) were sharp, whereas those due to apatite and whitlockite (β-$Ca_3(PO_4)_2$) were quite diffuse indicating poorly crystallized compounds. Additional sharp lines with *d*-values 6·21 Å and 2·78 Å respectively could not be ascribed to any of the phosphates found in human dental calculus, but agree well with the two strongest lines of weddellite ($CaC_2O_4,2H_2O$) and in one case three other weak lines fitting the weddellite pattern could be detected. If the formation of this compound is likely in the saliva or the cud of ruminants we cannot judge. It has never been found in human dental calculus, but is well known as a constituent of urinary calculi. Three lines in human dental calculus patterns tentatively attributed to whewellite (CaC_2O_4,H_2O) by Tovborg Jensen and Danø[1] were almost certainly due to the presence of octocalcium phosphate, later identified as a common minor constituent of human dental calculus[2]. The latter compound was not found in any of the samples, although the presence of brushite in one specimen indicates a high supersaturation of sheep saliva with respect to all calculus forming calcium phosphates, brushite being the most soluble of these phosphates at *p*H above about 6 (ref. 3). Considering the high value (about 8·2) given in the literature as an average for the total saliva of sheep[4] the formation of brushite is unexpected. It seems likely that the pH of the saliva from all glands is not identical, but unfortunately the localities of the two samples from the same jaw are unknown.

Whitlockite has not previously been found in animal dental calculus. The principal constituent of dental calculus from the horse is calcite[5,6], while samples from dog, ferret and hamster contain poorly crystalline apatite and sometimes small amounts of calcite[6]. In human dental calculus the formation of whitlockite is related to the presence of magnesium in the precipitating fluid, the magnesian whitlockite showing a characteristic shift of the diffraction lines compared with β-tricalcium phosphate. The diffuseness of the whitlockite lines in the patterns from sheep calculus makes it difficult to discern a similar shift. However, ignition (1,000° C for 1 h) of Scottish samples 2 and 3 gave magnesian whitlockite containing about 10 atomic per cent magnesium, indicating a significant magnesium content of the original material.

Selective Poisoning of Catalytic Activity

A RECENT investigation[1] has shown that the exchange reaction between alkylbenzenes and deuterium may provide a useful method of investigating changes in the catalytic activity of evaporated metal films subjected to thermal sintering. One of the most suitable alkylbenzenes for this purpose is p-xylene because it contains only two different kinds of hydrogen atoms—the six in the methyl groups and the four on the benzene ring. Nickel films laid down on a glass substrate at 0° C will catalyse the exchange of the first six hydrogen atoms (reaction I) about five times faster than the exchange of the remaining four (reaction II) at 0° C. Pre-sintering such nickel films for 30 min at 200° C before use reduces their activity for reaction I by a factor of about 600 but has an even more drastic effect of about 10^3 on the rate of reaction II. The earlier work did not establish whether these marked changes of catalytic activity on sintering were due solely to the influence of temperature on the films or whether contamination, and consequent poisoning of the films, had occurred by gas evolved from the reaction vessel. Because of this uncertainty, we have now carried out a series of experiments on the influence of carbon monoxide as a poison for reactions I and II.

Films, prepared as previously described[1], were subjected to the following treatment at 0° C: (1) admission of 10 mm of deuterium for 5 min; (2) evacuation for 40 sec; (3) admission of a known pressure of carbon monoxide with a 10-fold excess of deuterium for 15 min; (4) evacuation for 40 sec and then used as catalysts for the exchange of 1 mm of p-xylene and about 23 mm of deuterium. This complicated procedure was designed to ensure that the small quantities of carbon monoxide admitted would be adsorbed by displacement of deuterium only on the sites giving the greatest heat of adsorption and not merely randomly on the surface. The main features of the results for the rates of exchange at 0° C are summarized in Table 1. The figures in the fourth column were obtained from surface area data for similarly prepared nickel films[2] and an assumption of 7 Å² for the mean area of each nickel atom; they represent the maximum coverage of the surface if all carbon monoxide admitted was adsorbed and retained. The rate k_0 is the initial rate of disappearance of p-xylene-d_0 and corresponds to reaction I; k_6, the initial percentage rate of conversion of p-xylene-d_6 to products with more deuterium atoms, is a measure of the rate of reaction II. The rates quoted for experiments *G*, *H* and *J* were obtained by extrapolation of Arrhenius plots for rates at higher temperatures and each plot yielded an activation energy of about 20 kcal/mole for reaction I.

Table 1

Exp.	Weight of film (mg)	Molecules CO admitted (× 10^{17})	Approximate ratio of molecules of CO admitted to surface Ni atoms	k_0 (%/min)	k_6 (%/min)
A	10·5	0	0	50	8
B	12·3	1·2	0·04	60	13
C	16·7	1·6	0·04	45	3
D	10·8	2·0	0·07	18	0·05
E	10·9	2·8	0·10	21	0·02
F	11·1	5·1	0·18	1·8	$< 2 \times 10^{-3}$
G	11·8	8·1	0·27	0·03	$< 3 \times 10^{-4}$
H	8·8	16	0·65	0·02	$< 2 \times 10^{-4}$
J	8·5	160	7	$\sim 3 \times 10^{-4}$	—

Two runs were carried out on films laid down with the glass walls of the reaction vessel maintained at 200° C (after baking at 450° C) and the results were identical with those obtained previously[1] for films laid down at 0° C and presintered for 30 min at 200° C. Detailed rates for these experiments are not reported but were similar (about twice as fast) to those for experiment *G*.

It is convenient to discuss the results on the assumption that all carbon monoxide admitted in experiments *B*–*H* is adsorbed. A comparison of *B* and *C* with *A* suggests that the sites first covered by carbon monoxide are not important for the catalysis of either reaction. Presumably, the heat of adsorption of the hydrocarbon is too large on these sites, amounting to some 4 per cent of the surface, to permit easily reversible adsorption to occur. Experiments *C* and *D* show that adsorption of carbon monoxide on the next 3–6 per cent of the surface cuts down the rate of reaction II by more than a factor of 100 but only reduces the rate of reaction I by a factor of three. This is clear evidence that certain active centres on the nickel films are required to catalyse the exchange of the hydrogen atoms on the benzene ring of p-xylene and that these centres are selectively poisoned by carbon monoxide. A drastic reduction in the rate of reaction I is only obtained when more than 25 per cent of the surface is covered, indicating that some 20 per cent of the sites on the surface are efficient centres for this reaction.

We believe that the nickel films laid down with the glass maintained at 200° C will be substantially free of contamination. Such films, or films pre-sintered for 30 min at 200° C, contain practically no active centres for reaction II and very few for reaction I. It seems evident that thermal treatment, like poisoning by carbon monoxide, completely eliminates the centres for reaction II and also destroys most of the sites on which reaction I occurs as well. A possible explanation is that metastable metal atoms on the films are necessary to form the π-bonded adsorbed hydrocarbon intermediates[1,3] which are believed to be involved in the mechanism of the exchange reactions of the alkylbenzenes.

Rheopexy in Dilute Polymer Solutions at Low Shear Gradients

ONE of us has pointed out that theoretical consideration of the hydrodynamic interaction of a very long flexible chain in laminar flow suggests that under certain conditions an increase in the viscosity of a polymer solution may occur with increase in the shear gradient[1]. Such rheopexy should be favoured with a solution of a linear polymer of very high molecular weight in an extremely viscous solvent, otherwise the theory predicts only a decrease in solution viscosity with increasing gradient such as has been reported experimentally in numerous instances. Generally, examples of rheopexy reported for polymer solutions occur at high gradients and reasonably have been attributed to the onset of turbulent flow, but this would not provide a likely explanation of an increase in viscosity reported by Selby and Hunstad which begins at only about 100 sec^{-1}. The latter results are consistent with the theory mentioned here inasmuch as the system studied was a polymethylmethacrylate of high molecular weight ($\sim 10^6$) dissolved in a mineral oil with a viscosity of several hundred poise but are not directly apposite because of the large concentration of polymer (3 per cent)[2]. A direct test of the theory has been undertaken by Wolff, who reported viscosity data extrapolated to infinite dilution for solutions of polystyrene (M up to 10^7) in a chlorinated diphenyl ($\eta \sim 1$ poise), with the conclusion that no increase in viscosity occurred[3]. The present communication reports further preliminary experiments designed to test the theory.

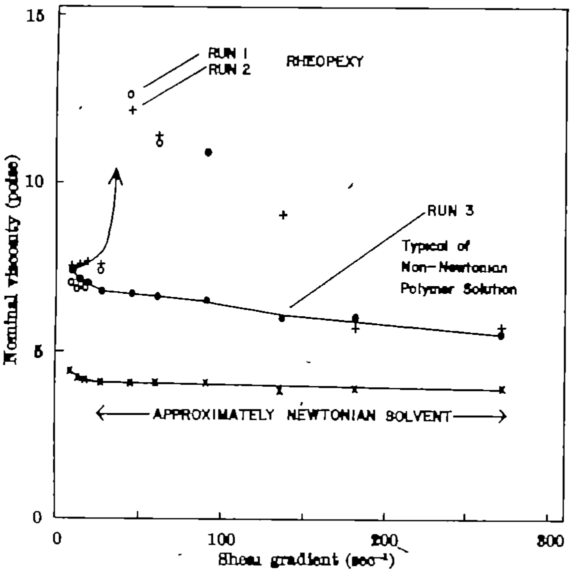

Fig. 1. Dependence of viscosity on shear gradient ×, Chlorinated diphenyl; ○, +, ●, solution of polymethylmethacrylate in chlorinated diphenyl

Polymethylmethacrylates, polymerized by conventional radical polymerization, of $M_w \sim 4\cdot2$ and $1\cdot0 \times 10^6$ were dissolved in a chlorinated diphenyl containing 0·2 per cent 4-tert-butylcatechol. Solutions were sheared at an ambient temperature of about 25° C in a plate and cone consistometer[4]. The results in Fig. 1 obtained with 2×10^{-3} g/ml. of the higher molecular weight polymer show an increase in nominal viscosity (the absolute calibration of the machine has not yet been checked) at low shear gradients, which is reproducible as a gross effect provided the solution is subjected to only limited shearing (cf. runs 1 and 2). After the more extensive shearing during run 2 plus 1 h at the highest gradient of 272 sec^{-1} the solution showed only a decrease in viscosity in two further runs (only run 3 is shown). However, when this same solution was cooled to near 0° C and its viscosity thereby increased to several hundred poise, marked rheopexy was again detected and could again be eliminated by prolonged shearing. Qualitatively similar results were obtained with the original solution in Cannon–Fenske capillary viscometers. By contrast, a more concentrated solution of the lower molecular weight polymer (5×10^{-3} g/ml.) showed no rheopexy at ambient temperature but only a decrease in viscosity with increasing gradient of the type generally reported for polymer solutions.

These experiments show that rheopexy is definitely observed in these solutions and at such low gradients that turbulent flow seems unlikely and, further, indicate that the occurrence of rheopexy is sensitive to viscosity and the length of the polymer molecules. Moreover, this latter sensitivity may be adduced to explain why rheopexy is eliminated by shearing with the acceptable postulate that the long polymer molecules are broken by the high shear forces applied. This general picture is consistent with theory but more critical and quantitative tests are necessary. The most important is to test whether, as required by theory, rheopexy can be observed in more dilute solutions. So far we have observed an effect near 0° C with concentrations of as little as $0\cdot13 \times 10^{-3}$ g/ml., but we are still trying to improve control of important experimental factors such as temperature in order to permit extrapolation of results to infinite dilution.

Colorimetric Determination of 3,6-Anhydrogalactose with the Indolyl-3-acetic Acid Reagent

THE sugar 3,6-anhydrogalactose is a major constituent of the agarose fraction of agar, of kappa carrageenin, and of some other polysaccharides from marine algae[1]. This sugar can be determined spectrophotometrically as 5-hydroxymethyl-2-furaldehyde[2] or by an adaptation of the resorcinol test for ketoses[3]. The rate of degradation of 3,6-anhydrogalactose to 5-hydroxymethyl-2-furaldehyde suggests that any method used for the colorimetric determination of fructose should be applicable to 3,6-anhydrogalactose. Steinitz[4] compared six methods for the determination of fructose in body fluids, and favoured the method of Heyrovsky[5], who used β-indolylacetic acid as the colour reagent. The present communication describes the use of this reagent for the determination of 3,6-anhydrogalactose.

A standard solution of 3,6-anhydrogalactose was prepared from 3,6-anhydro-L-galactose diethylmercaptal[6]. Heyrovsky's procedure[5] was followed except that the tube was placed in the thermoregulated bath immediately after the hydrochloric acid was added. The colour-development curves showed that at λ 530 mμ maximum absorbance occurred in 5 h at 23·5°; in 1 h at 37° and in 7 min at 80° C. Because of the rapidity of the reaction at the higher temperatures, careful attention to the details of the procedure were necessary. Beer's law was followed with amounts up to 0·25 μM of 3,6-anhydrogalactose. The absorbance of the mercaptal was 7 per cent greater than with the free sugar, presumably because of the mercaptan formed in presence of the acid. A similar increase in absorbance occurred when ethyl mercaptan was present with fructose.

The reaction was applied to the determination of 3,6-anhydrogalactose in agar[3], and compared with the results obtained with the resorcinol reagent[8]. The results are shown in Table 1. Apparently the agar was not completely hydrolysed at the two lower temperatures. At temperatures above 37° C blank values were high and the colour was not stable, as Heyrovsky[7] also found when the reagent was applied to fructose. At 80° C the absorbance continued to increase for 2 h after the tubes had been removed from the bath.

Table 1. EFFECT OF TEMPERATURE ON THE YIELD OF 3,6-ANHYDROGALACTOSE FROM AGAR

Reagent	Temperature	Time	% in agar
Resorcinol	80°	10 min	44
Indolyl-3-acetic acid	23 5°	22 h	34
	37°	2 h	38*
	80°	7 min	43*

* Calculated from maximum absorbance values.

It was shown that the indolyl-3-acetic acid reagent can be used at 23·5° and 37° C to determine free 3,6-anhydrogalactose. It shows no advantage, however, over the resorcinol test[6,8], for the quantitative determination of 3,6-anhydrogalactose in a polysaccharide.

A Lignin Carbohydrate Bond as revealed by Infra-red Spectroscopy

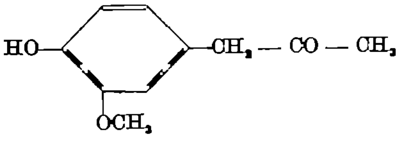
IN the course of spectroscopic investigation on the basic chemistry of lignins in wood and in unbleached kraft and sulphite pulps, we have recently obtained new evidence which suggests the existence of the long-sought covalent bond between lignin and carbohydrate in these materials. It appears to be an acetal or hemi-acetal bond, and, on cleavage, liberates a ketone group in the lignin. The work of others[1] indicates that the point of attachment may be mainly on the hemicellulose portion of the holocellulose.

We are examining the wood and pulp lignins by the method of high-resolution differential infra-red spectroscopy[2]. This is a quantitative application of the potassium bromide pellet technique, where the reference beam passes through an analytically determined amount of holocellulose (obtained by the *Tappi* method[3]) of the wood or pulp under examination in the sample beam of the spectrometer (Unicam *SP*–100). The quantity of holocellulose is calculated to cancel out the holocellulose spectrum in the sample, and only the spectrum of the lignin remains. The difference spectra are of generally good quality, and only two difficulties have been encountered. The first is that the *Tappi* holocellulose isolation fails to preserve all the acetyl groups, and the band due to the acetyl carbonyl is not completely cancelled. The second is that the holocellulose absorbs so strongly in the 1,000 cm^{-1} region that in that region the available light energy is reduced to the point that the difference spectrum is unreliable. In future work we intend to overcome these problems by using holocellulose isolated by milder methods, and by running the spectrum in the 1,000 cm^{-1} region on lower concentrations of sample, with ordinate scale expansion, if necessary.

We have now examined the differential spectra of eleven softwood and two hardwood species of wood, two kraft pulps (13·6 and 17·2 per cent lignin, respectively) and three sulphite pulps (11·8, 19·6 and 24·0 per cent lignin, respectively). We have also determined the spectra of thirty-five isolated lignins, obtained from different sources and by various techniques. These lignins included spruce milled-wood lignin, spruce and aspen dioxane lignins, spruce and poplar kraft alkali lignins, spruce and birch periodate lignins, spruce and birch lignosulphonic acids, and Klason lignins of thirteen wood species.

All the isolated lignins had an absorption band at 1,710 cm^{-1} ($\pm$ 15 cm^{-1}) of greater or lesser intensity, depending on the method of isolation, and this band was absent from all the differential spectra of wood and pulp lignins.

The results of earlier infra-red studies of isolated lignins do not agree on the assignment of the absorption band at 1,710 cm^{-1}. In an investigation of aspen native lignin, Smith[4] has presented evidence that a band near 1,710 cm^{-1} (actually 1,694 cm^{-1} in his measurements) is due to a carboxyl group of the type found in *p*-hydroxybenzoic acids. The band was not affected when the lignin was treated with sodium borohydride, but disappeared after alkali treatment. Marton[5] has studied milled-wood lignin (Björkman) from Norwegian spruce and also concluded that the band near 5·8μ (1,724 cm^{-1}) was due to carboxyl groups, since it remained after borohydride reduction of the lignin. However, Hergert[6] examined a series of native, milled-wood, and dioxane lignins, and found that the band was removed by borohydride, except when the lignin had been pretreated with alkali. From this evidence, and from an examination of model compounds, Hergert concluded that the 1,710 cm^{-1} absorption was due to a non-conjugated keto group of the type found in guaiacyl acetone (I), and he explained its behaviour on the basis of the enolizable nature of the ketone, its easy conversion to an enolate ion, and the air-oxidation of the unstable enolate to a carboxylic acid which could no longer be reduced by borohydride. According to Hergert's estimate the grouping represented in (I) occurs once in every twenty-five C_6–C_3 units of lignin.



I

The literature contains several other isolated pieces of work, some supporting the carboxyl interpretation, and some the ketone, but the weight of evidence suggests that the 1,710 cm^{-1} absorption band in lignin arises largely from an enolizable aryl-β-keto group with, possibly, a small contribution from carboxyl[7].

Support for the β-keto structure is given by the work of Adler, who recently stated from chemical and ultra-violet spectroscopic evidence that half the total carbonyl in milled-wood lignin from Norwegian spruce is in the beta position, and that there is one such carbonyl for every ten methoxyl groups in the lignin[8].

The ketone interpretation is also supported by our differential spectra of the lignin in kraft pulps. If the lignin-carbohydrate bond were an ester bond, and separation of lignin from carbohydrate required its hydrolysis, then the differential spectra of the unbleached pulps should show absorption in the neighbourhood of 1,730 cm^{-1}. In fact they do not. Hence it is unlikely that the new group in the lignin is a carboxyl group.

The evidence from whole wood and sulphite pulp is less clear. These differential spectra do show weak absorptions at 1,730–40, but they are probably artefacts due to poor compensation by the holocellulose for the acetyl groups in the hemicelluloses of the wood and the pulp, as explained here.

All published spectra of isolated lignins appear to contain the 1,710 cm⁻¹ absorption band ('appear to' because not all have been printed with adequate clarity for comparison). The band is also present in Freudenberg's dehydrogenation polymers, and Freudenberg and co-workers[9] have pointed out that the strength of the band is influenced by the method of preparation of the polymer.

These observations are consistent with the conclusion that an acetal or hemi-acetal bond exists between the carbonyl groups of lignin and the hydroxyl groups of some portion of the holocellulose. This was first suggested as a hypothesis by Holmberg in 1925[10], and is supported by the results of a number of chemical investigations[11]. The work reported here is the first evidence obtained by purely physical means in such a way that the wood and pulp lignins were observed without having been modified by chemical reactions.

BIOCHEMISTRY

Chemical Characterization of Kinins of Human Plasma

By the method of ammonium sulphate fractionation, human plasma can be separated into a part *A*, which is insoluble at 33 per cent saturation, and a part *B*, precipitated between 33 and 45 per cent saturation. When these precipitates are dissolved in water, both the solutions spontaneously develop the ability to cause contraction of the isolated rat uterus, apparently due to the liberation of plasma kinins. From the second preparation (precipitate *B*) the well-characterized kinins bradykinin and kallidin have already been isolated[1,2]. We have now undertaken detailed investigations of the neutral '33 per cent precipitate', *A*, with results which may be summarized as follows.

(1) The ammonium sulphate precipitate (*A*) contains a substance, apparently a proteolytic enzyme, which has been isolated (by a method to be described), and which liberates a kinin from 'preactive' human plasma[3]. This kinin can be distinguished from both bradykinin and kallidin and has been provisionally called kinin *E*.

(2) When the ammonium sulphate precipitate (*A*) is allowed to activate spontaneously in neutral solution, two kinins can be obtained which are different from either kinin *E*, bradykinin or kallidin. These have been referred to as kinins *F* and *S*.

These substances have been classed as plasma kinins on the grounds that they can bring about contractions of the isolated rat uterus, cause pain when applied to the exposed blister base, are unstable in plasma and are digested by pancreatic enzymes. All five compounds can be separated either by chromatography or by electrophoresis on paper. For each method the paper has been washed with 2 mM 'Versene' solution and then with water, in order to reduce adsorption of the peptides. Despite this precaution, however, substances *E* and *F* are often 'lost' during the separation, though whether by adsorption on the support or through destruction by the solvent is not yet clear.

Table 1

Solvent	*F*	*E*	*S*	Kall.	Brad.
BuOH/AcOH/H_2O	12	19	23	23	26
BuOH/Pyr./H_2O	Decomposed (?)	16	18	6	10

-The distance moved (cm) after 18 h chromatography of five plasma kinins on Whatman No. 1 paper washed for 24 h in 2 mM 'Versene' followed by water for 48 h. The strips were cut into 1-cm segments and eluted with Ringer's solution. The eluate was then tested for its ability to contract the isolated rat uterus. Crystalline synthetic bradykinin and kallidin were used.

Paper electrophoresis is particularly useful for the separation of bradykinin and kallidin from substance *S*, which migrates the fastest of the three (thus, at a field strength of 100 V/cm in 2 N acetic acid, *S* moved 24 cm; kallidin, 16 cm; bradykinin, 7 cm in 30 min). Substances *E* and *F* can also be resolved by this method; for example, in *p*H 7·4 pyridine/acetic acid buffer, at 100 V/cm, *E* moved 2 cm; kallidin, 4 cm; and *F*, 6 cm in 10 min, but after 30 min substances *E* and *F* could not be detected. In all cases migration was cathodic.

The chromatographic behaviour of all five kinins is summarized in Table 1, from which it appears that substance *S* and kallidin can be resolved in butanol/pyridine/water (1 : 1 : 1), but not in butanol/acetic acid/water (4 : 1 : 5). However, the latter solvent is the better for the identification of compounds *F* and *E*, since it brings about their inactivation at a slower rate.

From these results it appears that human plasma has a potential for the endogenous formation of several kinins. Moreover, since the isolated enzyme of precipitate *A* produces kinin *E* when added to human plasma, it cannot be plasma kallikrein, which forms bradykinin under these conditions[2]. Furthermore, substances *E* and *F* are formed at a rapid rate, whereas substance *S* reaches its maximum concentration only after about 3 h. Thus it is unlikely that substance *S* appears in reactions that produce 'kinin' rapidly; but it may be an important product of systems, such as those of acid or acetone-treated plasma[4-7], which react relatively slowly.

Blood- and Serum-levels of Water-soluble Vitamins in Man and Animals

VITAMIN-LEVELS in human blood and serum have recently been reported[1]. Except for cyanocobalamin (vitamin B_{12})[2], the titre of vitamins of the B-group in animal bloods and sera has not been documented. Comparative values would be an aid in determining the influence of these vitamins as animal growth factors, and also for evaluating their influence when these fluids are included in microbial and tissue culture growth media. Here we report the vitamin titre of freshly drawn blood and serum of cattle, sheep, chicken, rabbit and horse, the biological fluids of which are commonly used for experimental work. Eight pooled samples from each species were obtained from Cappel Laboratories of West Chester, Penn. These fluids were assayed for: (*a*) thiamine with *Ochromonas malhamensis*[3]; (*b*) pantothenic acid with *Lactobacillus plantarum*[4]; (*c*) nicotinic acid and amide with *Tetrahymena pyriformis*[5]; (*d*) B_6 group (pyridoxine, pyridoxal, pyridoxamine) with *T. pyriformis*[6]; (*e*) unconjugated pteridines with *Crithidia fasciculata*[6]; (*f*) folic acid with *L. casei*[7]; vitamin B_{12} titres were determined with *L. leichmannii*, *Euglena gracilis*, *O. malhamensis* and *Escherichia coli* 113–3[8] for comparison. Table 1 gives the averages of the vitamin titres of blood and serum received at different times during the year to ensure adequate sampling. The standard diets of these animals contained no vitamin supplementation during any of the testing periods involved in this work.

The concentration of folic acid did not vary to any great extent in these six species. The same can be observed for thiamine, with the exception of the rabbit which was the representative rodent. The rabbit carried up to ten times as much of this vitamin than other species. A similar picture was seen in the case of vitamin B_{12} where the rabbit showed 5–100 times more B_{12} than man and the other species tested.

Table 1. COMPARISON OF THE VITAMIN TITRES OF WHOLE BLOOD AND SERUM OF ANIMALS AND MAN

(mμg/ml.)

	Man	Cattle	Sheep	Horse	Rabbit	Chicken
Thiamine						
Blood	30	52	45	25	182	14
Serum	27	22	11	15	132	5
Folic acid						
Blood	43	30	18	35	39	18
Serum	15	15	10	20	24	8
B_6 group						
Blood	52	250	60	70	34	50
Serum	35	210	127	50	57	56
Pteridine						
Blood	48	510	470	800	410	76
Serum	27	120	57	120	445	300
Pantothenic acid						
Blood	1,150	395	420	700	440	715
Serum	925	2,340	2,270	680	450	665
Nicotinic acid						
Blood	7,250	1,100	2,200	1,700	2,200	1,700
Serum	65	250	240	190	210	220
Vitamin B_{12}						
Blood	0·30	0·20	2·6	3·0	19	1·8
Serum	0·40	0·22	3·5	3·5	18	0·9

The values for the B_6 group were substantially elevated in the two ruminants tested, cattle and sheep. The unconjugated pteridines, which were included with the vitamins, were about 20 times higher in the four mammalian species than in man. On the other hand, nicotinic acid was 3–5 times higher in human blood than in any of the other animals tested. The most striking result is the inversion of the relation of the nicotinic acid titre in the serum. Here the sera of the five animal species contain 3–5 times more nicotinic acid than human serum. The nicotinic acid ratio between blood and serum is 100 : 1 in man, but 4 : 1 to 10 : 1 in the animals. Another feature is the high content of pantothenic acid in ruminant serum.

A different picture in the blood : serum ratio appears to characterize the chicken. The bird contains substantially more unconjugated pteridine in the serum than in the blood, in contrast to mammals. It contains only half as much vitamin B_{12} in the serum as in the blood, while in man and the other mammals the B_{12} ratio for blood to serum is about unity.

These unexpected discrepancies may be due to a variety of factors, especially diet. Since man was the only carnivore included in this investigation, these multiple differences existing between man and animals may be based on the diet. Moreover, possible differences existing between man and other carnivores may be due to the large quantity of dairy products and fats in the human diet, which probably accounts for the peculiarity of the human nicotinic acid picture. Secondly, the variation in the vitamin picture may be due to the position of these species in evolutionary development. The chicken and perhaps all birds can be expected to display differences in a parameter regulated by diffusion because of the different nature of their blood corpuscles. It is rather surprising in how many facets their vitamin picture is congruent with that seen in mammals.

This investigation was supported by grants from the United States Public Health Service, the National Vitamin Foundation and the National Association for Mental Health.

Improved Recoveries of Protein from a Starch–'Pevikon C-870' Gel

A METHOD for the elution of proteins from starch gel has been described[1] involving the setting of starch gel segments into a 'Pevikon C-870' (PVK) block and then, by performing electrophoresis, proteins are recovered from PVK. This technique affords a good recovery of proteins contaminated by a negligible amount of soluble starch; but it is time-consuming if many gel segments have to be handled.

The experiments reported here constitute an alternative procedure: hydrolysed starch (Connaught Laboratories) is thoroughly mixed with PVK (Stockholms Superfosfat Fabriks Aktiebolag) in buffer solution and the suspension is heated until, after being almost solidified, it becomes less viscous near boiling point. The starch–PVK gel appears white and the mechanical strength is slightly inferior to that of starch gel.

Up to 40–70 mg of human serum proteins were electrophoretically separated either with the gel slab (17·0 × 30·0 × 0·65 cm) in vertical position and with the buffers indicated by Smithies[2] for 15 h using a potential gradient of 7 V/cm, or with the gel (30·5 × 21·0 × 1·0 cm) in horizontal position according to Poulik[3] for 9 h with a potential gradient of 8 V/cm. Electrophoresis was performed at room temperature, a running-water cooling system being used only for the gel in horizontal position.

In order to obtain maximum recovery of proteins from the gel, high resolving power and satisfactory mechanical strength of the gel, several experiments were carried out and the concentration selected was: starch (Lot 150) 10·5 g; PVK 126 g; buffer solution 100 ml. The starch–PVK (g): buffer solution (g) ratio is 1·36: if it was increased (> 1·42) the preparation of gel was very difficult and protein mobilities decreased progressively. On the other hand, by lowering the ratio (< 1·30) the gel tended to melt on handling.

Electrophoretic and autoradiographic patterns of human serum as obtained by using either starch or starch–PVK gel are compared in Fig. 1. The starch–PVK gel retains the high resolving power typical of the starch gel although the localization of some proteins is changed.

Protein recoveries were tested as follows: human serum proteins were labelled[4] with iodine-131 and electrophoretically separated. The top half of the gel was stained[5] and, after washing, autoradiography was carried out. Selected segments (2·0 × 1·0 × 0·4–0·5 cm) of the bottom half of the gel were put into glass tubes, 0·15 M sodium chloride solution being added up to a volume of 3 ml. The tubes were frozen at −40° C three times for 8 h each time, and afterwards were counted for total radioactivity. Elution of

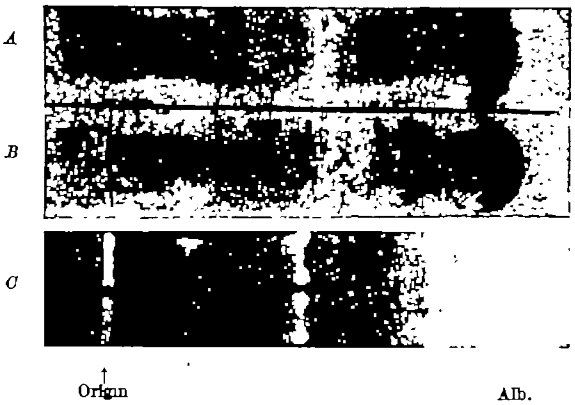

Fig. 1. Stained starch–PVK gel (*A*) and starch gel (*B*) electrophoretic patterns of human serum. Starch–PVK gel autoradiographs (*C*) of human ^{131}I-serum after being separated by electrophoresis (vertical)

proteins was accomplished by squashing the gel in a metal-glass syringe, a filter paper disk preventing the gel mass escaping. After centrifugation (1,500*g*, 30 min) the clear supernatant was brought up to 3 ml. and counted in order to determine the percentage of recovered radioactivity. This procedure was preliminarily tested and only 2–4 per cent of original radioactivity was lost in handling.

Table 1 reports percentages of eluted radioactivity and of iodine-131 trichloroacetic acid (TCA, final concentration 10 per cent) soluble radioactivity estimated on the eluates. Results were easily reproducible.

Table 1. Percentages* of recovered radioactivity from starch (10·5 g per cent) gel and from starch–PVK (10·5–126·0 g per cent) gel after electrophoretic separation of human serum ^{131}I-proteins by using Poulik's modification of Smithies's method. Percentages of ^{131}I-TCA soluble radioactivity were estimated on the eluates

	Albumin	Post-albumins	Trans-ferrin	Hapto-globin	γ-Globulin
Starch-gel	90	51	51	30	27
^{131}I-TCA soluble radioactivity	2·8	4·8	6·6	5·8	8·2
Starch–PVK gel	95	75	76	67	66
^{131}I-TCA soluble radioactivity	2·3	3·7	5·4	4·1	6·7
Increase in recovery	5	24	25	37	39

* Each value is an average of at least two electrophoretic runs.

The slightly higher recovery of albumin from the starch–PVK gel was also confirmed by photometric measurement of the eluates containing bromophenol blue bound to the albumin. The relatively high values of ^{131}I-TCA soluble radioactivity are mainly due to the freezing of proteins, as the values of the original ^{131}I-sera were about 1 per cent. The eluted radioactive fractions, after being concentrated by pressure dialysis, were again electrophoretically separated with some carrier serum and the radioactive peaks were located in their original positions by counting small pieces of stained gel.

Samples of starch gel and of starch–PVK gel were cut with a freezing microtome, and slices of about 20μ were examined by microscopy. With the concentration of starch–PVK gel used here, the different-sized and irregular PVK granules appeared closely interposed in the starch chain net (Fig. 2).

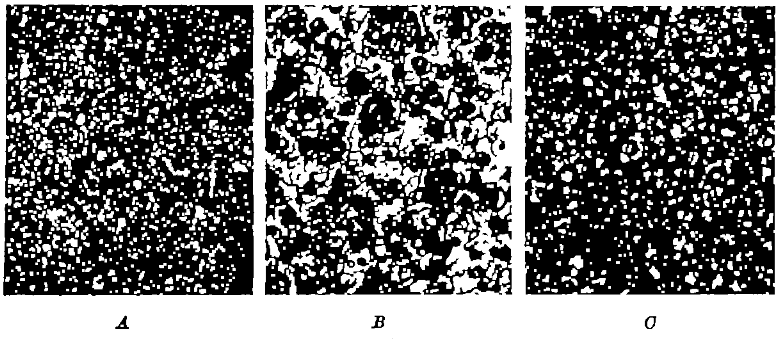

Fig. 2. Photographs of: *A*, starch-gel section; *B*, starch (10·5 g)–PVK (21·0 g) gel section; *C*, starch (10·5 g)–PVK (126·0 g) gel section (× c. 36)

It is known that proteins are easily eluted from PVK[6,7] and that increase in protein recoveries depends on the PVK concentration (Table 2); consequently, the higher protein recoveries from starch-PVK gel are due to the PVK itself as well as to the gel broken down during freezing.

Table 2. Percentages of recovered radioactivity after electrophoretic separation of human ^{131}I-serum by starch gel and starch–PVK gels

Starch (g)–PVK (g) per 100 ml. buffer solution		Haptoglobin	Transferrin	γ-Globulin
10·5	—	29	51	27
10·5	15·7	31	62	36
10·5	31·5	42	70	45
10·5	42·0	39	74	47
10·5	52·5	54	70	50
10·5	68·3	61	73	62
10·5	84·0	62	74	61
10·5	99·8	66	73	63
10·5	115·5	67	77	—
10·5	126·0	67	75	66
10·5	141·8	68	77	67

The amount of soluble starch, as investigated by addition of iodine to the eluates, was slightly increased in the starch–PVK samples.

It is concluded that starch–PVK gel can be used for separating and recovering proteins when presence of soluble starch does not interfere with their estimation.

Reduction of Glyceric Acid to Glyceraldehyde by Lithium Aluminium Hydride

CARBOHYDRATE acids generally can be converted into the corresponding aldoses by amalgam reduction of a lactone. In cases where lactonization does not really occur or where lactones are unstable, few alternative procedures are available for bringing about this conversion.

We now find that a possible route exists for this purpose by conversion of a suitably protected (for example, isopropylidene) aldonic ester into the *N*-methyl-*N*-phenylamide[1], followed by its reduction with an ethereal solution of lithium aluminium hydride[2]. The reactions are conducted at room temperature, predominantly in non-aqueous media.

Using methyl isopropylidene-DL-glycerate, the reduction was accomplished in the following way. A Grignard reagent was formed from equimolar quantities of methyl magnesium iodide and *N*-methylaniline and to this the isopropylidene ester (0·01 mole) was added under nitrogen at 0°. After 30 min at room temperature the mixture was washed successively with dilute sulphuric acid and with water at −10°. Evaporation of the solvent from the dried separated organic layer gave *N*-phenyl-*N*-methyl isopropylideneglyceramide (b.p. 87°–89°, 0·008 mm, n_D^{18} 1·5230; found, N, 5·8 per cent; $C_{13}H_{17}NO_3$ requires N, 5·95 per cent). The substituted amide was treated with lithium aluminium hydride (0·05 mole) in anhydrous ether for 18 h at room temperature. After addition of ethyl acetate, the solution was washed with dilute sulphuric acid (15 ml. 5 N). The aqueous layer was neutralized by passage through a column of 'Amberlite *IR* 120 (H$^+$)'

and then by addition of $BaCO_3$. Evaporation of the solvent gave DL-glyceraldehyde (30–40 per cent yield), characterized chromatographically and by preparation of the 2,4-dinitrophenylhydrazone (m.p. 157° alone or mixed with an authentic sample, the infraspectrum of which was identical).

Urinary Amino-acids on Phenylalanine–Tyrosine-supplemented Diets

It has been previously demonstrated[1] that feeding rats diets high in DL-phenylalanine and L-tyrosine caused the animals to excrete phenylpyruvic acid in their urine. Along with the excretion of phenylpyruvic acid, psychological tests on the animals revealed a disturbance in the temporal discriminate learning pattern. These experimental changes have been compared with those accompanying phenylketonuria.

The foregoing results have been corroborated[2] and have also been extended[3] by feeding excessive quantities of the L-isomer of phenylalanine. However, the influence of these diets on the renal threshold of other amino-acids has not been studied. It is possible that this could be important in assessing any toxic effects of such diets. The following experiments were therefore designed to evaluate this effect.

Eight experimental and four control rats (3 weeks old) were placed on commercial rat chow (Rockland). The diet of the experimental group was supplemented with 3·75 per cent DL-phenylalanine and 3·75 per cent L-tyrosine. All animals were housed individually in metabolic cages, and 24-h urines were collected over a six-week period. Gains in weight in all animals were satisfactory.

Although it has been reported[4] that diets containing 5 per cent DL-phenylalanine or 5 per cent L-tyrosine have a growth-depressing effect when fed in low protein diets to weanling rats, significant depression of growth was not observed in this study at the 3·75 per cent level. Presumably the alteration in the balance of the free amino-acids in plasma was not sufficient to exert deleterious effects.

Aliquots of urine were analysed weekly for phenylpyruvic acid[5], and at the end of the sixth week pooled aliquots of the control and test urines were prepared[6] for ion-exchange chromatography by removing ammonia *in vacuo* and adjusting the *p*H to 2·2. At the completion of this experiment, it was repeated with a second group of animals.

In agreement with previous findings, phenylpyruvic acid (PPA) excretion was markedly elevated on the experimental diet. The excretion of PPA was observed within 12 h after placing the animals on the diet; however, no attempts were made to assess the behavioural consequences of such a regimen.

The individual urinary free amino-acid excretion of the control and 'phenylketonuric' rats is shown in Table 1. Increases in threonine, serine, glutamine, cystine, cystathionine, lysine and 1-methyl histidine were noted while decreases were observed in aspartic and glutamic acid, glycine, alanine. Phenylalanine and tyrosine concentrations were not measured because of the possibility of contamination from the diet. The total excretion in mg/24 h was 15·09 for controls and 15·66 for the experimental animals (phenylalanine and tyrosine not included). The results of the duplicate experiment were consistent with the findings already reported.

Table 1. Free Amino-acid Excretion

Amino-acids	Control (mg/24 h)	Exp. (mg/24 h)
Taurine	8·20	8·60
Aspartic acid	0·31	0·16
Threonine	0·20	0·68
Serine	0·22	0·38
Glutamine	0·32	0·98
Glutamic acid	0·72	0·50
Glycine	2·60	0·99
Alanine	0·96	0·55
Valine	0·10	0·10
Half-cystine	0·16	0·66
Cystathionine	0·10	0·20
Methionine	0·16	0·32
Isoleucine	0·19	0·07
Leucine	0·09	0·09
Tyrosine	0·19	—
Phenylalanine	0·18	—
β-Alanine	0·09	0·06
Lysine	0·31	0·66
3-Methyl histidine	0·10	0·20
1-Methyl histidine	0·14	0·23
Proline	0·12	0·18

An explanation of the differences between the control and experimental groups depends on a better knowledge of the factors influencing the excretory pattern in the rat. Although no particular correlation between the structure of the amino-acid and its excretion pattern was evident from the data, it was apparent that the supplemented diets did exert an influence on the excretion of the amino-acids. Similar experiments[7] in which galactosaemia was produced in the rat did not result in any explanation of the aminoaciduria in this condition.

Although the excretion patterns in the rat and in man are considerably different, attempts were made to correlate, at least qualitatively, the amino-acid pattern with that previously reported in humans[8]. Glycine and alanine excretion, which was decreased in the experimental animals, was also decreased in the phenylketonuric subject. On the other hand, many of the amino-acids which were excreted in excessive amounts by the animals were excreted in small amounts by the human. However, it is not possible to determine the significance of this phenomenon until additional subjects have been evaluated.

Formation of Tyrosine-α-ketoglutarate Transaminase Activity *in vitro*

In the course of experiments designed to clarify the role of hydrocortisone and tyrosine in the stimulation of tyrosine-α-ketoglutarate transaminase activity, we observed small apparent increases of enzymatic activity in an *in vitro* system. This system is essentially that of Lingrel and Webster[1], with some modifications. No attempt was made in these experiments to distinguish between synthesis of apoenzyme and release of active enzyme, in contrast to the studies of Pitot and Cho[2] on the release of tryptophan pyrrolase activity.

The results are shown in Table 1; they are expressed as the difference in the number of μmoles of *p*-hydroxyphenylpyruvate produced in a 20-min incubation period per ml. of 600*g* supernatant between the beginning and the end of a 10-min pre-incubation period. The complete system is as follows: 6 ml. of a 600*g* supernatant from a rat liver homogenate prepared according to the method of Zamecnik and Keller[3]; 2·3 ml. of 0·1 M *tris*, *p*H 7·8; 1·2 ml. of 0·1 M *tris*, *p*H 7·8, containing 0·1 M potassium chloride; 10 μmoles each of ATP and DPN, 90 μmoles of α-ketoglutaric acid[4], 10 μmoles of crystalline manganese chloride, 1 mmole of glycine, all added as solid; 0·1 ml. of 0·1 M magnesium chloride; and water to 10 ml. Hydrocortisone acetate, 1 mg, and tyrosine, 6·5 mg, were also added in solid form. The system was shaken in a gyratory water-bath shaker at 37° C for 10 min; 1·0 ml. aliquots were removed for incubation at the beginning and at the end of the pre-incubation period. These aliquots were added to a system containing 8·0 ml. of 0·2 M phosphate buffer, *p*H 7·2, 0·5 ml. of a 300 μg/ml. solution of pyridoxal phosphate, 0·5 ml. of 0·3 M α-ketoglutarate, and 1·0 ml. of 0·06 M sodium diethyldithiocarbamate. This system was incubated at 37° C in the water-bath shaker; the reaction was started by the addition of 5·0 ml. of 0·012 M tyrosine made up in 0·2 M phosphate buffer, *p*H 7·2, and stopped at the end of 20 min by the addition of 0·5 ml. of 100 per cent trichloroacetic acid. The TCA precipitates were centrifuged and 2·0 ml. of the clear supernatants were taken for assay of *p*-hydroxyphenylpyruvic acid by the Briggs method[5], as modified by Canellakis and Cohen[6], except that 2·0 ml. of water and 4·0 ml. of the 'mixed reagent' were added to the 2·0 ml. of TCA supernatant.

All the experiments recorded here were performed with preparations derived from the livers of adrenalectomized male Wistar rats (Charles-River Breeding Laboratories, Brookline, Mass.). As can be seen from Table 1, the addition of hydrocortisone and tyrosine had no effect on the apparent increase. In this connexion, it should be noted here that Goldstein *et al.* have been able to stimulate both tyrosine-α-ketoglutarate transaminase activity and tryptophan pyrrolase activity in isolated perfused rat liver by means of hydrocortisone; this stimulation was prevented by puromycin[7]. There also appears to be a partial requirement for DPN in our *in vitro* system. In none of the experiments was there a significant decrease in the 10-min value as compared with the zero-time value. The increases were proportional to the amount of 600*g* supernatant in the pre-incubation system, and there was no increase when the supernatant was incubated with tyrosine and α-ketoglutarate alone, thus ruling out the possibility that the increases reflected simply endogenous formation of *p*-hydroxyphenylpyruvic acid. It also appears that the rate of increase observed here is roughly the same as that observed for the *in vivo* stimulation, at least in the early stages.

Table 1. APPARENT INCREASE OF TYROSINE-α-KETOGLUTARATE TRANSAMINASE ACTIVITY *in vitro*

System	No. of experiments	Δμmoles *p*-hydroxyphenylpyruvate/10 min pre-inc.
Complete	12	0·325 ± 0·118*
Complete + hydrocortisone and tyrosine	7	0 297 ± 0·119
Complete − DPN	2	0·164 ± 0·108
Control†	4	0 046 ± 0 101

* Average maximum error (see text for explanation).
† 6 ml. supernatant + 3·5 ml. *tris* buffer + 1·5 ml. water.

One of the major problems encountered in conducting these experiments was the difficulty in obtaining completely reproducible results; about one experiment in every four or five failed to show the expected result. Largely as a result of this, DPN was the only component of the system the necessity for which was explicitly tested; however, there appears to be a dependence on ATP also[8]. GTP (10 μmoles) and pyridoxal phosphate (120 μg) in some of the later experiments were added, although some experiments were successful without these additions.

The error indicated in Table 1 is not the standard error of the mean; rather, it is an estimate of the magnitude of the total error arising from the individual pipetting steps of incubation and assay. The magnitude of this error is about 2 per cent of the total activity for each time value. Since the zero-time activity was not a zero value, the overall error is about 4 per cent of the total activity. The increases are in the neighbourhood of 10 per cent of the total activity; thus the error is a rather large fraction of the increases. This error is about 1·5 times the standard error of the mean; strictly speaking, therefore, this represents an upper limit to the magnitude of the error.

These experiments do not rule out the possibility that the observed increases are due to an activator, analogous to the iron-porphyrin compounds in the case of tryptophan pyrrolase[9,10]. However, to our knowledge, there has been no evidence presented which indicates the existence of an activator. The available evidence, albeit of an indirect nature, points rather to protein synthesis more or less directly[7,11,12].

The small size of the increases and the difficulties with reproducibility suggest the existence of some unknown limiting factor or factors. RNA and a mixture of pentose nucleotides have been shown to have an effect *in vivo* which appears to be more specific than simply a stress mechanism[13,14]; perhaps it is possible that something like 'messenger RNA' breaks down rapidly in this system. Further work will be undertaken to clarify these various points.

Microsomal L-Gulonolactone Dehydrogenase

IT has been demonstrated previously by several workers[1–4] that rat liver microsomes readily convert L-gulonolactone into L-ascorbic acid in the presence of oxygen. Recently, it has been found that the microsomes from the livers of goat and the rat can also convert L-gulonolactone into L-ascorbic acid under anaerobic conditions in the presence of a suitable electron acceptor. Various dyes were tested for their ability to act as electron acceptor with this enzyme; these included methylene blue, phenazine methosulphate, neotetrazolium chloride, 2,6-dichlorophenol indophenol and cytochrome *c*. Of these only phenazine methosulphate and 2,6-dichlorophenol indophenol were reduced by the enzyme in the presence of a substrate; the ability of 2,6-dichlorophenol indophenol as electron acceptor was about one-fifth compared with that of phenazine methosulphate (Table 1).

Table 1. SYNTHESIS OF L-ASCORBIC ACID UNDER ANAEROBIC CONDITIONS IN THE PRESENCE OF A SUITABLE ELECTRON ACCEPTOR

Electron acceptor added	Concentration used	Ascorbic acid formed (µmole) by: Rat liver microsomes D-Glucuronolactone	Rat liver microsomes L-Gulonolactone	Goat liver microsomes D-Glucuronolactone	Goat liver microsomes L-Gulonolactone
Methylene blue	2×10^{-4} M	0	0	0	0
Phenazine methosulphate	0·5 mg	0·31	0·60	0·44	0·82
Neotetrazolium chloride	1 mg	0	0	0	0
2 : 6-Dichlorophenol indophenol	2×10^{-4} M	0·05	0·12	0·08	0·17
Cytochrome *c*	1 mg	0	0	0	0

The test system contains: 20 mM sodium phosphate buffer, *p*H 7·4, 10 mM D-glucuronolactone, 0·25 ml. of microsomal dispersion (250 mg equivalent of wet liver), 50 mM KCN, phenazine methosulphate, 0·5 mg (kept in the side-arm of the Thunberg tube) in a total volume of 2·5 ml.; incubated for 20 min at 37° under anaerobic conditions. Ascorbic acid was estimated by Roe and Kuether's method (ref. 6).

When L-gulonolactone (5 mM) was used as substrate, the concentration of cyanide was 1 mM.

D-Glucuronolactone has also been found to be converted into L-ascorbic acid (as estimated by Roe and Kuether's[6] method after the removal of cyanide by acidification with hydrochloric acid and evaporating off the hydrocyanic acid) by goat liver microsomes under anaerobic conditions in the presence of phenazine methosulphate and 0·05 M potassium cyanide.

In a recent communication Bublitz[7] reported that 2,6-dichlorophenol indophenol dye was reduced by rat liver microsomes in the presence of phenazine methosulphate and L-gulonolactone under aerobic conditions and he termed this enzyme as L-gulonolactone dehydrogenase. According to him this L-gulonolactone dehydrogenase could only be solubilized with rattlesnake venom but not by bile salts and any other agent. Contrary to the observations of Bublitz[7], it has been found in this laboratory that L-gulonolactone dehydrogenase from rat or goat liver microsomes could be effectively solubilized with sodium deoxycholate according to the method of Chatterjee *et al.*[4] and the enzyme could be further concentrated by the addition of ammonium sulphate to a concentration of 30 per cent saturation.

The maximum formation of L-ascorbic acid takes place after an incubation period of 15 min and the optimum concentration of phenazine methosulphate has been found to be 0·5 mg; $\alpha\alpha'$-dipyridyl, ethylenediamine tetraacetic acid and 8-OH quinoline (10^{-3} M each) have no effect on the enzymatic activity. L-Gulonolactone dehydrogenase component has been found to be more stable than the oxidase. It has been found to retain its full activity even at *p*H 5·4. The oxidase activity is almost completely lost by keeping the soluble enzyme preparation at 45° in a water bath for 5 min, but this heat-treated enzyme preparation has been found to possess both L-gulonolactone dehydrogenase and D-glucurono reductase activities.

L-Gulonolactone dehydrogenase has been obtained free of any L-gulono oxidase activity by electrophoretic separation of the soluble enzyme at 0° on paper (Whatman 3 *MM*) in 0·1 M sodium phosphate buffer, *p*H 7·4, at a potential gradient of 6 V/cm for 3 h, the length of the run being 5·5 cm. The protein band (5·0–5·5 cm from the line of application) was eluted with 0·05 M sodium phosphate buffer, *p*H 7·4, containing 0·1 per cent sodium deoxycholate in a period of 30 min at 5°. Though there is not much increase in the specific activity the foregoing preparation has been found to convert both D-glucuronolactone and L-gulonolactone into L-ascorbic acid in the presence of phenazine methosulphate but not in the presence of air. A dehydrogenase preparation free of any oxidase activity has also been obtained by negative adsorption of the soluble enzyme on diethyl amino ethyl cellulose (DEAE-cellulose) column equilibrated with 0·01 M sodium phosphate buffer, *p*H 7·4. This has already been reported by Bublitz[7]. The enzyme preparation thus obtained can convert both D-glucuronolactone and L-gulonolactone into L-ascorbic acid in the presence of phenazine methosulphate but not in air, D-glucuronolactone requiring in addition cyanide in the system. This enzymic activity has been found to be inhibited by *p*-chloromercuribenzoate, the inhibition being reversed by GSH, showing the requirement of essential sulphydryl groups for its activity.

Fungitoxicity of 2,4-Dichloro-3,5-dinitrobenzoates

MANY aromatic compounds containing halogen substituents activated by the presence of electronegative groups, particularly nitro groups, in *ortho* and *para* positions are fungitoxic. For example, 2,4-dinitrofluorobenzene and its 5-halogenated derivatives protect cotton fabric from attack by *Myrothecium verrucaria*[1], 1,5-dichloro-2,4-dinitrobenzene is a soil fungicide[2] and 1-chloro-2,4-dinitronaphthalene controls a number of plant pathogenic fungi[3]. The influence of the introduction of a carboxy or carboalkoxy substituent into compounds of this type has not received much attention although the fungicidal activity of certain chlorodinitrobenzoates is reported in recent patent literature[4].

Table 1. 2,4-DICHLORO-3,5-DINITROBENZOATES

Ester	m.p. (° C)	Formula	Analysis Found (%) C	Analysis Found (%) H	Analysis Required (%) C	Analysis Required (%) H
Methyl	84	$C_8H_4Cl_2N_2O_6$	32·9	1·1	32·5	1·4
Ethyl	101	$C_9H_6Cl_2N_2O_6$	35·2	1·6	35·0	1·9
Isopropyl	117	$C_{10}H_8Cl_2N_2O_6$	37 3	2·5	37·15	2 5

We have examined simple aliphatic esters of 2,4-dichloro-3,5-dinitrobenzoic acid[5] (Table 1) as protectant foliage sprays in the greenhouse for the control of *Alternaria solani* on tomatoes, *Erysiphe graminis* on oats and *Peronospora tabacina* on tobacco. A standard greenhouse test[6] was used for assessing control of *A. solani* and basically similar techniques were adopted with *E. graminis* and *P. tabacina*. The benzoates (prepared by Fischer esterification of the parent acid) were fungitoxic (Table 2). The methyl ester in particular gave good control of the three pathogens and in a more detailed examination against *A. solani* it had an ED_{95} value of 0·01. Tetramethylthiuram disulphide in the same experiment had an

Table 2. FUNGITOXICITY OF 2,4-DICHLORO-3,5-DINITROBENZOATES

Ester	Concentration (p.p.m.)	Disease (% of unsprayed control) *A. solani*	Disease (% of unsprayed control) *E. graminis*	Disease (% of unsprayed control) *P. tabacina*
Methyl	500	1	0	0
	100	1	0	10
Ethyl	500	0	0	60
	100	4	1	80
Isopropyl	500	25	0	20
	100	75	0	40
Free acid	500	100	90	100

ED_{50} of 0·08. The free acid was much less active, presumably because the presence of the polar carboxy group reduced the ability of the molecule to penetrate the fungal cells.

We detected no phytotoxicity with these compounds at 500 p.p.m., the highest concentration tested, nor did we observe symptoms of plant growth effects known to be associated with certain halogenated nitrobenzoic acids and their esters[7,8].

The reactivity of the halogen groups is almost certainly responsible for the fungitoxicity of the 2,4-dichloro-3,5-dinitrobenzoates. In this respect their mode of action probably resembles the pathways of fungitoxicity suggested for chloranil, dichlone[9–11] and 2,4-dinitrofluorobenzene[12], where labile halogen atoms are considered to react with essential amino or mercapto groups in the micro-organisms. This view is supported by the knowledge that the elimination of the chlorine atom of 2,4-dinitrochlorobenzene by amines[13] or mercaptans[14] occurs in mild conditions. Likewise, both the chlorine atoms of methyl 2,4-dichloro-3,5-dinitrobenzoate were readily replaced, for example, by methylamino and phenylthio groups to give methyl 2,4-di(methylamino)-3,5-dinitrobenzoate (m.p. 208°. Found: N, 19·7. $C_{10}H_{12}N_4O_6$ requires N, 19·7 per cent) and methyl 2,4-di(phenylthio)-3,5-dinitrobenzoate (m.p. 104°. Found: C, 54·4; H, 3·2. $C_{20}H_{14}N_2O_6S_2$ requires C, 54·3; H, 3·2 per cent) respectively. Neither reaction product was fungitoxic at 500 p.p.m.

PHYSIOLOGY

Antihistaminic Action of Lysozyme

It was previously shown that heparin and mucin bind histamine[1,2]. For this reason we worked with an enzyme acting on mucopolysaccharides, and looked for some modifications of histamine action. Lysozyme inhibits the action of histamine on the isolated guinea pig's ileum. The threshold is about 10^{-8} (w/v). No inhibitor action was observed towards acetylcholine, serotonin and barium.

When injected intravenously into a guinea pig the lysozyme counteracts the bronchospasm produced by intravenously injected histamine. The method used is very much like that of Konzett and Rossler[3]. The threshold is about 10 µg per animal. No inhibitory action was observed towards the bronchospasm elicited by acetylcholine and serotonin (Fig. 1).

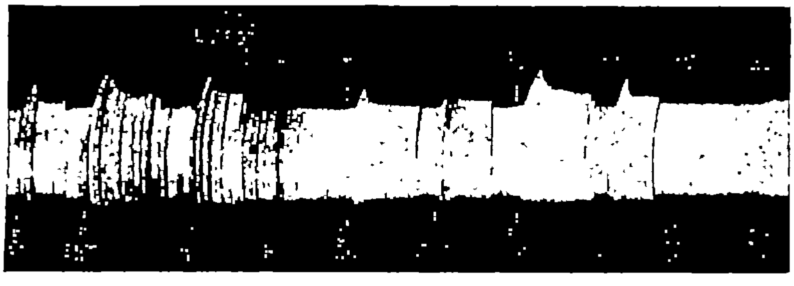

Fig. 1. Effect of lysozyme on the bronchospasm produced in a male guinea pig (500 g) by histamine dichloride (*H*), acetylcholine chloride (*AC*) and serotonin creatinine sulphate (5HT). Doses in µg. Time in min from lysozyme injection

Lysozyme prevented the shock produced in guinea pigs by the intravenous injection of histamine. In our experiments, 5 mg of lysozyme were injected intravenously and then histamine was given by the same route 10 min later. In such conditions, the LD_{50} becomes 300 times greater.

These investigations[4] suggest that lysozyme is a natural antihistaminic.

Lubrication in Synovial Joints

A CRITICAL review of the work of Barnett, Davies, Charnley and MacConaill[1–4] indicates that there exists a tendency to explain the lubricating conditions in synovial joints by either the lubricating properties of synovial fluid, or by the lubricating properties of the articular surfaces. The proponents of these hypotheses applied the theories of hydrodynamic lubrication or boundary lubrication, respectively. Neither of these theories can explain, however, the lubrication in joints; both are much too crude for this purpose. The nearest approach to reality could be given, perhaps, by the recent elasto-hydrodynamic theories[5,6], but even in these, when applied to synovial joints, a discrepancy exists between the factual evidence and the theoretical results. In fact, a discrepancy between the experimental and the calculated values of rates of shear, or between the calculated and the experimental values of viscosity of synovial fluid, is of an order of 100,000. That the synovial fluid is indeed required for proper lubrication and functioning of joints may be judged from the effect of a fall in temperature on the increased resistance of joints to movement, and also on a decrease in the exertible external force[7]. Both phenomena would be due to an increase in the viscosity of synovial fluid and, to some degree, also due to the changes in the elasticity of the cartilage. A decrease of the viscosity of synovial fluid and a change of the rheological characteristics of this fluid from the thixotropic type into a Newtonian type was observed in cases of rheumatoid arthritis[8–11]; in such cases the joint temperature was higher than anticipated from relative clinical activity[8].

A normal synovial fluid exhibits non-Newtonian, thixotropic, properties. Its viscosity is low at high rates of shear, and it is high (reversibly) at low rates of shear. As the product of viscosity and of the rate of movement is nearly constant, synovial fluid is capable of carrying a constant load; the load-bearing properties of synovial fluid are independent of the rate of movement. The synovial fluid shows also some degree of elasticity[12]. On repeated shearing the consistency of fluid may increase[13,14]. The elastic properties of synovial fluid have two important consequences. First, the fluid cannot be squeezed out from the space between the articular surfaces: secondly, a sudden impact causes a development of transient and instantaneous dilatant properties which help to cushion the shock of impact on the articular surfaces. A simultaneous elastic deformation of the cartilage decreases the pressure by increasing the contact area and by permitting, most likely, an existence of a fluid film of nearly constant thickness. The latter is promoted also by the synovial fat pads, which, as suggested by Barnett *et al.*[2,15], reduce the thickness of film while not taking part in the actual load-bearing mechanism.

Due to the elastic deformation (in the plane normal to the plane of the articular surfaces) of cartilage, the length of the contact area between surfaces is much increased. This permits the film thickness to be independent of load. Perhaps the term 'contact' is not exactly a correct one, as a film of synovial fluid will be interposed between these surfaces. The degree of deformation in the cartilage will depend on the elasticity and the thickness of the cartilage, and on the load.

The elastic deformation of cartilage may exist also in the plane parallel to the plane of articular surfaces. The lateral-transverse movements of these surfaces decrease the actual velocity gradient existing in the film of synovial fluid.

The velocity gradient is decreased also due to the fact that only reciprocating movements may exist in synovial joints. The thixotropic break-down of synovial fluid will correspond to some equivalent equilibrium level of rate of shear, this level being much lower than the nominal rate of shear[16].

It can be stated that so long as the synovial fluid is normal (that is, it is thixotropic and elastic) and so long as the articular cartilage remains elastic, the articulate surfaces are never in an immediate contact and, consequently, the boundary lubrication does not take place. The elasto-hydrodynamic lubrication involving lateral-transverse movements of the cartilage is paramount.

If, however, the pathological changes in synovial fluid will deprive it of its content of hyaluronic acid and/or of the hyaluronic acid–protein complex, the resulting decrease in viscosity and a change in rheological type of synovial fluid will impair lubrication. A subsequent damage to the articular surfaces, due to high friction, will consist of lesions, fibrositis and adhesions. In the absence of a thixotropic and elastic (and wetting) fluid, only a boundary-type of lubrication may exist.

If some pathological changes occur, in the first place, in the articular cartilage, while the synovial fluid is still normal, a decrease in the degree of smoothness, elasticity and resiliency of the articular surfaces will affect the synovial fluid. A decrease in the normal (vertical) and lateral deformations of cartilage will lead to large increases in local pressures and to an increase in the velocity gradient across the gap between the opposing surfaces. Synovial fluid will be forced to perform under much higher rates of shear than under usual conditions. Both phenomena, that is, the decrease in contact area and the increase in the rate of shear, will lead to a degradation of hyaluronic acid–protein complex, in a manner analogous to mechanical degradation of polymers[17,18]. A degradation of synovial fluid (that is, a decrease in its molecular weight) will impair its lubricating properties, will prevent its action as a shock-absorber, and, finally, it will permit even this fluid to be squeezed out from the space between the surfaces.

A decrease in the lubricating action of synovial fluid will lead to tear and wear of cartilage[1], and to an increase of the intra-articular temperature[8], which, in their turn, will cause a further deterioration of joint structure.

The recent controversy between Charnley, on one hand, and Barnett, Davies and MacConaill, on the other, indicates the complexity of problems related to joint lubrication. The controversy, as indeed pointed out by the latter, is more of an argument about words than about things. However, some aspects could be appraised.

Charnley is right in saying that hydrodynamic lubrication is not suited to a reciprocal motion and that it is not achieved under large loads and small movements; but the lubrication theory mentioned is based on the classical hydrodynamic theory and not on the modern modifications of the same. Charnley states that as the coefficient of friction is constant for all speeds of movement, the lubrication must be of the boundary type. This does not necessarily follow; because, as the product of the rate of movement and of the viscosity of synovial fluid is nearly constant, friction will depend only on the load, even if the classical hydrodynamic theory of lubrication were applied. Barnett *et al.* state, on the other hand, that one should not deduce from the fact that the boundary lubrication implies affinity between the lubricant and the surfaces that this affinity implies boundary lubrication. Barnett, Davies and MacConaill are correct in stressing that the essential characteristic of joint lubrication is the existence of a fluid film. They neglect, however, the importance of the resiliency of articular cartilage, which point is well appreciated by Charnley. Neither Charnley nor Barnett *et al.* noted the existence or the significance of the lateral elastic deformations of articular surfaces.

It should be evident that both the synovial fluid and the articular cartilage play an important part in the joint lubrication. An application of the obsolete forms of hydrodynamic and boundary theories to the foregoing problem may be thus rather futile.

Effect of Tetanus on the Parental Behaviour in the Rat

PREVIOUS experiments on the placental barrier to tetanus toxin in the rat revealed that mothers suffering from tetanus were able to deliver a healthy litter[1]. While some of these mothers cared for their new-born, others neglected them. The present investigation was therefore undertaken to determine to what extent tetanus might affect parental behaviour, and the effect of this behaviour on the offspring.

The œstrous cycle and the date of copulation were determined for 40 albino rats of the Wistar strain. At various intervals of time, 3–5 minimum lethal doses of tetanus toxin (supplied by courtesy of Lederle Laboratories, Pearl River, New York) (0·1 ml./100 g of body-weight) were injected into the gastrocnemius muscle or the femoral vein of each pregnant female. Injected animals were kept in breeding cages under standard conditions adapted for our animal quarters. The criteria

Table 1. THE EFFECT OF TETANUS ON PARENTAL BEHAVIOUR IN THE RAT

3–5 minimum lethal doses of tetanus toxin were injected intravenously or intramuscularly into each pregnant rat. Criteria of the parental behaviour were: nest building, cleaning the new-born, retrieval, and nursing of the young

Group No.	No. of animals	Time of injection	Maternal symptoms during delivery	Parental behaviour	Survival period of the mother	No. of surviving young relative to the total
1	14	79–144 h prior to parturition	Generalized tetanus	Poor to absent	Av. 149·3 h (130–164 h)	2/129
2	10	52–72 h prior to parturition	Advanced tetanus	Limited	Av. 145·5 h (139–158 h)	48/103
3	6	24–48 h prior to parturition	Beginning tetanus	Good	Av. 120 h (96–145 h)	49/55
4	8	0–144 h after parturition	None	Good	Av. 72·6 h (65–87 h)	70/83

of parental behaviour were determined by: nest-building, licking of vulva, cleaning of the new-born, eating of the afterbirth, retrieving, nursing and suckling[2].

In Table 1 groups of animals are tabulated according to the time of toxin injection and the results obtained. The greatest percentage of death among the new-born (98 per cent) occurred in Group 1. These animals exhibited symptoms of tetanus hypersensitivity and excitability during preparturitional nesting periods. As tetanus progressed to generalized spasticity of the body, the animals became too seriously handicapped to lick the vulva and to assist the foetuses during delivery. Parturition was uneventful, with the exception of four cases of prolonged periods of labour and two deaths which occurred during delivery as a result of tetanus. At birth, most of the offspring were alive and appeared healthy. However, due to maternal neglect, the majority died while still wrapped in the foetal membranes attached to the placenta. In some instances the mother cleaned the young but did not eat the placenta. These conditions prevented effective nursing of the young. In group 2, milder symptoms of tetanus were present at the time of parturition. The majority of these mothers were able to lick the vulva, clean the young, and eat the afterbirth. Symptoms of generalized tetanus, however, developed soon after delivery and interfered with the retrieving, nesting, and nursing activities. The young were found scattered in the cage, cold and starving. Only 47 per cent of the new-born survived the mother.

In groups 3 and 4 the percentage of new-born survivals increased to 89 and 84 per cent respectively. Initial symptoms of tetanus were present at the time of delivery in group 3 only, but in both these groups the symptoms of tetanus progressed to death. Here also, general tetanus prevented adequate maternal care.

New-born rats, taken from each group and transferred to a foster mother, survived. Although histological examination of the mammary glands indicated glandular activity in all four groups of the tetanus-injected animals, this does not imply that milk ejection was not affected in some cases. Milk ejection is known to be inhibited by emotional stress, pain, disturbances of the autonomic nervous system, and electrical stimulation or lesions of the hypothalamus[3]. The stress of tetanus experienced by the mother during parturition might have inhibited milk ejection in our experiments. As a note of interest, pregnant rats injected with tetanus toxin prior to parturition had a prolonged survival period as compared with postpartum injected rats.

Lehrman[2], in his detailed discussion of parental behaviour in birds and infra-human mammals, lists many external and internal conditions which influence the parent–young relationship. Mechanical prevention of the licking phenomenon, trauma to the nervous system, hormonal changes, and various external stimuli could perhaps reproduce most of the behavioural deviations observed in our experiment. Tetanus toxin acts on the central nervous system by suppressing synaptic inhibition[4]. It also effects higher nervous activity and disturbs the conditioned behaviour of the rat[5]. The convulsive state, locomotor and autonomic disturbances present in tetanus may contribute to the effect of tetanus on maternal behaviour and lactation in the rat.

Although the present investigation of parental behaviour in tetanus was of general nature, it adequately demonstrates that a neurotropic bacterial toxin can influence considerably the parental behaviour of the rat and thus effect the survival of the new-born.

This investigation was supported in part by the American Cancer Society, Institutional grant C–168, Hahnemann Medical College and Hospital, Philadelphia, Pa.

Sensory Deprivation and Augmentation in the Examination of Enzyme Adaptation

THE formation of new enzymes in bacteria was first described by Wortman[1] in 1882. Since then the subject has been extensively examined, and is now well recognized. For example, certain strains of *Esch. coli* do not possess the enzyme β-glucuronidase in detectable amounts. If these strains are grown in a medium containing glucuronides or related compounds they quickly synthesize the enzyme. This induction of enzymes has been shown to involve other enzymes as well as β-glucuronidase and, furthermore, is due to actual new enzyme formation and not merely to increased enzyme activity nor to the emergence of a mutant strain (although this latter mechanism can also operate). The whole subject has been reviewed by Pollock[2]. The opposite phenomenon of enzyme repression, in which non-optimal amounts of a substrate in the bacterial environment result in a decrease or disappearance of the enzyme, is also well known. This has been shown to be due to actual inhibition of enzyme synthesis[3].

Similar enzyme induction in mammals, in which it is usually known as enzyme adaptation, has also been extensively studied and there can be no doubt that it is a valid concept. However, the vast majority of experiments in mammalian enzyme adaptation have depended upon alterations in dietary intake of substances (including parenteral administration), hormone administration or endocrine gland ablation. The subsequent enzyme assays were generally made on whole organs such as liver, kidney, muscle, etc.[4]. The changes found are thus often difficult to evaluate in relation to the known functions of a particular cell which in these organs are multifarious. Difficulties in producing a constantly high intracellular level of a substrate may well militate against an attempt to test the phenomenon experimentally as has been implied by Burnet and Fenner[5]. Some other means of producing this than the foregoing methods must be found, and it is suggested that enforced changes in the rate of the normal activity of individual cells would be a more specific method. One drawback to such a procedure is that more than one enzyme system would be directly involved. Nevertheless, the experiment would probably be worth while. For example, the injection of large amounts of pilocarpine in mice has been shown to cause a decrease in activity of alkaline phosphatase[6] and succinate dehydrogenase[7] in the plantar sweat glands, also physical rotation of rabbits on special turntables causes an initial fall in succinate dehydrogenase and cytochrome oxidase activities in the neurones of Deiters's nucleus[6]. Repeated daily stimulation for 7 days, on the other hand, results in an increase in activity in these two enzymes.

The inference to be drawn from these experiments is that excessive activity of a cell or tissue will result in an initial loss of enzyme either by protein catabolism as has been suggested[8] or by loss into tissue fluids or secretions[7], for example, urine and sweat. The enzyme is afterwards resynthesized and increasing amounts appear as the hyperactivity continues. It may then be supposed that the increased enzyme activity is probably the result of increased amounts of intracellular substrate made available by the continued stimulation.

Decrease in enzyme activity in mammalian cells other than as a concomitant of pathological processes does not appear to occur so frequently. In relation to the present hypothesis, however, it would be expected to occur in cells undergoing disuse atrophy and, in fact, it has been shown that malic dehydrogenase activity in muscles decreases in simple disuse atrophy as well as in paralytic poliomyelitis[9]. Such enzyme changes may well be the first manifestations of disuse atrophy. Disuse atrophy, however, is usually the result of pathological processes which may themselves cause changes in the enzymes being investigated. Experimentally the least pathogenic of techniques producing disuse of an organ would seem to be some form of sensory deprivation without physical restraint, that is, alterations in the animals' environment not alteration of the animals themselves. The most practical form this could take would be neuronal deafferentiation, for example, visual or auditory deprivation. Subsequent examination of the geniculate bodies and visual cortex might disclose enzyme changes of disuse atrophy.

If, in fact, such changes were found significant light may be thrown on the pathogenesis of transneuronal degeneration. This is a phenomenon first described in the lateral geniculate body in 1913 by Minkowski[10], and despite several claims to the contrary[11] had not been conclusively shown to occur elsewhere in the nervous system until recently when it was found in the trigeminal ganglion[12,13] and in the auditory pathways[14]. In this condition section of the optic (trigeminal, auditory) nerve leads not only to degeneration of the primary neurones but also to the second and even third order neurones far removed from the site of operation (eye enucleation, alcohol injection of ganglion, ablation of the cochlea). The degeneration or atrophy in these higher order neurones is thus trans-synaptic and, although several explanations have been advanced, for example, reparative gliosis, none is wholly satisfactory. On the other hand, disuse atrophy with enzyme loss as envisaged here would provide a wholly adequate explanation subject to the proviso that for practical purposes these neurones form synapses with the corresponding lower order neurones and with no other part of the nervous system. In such a case deafferentiation leads to the non-receipt of stimuli by otherwise intact higher order neurones and results in disuse atrophy. The lateral geniculate body in man is stated to receive synapses only from the optic tract[15]. Claims to find transneuronal degeneration in other parts of the nervous system[11,15] have not been confirmed or successful. Owing to the richness of interconnexions between nerve roots, nerve tracts and sensory and motor neurones in the spinal cord together with the multifocal origin of synapses on any one nerve cell, it would appear almost impossible to deafferentiate any single neurone completely in this situation.

In monkeys transneuronal degeneration has been shown to occur as early as the 7th day following optic nerve section[16]. In these animals all the cells of the lateral geniculate body project to the cerebral cortex and there are no association neurones, whereas in the cat, in which it takes some 63 days for transneuronal degeneration to appear, the lateral geniculate body contains many small non-degenerating cells whose axons terminate on nearby neurones[16]. These neurones possess an average of 40 synaptic end-bulbs in contact with their surfaces[17], and these may originate from association neurones[15]. Thus differences in the rates of onset of transneuronal degeneration between species are probably not due to species-specific metabolic differences but to differences in anatomical richness of connexion.

The hypothesis presented here can be summarized briefly. It is that the amount of activity of a given enzyme in a cell (or organ) is dependent, *inter alia*, on the overall activity of that cell. It is, in a teleological sense, a biological manifestation of the economic principle of 'supply and demand'. This hypothesis of supply and demand can be extended back so that not merely enzymes are affected but also RNA, and possibly messenger RNA and ultimately DNA. This is to some extent supported by the work of Cook *et al.*[15], who showed that in neurones undergoing transneuronal degeneration there was a progressive loss of Nissl substance which contains RNA. They also found a decrease in the nuclear and nucleolar sizes. Furthermore, it has been shown that the rate of turnover of Nissl substance is accelerated by activity of the neurone[8,18].

Experimental procedures designed to test the hypothesis can be made using either sensory deprivation or augmentation, but these techniques will, of course, only show whether the principle is tenable in the nervous system. It should be possible to devise other techniques enforcing under- or over-activity in other systems such as the locomotor organs or digestive tract.

Protein Digestibility and Ingestion

Bender[1] has directed attention to the importance of the correct definition and usage of terms adopted in discussions on protein nutrition, in particular to the distinction between 'apparent' and 'true' as adjectives qualifying absorption and retention. Thus the 'apparent digestibility' (AD) of a protein is the ratio of the difference of the ingested and fæcal nitrogen to the ingested nitrogen, expressed as a percentage, while the 'true digestibility' (TD) makes allowance for the nitrogen in the fæces of non-dietary origin (the so-called metabolic nitrogen, F_s), which is subtracted from the total fæcal nitrogen; true digestibility is therefore always greater than apparent digestibility.

It is reasonable to assume that the true digestibility of a particular protein, or foodstuff, is a constant figure, something peculiar to the protein itself, and independent of the level at which it is fed, or the quantity consumed. It may also be assumed, and commonly is, that F_e is constant and independent of dietary nitrogen intake (I). If these assumptions are made it is easy to show that the relation of apparent digestibility to dietary nitrogen intake is hyperbolic:

$$AD = TD - F_e\,(100/I) \qquad (1)$$

There have been several reports in the literature of apparent digestibility varying with intake of nitrogen, or with percentage of nitrogen in the diet, which usually amounts to much the same thing, true digestibility remaining constant[1–6]; this communication merely attempts to consider the matter quantitatively. A similar treatment was used by Greaves and Scott[7] in analysing data obtained with cats, though there it was assumed that F_e was related to the total weight of dry food consumed: in this case I in equation 1 becomes the percentage of nitrogen in the diet.

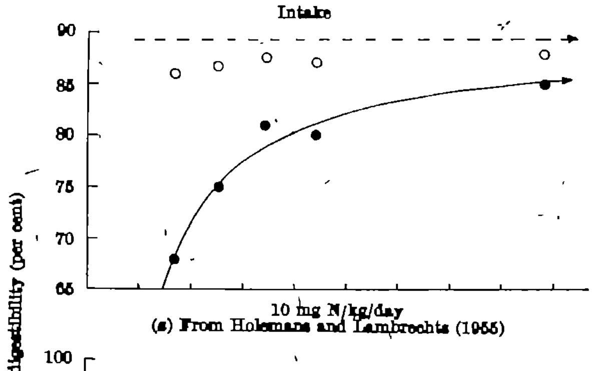
The results of Holemans and Lambrechts[8] and Phillips and Ladell[9], both obtained from human subjects, allow calculations to be made which permit curves of the type described by equation (1) to be fitted; the results of doing so are shown in Fig. 1. The equations of the curves are, respectively:

$$y = 89{\cdot}2 - 35{\cdot}3\,(100/x) \qquad (2a)$$

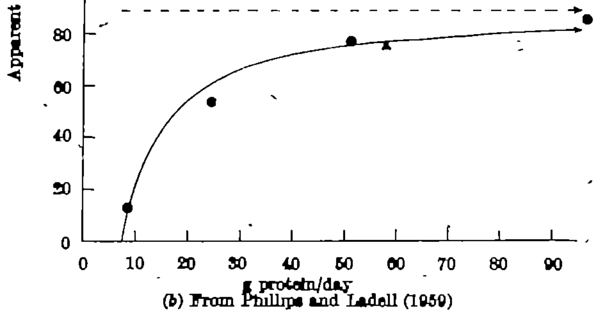
$$\text{and } y = 88{\cdot}7 - 6{\cdot}84\,(100/x) \qquad (2b)$$

and it is seen that they fit the experimental points closely. (The equations are obtained by calculating by the method of least squares a straight line regression of AD on the reciprocal of I. The negative slope of the line is then $(-)\,F_e$, and the intercept on the y-axis is TD.)

The units of the x-axis in the two parts of Fig. 1 are different, and are indicated in the caption. The curve in Fig. 1b was calculated from the observations represented by the black circles: the triangle represents an experiment in which a different source of protein was used but nevertheless it fits the line well.



(a) From Holemans and Lambrechts (1955)



(b) From Phillips and Ladell (1959)

Fig. 1. Variation of apparent digestibility of protein with dietary intake

By comparing equation 2 with 1, the true digestibility of the protein in the two experiments is seen to be 89·2 per cent and 88·7 per cent, and these values are indicated by horizontal dotted lines in Figs. 1a and b. Similarly, F_e in the first instance is seen to be 35·3 mg nitrogen/kg body-weight/day (Fig. 1a), and in the second 6·84 g protein/day (Fig. 1b). Phillips and Ladell[9] themselves estimate F_e by a different method to be 8·9 g protein/day; Holemans and Lambrechts[8] estimated F_e in their experiment to be 30 mg nitrogen/kg body-weight/day, and using this figure they calculated values for true digestibility at each level of intake: their results are plotted in Fig. 1a as open circles.

Pellett[6] suggested that the rise in apparent digestibility from 56 to 80 per cent which he observed when his pig was transferred from a 4·5 per cent protein diet on which it had subsisted for over 6 months, to a diet containing 7·5 per cent protein, was due to an increased production of digestive enzymes. While it has been conclusively shown that pancreatic function is depressed in cases of severe protein malnutrition[10,11] it is nevertheless true that a substantial rise in apparent digestibility would be expected to have occurred for the reasons advanced here. What lends greater support to Pellett's interpretation is his observation that whereas the rise in apparent digestibility mentioned here was immediate, when the pig was returned to the 4·5 per cent protein diet the apparent digestibility took several weeks to return to the original low level, falling finally to 30 per cent in the week before the animal's death. Furthermore, if one attempts to construct a line for Pellett's data in the manner of Fig. 1 it is immediately apparent that the change in the dietary level cannot of itself have been a sufficient cause of the change in apparent digestibility.

The fact that it is possible to fit so closely a theoretical curve of the type described by equation 1 to experimental data argues that the assumptions on which equation 1 is based, namely, the constancy and independence of intake of nitrogen of true digestibility and F_e, are reasonably valid. It is suggested that the process of fitting such a curve to experimental pairs of observations of apparent digestibility and dietary nitrogen intake may, in certain circumstances, be a useful means of estimating true digestibility or F_e, and relevant and important when conclusions are being drawn about the efficacy of digestion in experimental situations.

PHARMACOLOGY

Cholinergic–Adrenergic Dual Action of γ-Aminobutyric Acid Methylester on a Preparation of Toad's Sinus–Atrium

THE effects of γ-aminobutyric acid methylester, $NH_2(CH_2)_3COOCH_3$ (I), its N-monomethyl (II), N-dimethyl (III) and N-trimethyl (IV) substituents were recently examined on the isolated heart of a toad by Takahashi[1]. He reported the positive inotropic effect induced by (I) and (II), no effect by (III) and the negative

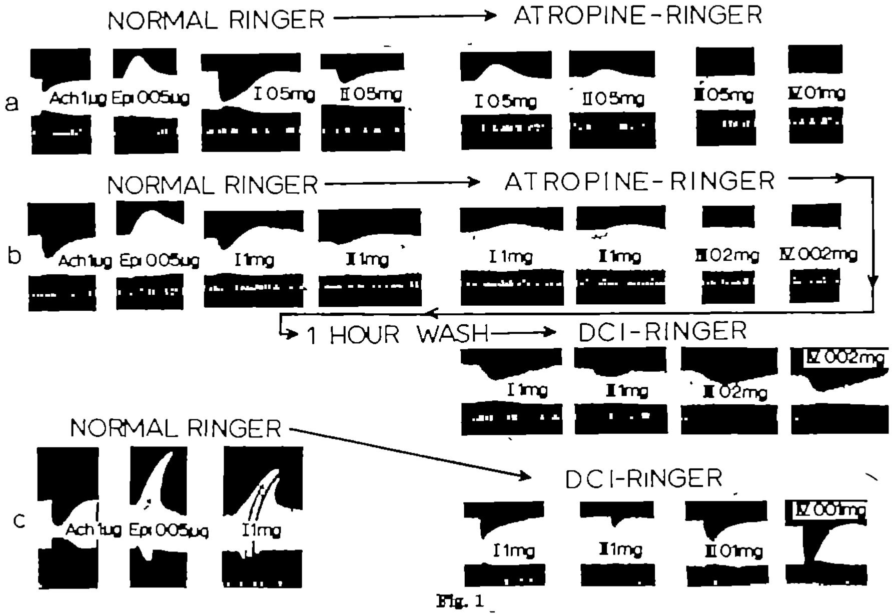

Fig. 1

inotropic effect by (IV). The induction of a quite opposite response by the difference of methyl moiety at the terminal nitrogen stimulated our interest to clarify the mode of action of these compounds. In this experiment a sinus–atrium preparation of a toad's heart was used, of which double cannulæ were so constructed that the Ringer solution perfused thoroughly the inner surface of sinus and atrium. The inner cannula was attached through rubber tubes to Mariotte bottles which contained normal Ringer, atropine-Ringer (0·01 mg/ml.) and dichlorisoprenaline (DCI)-Ringer (0·02 mg/ml.) solution. Perfusion pressure was 20 cm water, and 0·1 ml. of the drug solution was injected into the tube to the cannula. Experiments were performed during September–October, 1961, and during February–March, 1962.

The results obtained in the normal Ringer perfusion were somewhat different from those reported previously. When the normal Ringer solution was perfused to the sinus–atrium preparation of the non-treated animals, (I) and (II) in a dose of 0·5–1 mg usually induced the positive inotropic response on autumn animals (Fig. 1c), but the spring animals showed the negative inotropic response (Fig. 1a), occasionally followed by a positive inotropic one (Fig. 1b). In every preparation either the positive or the negative inotropic response was stronger in (I) than in (II). Meanwhile (III) and (IV) showed simply the negative inotropic response in every case in both seasons, the potency of which was around ten times larger in (IV) (0·01–0·02 mg) than in (III) (0·1–0·2 mg) for obtaining a 50 per cent decrease of contraction.

When the perfusing fluid was changed to atropine-Ringer solution, the negative inotropic effect previously observed by injection of these compounds, that is, (I) and (II) on spring animals, and (III) and (IV) in both seasons, disappeared, and the positive inotropic response occurred in the same dose of (I) and (II) (Fig. 1a and 1b). On the contrary, when the DCI-Ringer was perfused, the positive inotropic response commonly induced by (I) and (II) on autumn animals was completely blocked and a negative inotropic effect came out (Fig. 1b and 1c).

Concerning the cholinergic and adrenergic receptors Burn *et al.*[2] have developed the concept of cathecholamine release induced by acetylcholine of which action could be released by atropine on the rabbit atrium[3]. However, on the toad's sinus–atrium preparation with the atropine-Ringer perfusion, acetylcholine did not induce a positive inotropic effect even in the quite large range of dose used (0·01–250 µgm). Meanwhile, Japanese physiologists have carried out extensive investigations on the characteristic response of the trans-membrane potential of the toad's atrium tissue on sympathetic and parasympathetic stimulation and also on the administration of adrenaline and acetylcholine[4]. They confirmed the cholinergic excitation through the typical pattern of the trans-membrane potential when adrenergic reaction of adrenaline was ended and suggested one possible way to explain this phenomenon, such as acetylcholine release by administration of adrenaline[5]. However, neither the Burn's concept nor the Japanese physiologists' suggestion could explain the phenomenon by use of γ-aminobutyric acid methylester (I) and *N*-methyl γ-aminobutyric acid methylester (II) in the toad's heart. The experimental evidence here suggests that the adrenergic and cholinergic receptors of the toad's heart have a common part in response to the drug and there is probably neither a release of catecholamine induced by acetylcholine nor a release of acetylcholine induced by catecholamine. We believe that there is not enough differentiation of the adrenergic receptor from the cholinergic receptor in phylogenetically underdeveloped vertebrates.

In addition, these compounds have a simple negative inotropic action on Langendorff's preparation of the guinea pig and dog's heart lung preparation, especially prominent in (IV), which was prevented by atropine. Neither such dual activity nor the positive inotropic effect after atropine treatment was observed in the hearts of warm-blooded animals at all.

We thank Dr. O. Ikeda, Daiichi Seiyaku Laboratory, for supplying the compounds used.

Histamine-liberating Effect of Magnesium Deficiency in the Rat

Dietary magnesium deficiency in the rat gives rise, after a few days, to a characteristic peripheral vasodilation with erythema and œdema[1]. This change lasts for about a week, regresses and then re-appears later on. The signs of magnesium deficiency have been tentatively ascribed to a secondary vitamin B deficiency[2] and have also been compared to human neurodermatitis[3]. However, it was shown recently that magnesium deficiency induces a decrease in the number of subcutaneous mast cells[4], as well as an impairment in mast cell regeneration[5]. These observations are indicative of a change in histamine distribution that could be ascertained by measuring plasma and urinary histamine.

Male Sprague–Dawley rats (100–110 g body-weight) were fed a magnesium-deficient casein diet[6], and received demineralized water as drinking fluid; controls were

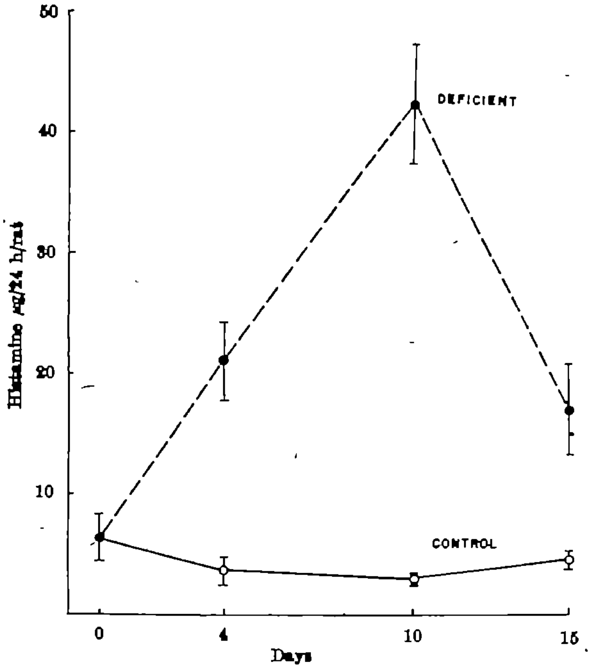

Fig. 1. Effect of a magnesium-deficient diet on urinary-free histamine secretion in male rats. Vertical lines indicate standard errors; each point represents the average of four pooled urine samples of three rats each

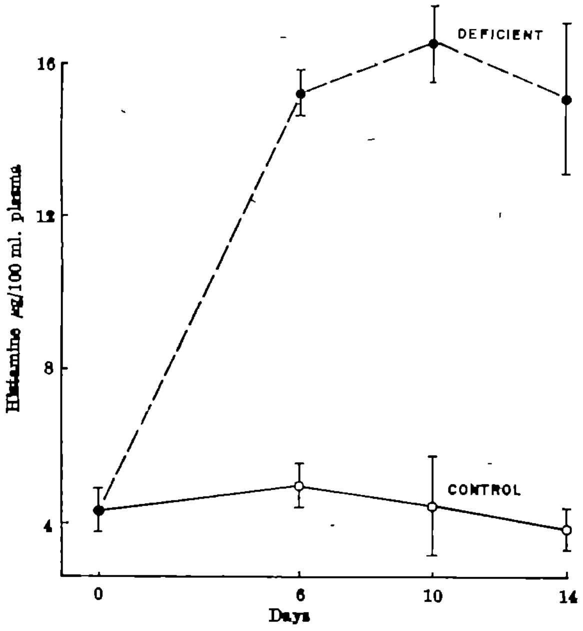

Fig. 2. Plasma histamine in magnesium-deficient rats. The higher values coincide with the period of maximal peripheral vasodilation. Each point is the average of five rats

given the same diet into which had been blended 0·6 g of magnesium sulphate per 100 g of diet. Metabolism cages were used for collection of urine; three rats were placed in each cage and urine samples were collected into bottles containing 0·3 ml. of concentrated hydrochloric acid[7]. The free histamine in the urine was determined by the guinea pig ileum assay; plasma histamine was measured by Lowry's method[8].

As shown in Figs. 1 and 2, both urinary and plasma histamine increase significantly in magnesium-deficient rats. This finding together with the fact that magnesium deficiency induces peripheral vasodilation[1], mast cell degranulation[4] and a decrease in tissue histamine[5] indicates that an endogenous histamine liberation occurs comparable with that observed after injection of histamine liberators such as compound 48/80 (refs. 9 and 10). There is yet no satisfactory explanation for this phenomenon. The release of histamine could be a direct effect of the deficiency or the result of accompanying changes in tissue concentrations of other ions such as calcium and potassium[11]. Another alternative could be that the lack of magnesium induces a decrease in the binding capacity of tissues for histamine, thereby causing a passive release of the amine. We are now testing these hypotheses in an investigation of the mechanism of histamine release.

Tryptamine in the Blood and Urine of a Patient with a Carcinoid Tumour

PATIENTS with the carcinoid syndrome typically show high blood levels of 5-hydroxytryptamine and increased urinary excretion of 5-hydroxyindolyl-3-acetic acid. Variants of the tumour have, however, been described in which the major secretion is 5-hydroxytryptophan[1].

Recently, during studies of blood of a male patient with a carcinoid tumour with extensive metastases, an indole compound was detected which failed to give the fluorescence or colour reactions typical of 5-hydroxyindole compounds.

This substance was not detected in similar examinations of blood samples from normal individuals or from another carcinoid patient. The identity of this compound with tryptamine was indicated by the following evidence:

(*a*) R_F values identical with authentic tryptamine on paper chromatograms in three solvent systems: (1) 20 per cent potassium chloride (w/v); (2) butan-1-ol/acetic acid/water (12 : 3 : 5 by vol.); (3) propan-2-ol/aqueous ammonia solution (sp. gr. 0·88)/water (20 : 1 : 2 by vol.).

(*b*) Norharman formation, detected by fluorescence characteristics following condensation of tryptamine with formaldehyde and subsequent dehydrogenation of the tetrahydronorharman with hydrogen peroxide[2].

This patient was also found to be excreting large amounts of tryptamine in the urine as estimated by the method of Sjoerdsma, Oates, Zaltzman and Udenfriend[3]. In a 24-h urine sample the excretion was 84 mg, which is about 1,000 times the normal level of 0·036–0·12 mg/day (ref. 3). It is of interest that the urinary indolyl-3-acetic acid and its acid hydrolysable conjugates showed little or no rise above the normal concentrations, estimated by the method of Weissbach, King, Sjoerdsma and Udenfriend[4]. The urinary indolyl-3-acetic acid was found to be 12 mg/24 h (normal, 3·1–8·1 mg/24 h). After preliminary acid hydrolysis of the urine, the estimates increased to 15 mg/24 h (normal, 3·2–13·8 mg/24 h).

So far as we are aware, this is the first report of the finding of tryptamine in human blood either in normal human beings or patients with carcinoid syndrome.

This work was done with the help of Mr. Adam Smith, Western General Hospital, Edinburgh, whose patient this is.

HÆMATOLOGY

Distribution of Haptoglobin among Thais

HAPTOGLOBIN type distribution has been determined on 682 Thais. All were normal, healthy male adults in the Royal Thai Army. Almost without exception their place of birth was confined to the provinces of north central and north eastern Thailand. This area of the kingdom was chosen for the survey as the one in which the population would be the most representative of the Thai people. It was felt that in this region there would be a minimum of disturbance of the Thai haptoglobin gene frequencies by recent (that is, past several centuries) admixture with non-Thai groups such as Burmese, Chinese, or Malayans. The blood samples were heparinized and centrifuged and the plasmas transferred to merthiolated vials immediately after collection and afterwards transported to our laboratory for electrophoretic analysis. Haptoglobin type identification was accomplished by the Smithies vertical starch-gel electrophoresis procedure[1] with minor modifications.

Table 1. HAPTOGLOBIN DISTRIBUTIONS IN ASIAN ETHNIC GROUPS

Ethnic groups	No. of subjects tested	Percentage distribution of haptoglobin types				Gene frequency	
		0–0	1–1	2–1	2–2	Hp^1	Hp^2
Thais (present work)	682	2·3	5·7	37·1	54·8	0·24	0·76
Chinese in Taiwan (ref. 2)	172	0	9·3	37·7	52·9	0·28	0·72
Chinese in Malaya and Australia (ref. 3)	167	1·2	10·8	34·1	53·9	0·28	0·72
Malays (ref. 3)	236	0·8	5·1	36·0*	58·1	0·24	0·76
Japanese (ref. 4)	349	1·4	6·0	35·0	57·6	0·24	0·75
Indians, Malaya (ref. 3)	219	1·8	1·8	14·6*	81·7	0·09	0·91
Indians, United States (ref. 5)	74	0	4·0	28·4	67·6	0·18	0·82

* Percentages shown for 2–1 haptoglobins include for Malays and Indians in Malaya, 0·4 and 0·9 per cent, respectively, of type 2–1 modified haptoglobins. No cases of 2–1 modified form were reported for the other ethnic groups in Table 1.

The group studied appears to be a reasonably homogeneous sample; the haptoglobin distribution obtained for the group as a whole is essentially the same as the separate distributions obtained by dividing the group into provincial sub-groups. By contrast, preliminary studies on smaller groups of individuals from the extreme northern portion of Thailand near Burma indicate a somewhat different distribution. A summary of the results of the study appears in Table 1 along with the haptoglobin distributions which have been reported for other Asian ethnic groups[2–5]. Based on the small numbers reported, the distributions of the Thai, Malayan, Japanese, and Chinese groups appear to be closely similar. The Thai, Malayan and Japanese groups, all with Hp^1 gene frequencies of approximately 0·24 according to present knowledge, resemble each other slightly more than they resemble the Chinese group, which has been reported[2,3] to have an Hp^1 gene frequency of approximately 0·28. (Current investigations in our laboratory on a larger series of Chinese inhabitants of Taiwan suggest that the frequency for their Hp^1 gene may prove to be slightly higher than the 0·28 value reported earlier[2].) The two small Indian groups examined in Malaya[3] and the United States[5] appear to exhibit a lower Hp^1 gene frequency than the other Asian ethnic groups. With respect to haptoglobin gene type distributions the Thai, Malayan, and Japanese groups fall between the Indian and Chinese groups; however, because both the latter groups are huge in number and diverse in nature, they may be expected to show variation in distribution of haptoglobin genotypes. A more detailed presentation of the provincial distribution of the Thai haptoglobin types and their accompanying hæmoglobin types will be presented elsewhere.

We thank the medical officers and technicians under Colonel Boon-Yang Vejjabool, Royal Thai Army Medical Corps, for collecting the blood specimens used in this work. Catalase Activity in Young Red Cells

THE process of ageing of mature red blood cells is thought to be related to a progressive deterioration of one or more metabolic functions on which the morphological integrity of the cell appears to depend[1]. At present, there is insufficient evidence available to permit an identification of the critical processes within the cell that control and delineate its life span. Recent investigation of this problem has been focused at the enzyme-level, and it has been reported that young red cells have increased levels of catalase[2] as well as other enzymes[3,4] which fall progressively as the cells age.

Investigations on red cell ageing carried out in this laboratory have provided evidence that another enzyme, glutamic-oxaloacetic transaminase (GOT), was markedly elevated in young cells[5,6]. During subsequent clinical application of these findings to the evaluation of erythropoiesis in anæmia[7], it was considered desirable to compare the red cell levels of GOT and catalase to determine which of these enzymes might provide the most sensitive indication of the proliferation of young cells into the peripheral blood. It is the purpose of this report to present data which are not in accord with the presently accepted view[1,2] that catalase is significantly elevated in young red cells.

Enzyme analyses were carried out directly on diluted hæmolysates prepared from washed red cells or on hæmolysate fractions obtained after serial osmotic hæmolysis[8]. GOT was estimated by a slightly modified enzyme-linked spectrophotometric assay procedure[9]. Catalase activity was determined as outlined by Beutler *et al.*[2] without modification. The hæmoglobin content of the various solutions was estimated from the optical density at 540 mμ, based on previous calibration with a manometric oxygen capacity method. When used, radioactively tagged red cells were obtained from hæm-

Table 2. GOT AND CATALASE ACTIVITY IN WASHED RED CELL SAMPLES FROM PATIENTS WITH NORMAL AND HIGH GOT-LEVELS

Subjects	No.	GOT (U/100 mg Hb)	Catalase (U/100 mg Hb*)
Group *A*	13	390 (260–480)	1,182 (710–1,440)
Group *B*	16	801 (540–1,170)	1,019 (690–1,320)

*Unit equals millimoles hydrogen peroxide destroyed.

atological normal subjects 6–10 days after the administration of 10 μc. of ferrous-59 citrate.

Successive exposure of washed red cells labelled with iron-59 to hypotonic saline solutions ranging from 0·9 down to 0·1 per cent has already been shown to produce a number of hæmolysate fractions which reflect a rough separation of cells of different ages in normal human subjects[10] and in rats[6]. Identical treatment of human red cells labelled with iron-59 provided similar results. A typical experiment (average of 2) in which the ratio of specific radioactivity of each sample to that of the whole blood is presented for each of the hæmolysate fractions (Table 1, col. *A*) indicates the adequate separation of young and old cells that this procedure can provide. Enzyme analyses were carried out for catalase and GOT activity in normal blood samples after exposure to the identical serial osmotic lysis. The elevated ratios of the GOT activity of the individual hæmolysate fractions to that of the whole unfractionated red cell sample (Table 1, col. *C*) reflect the increased enzyme activity due to the contribution of lysed young cells, substantiated by the increased radioactivity ratios in the same fractions (Table 1, col. *A*). This increase is clearly absent in the catalase data (Table 1, col. *C*). The presence of two populations of young cells, suggested by the high radioactivity ratios in the first 5 fractions, has already been observed[1,6,10]. Although there is no clear explanation for this finding, it may reflect an 'infant mortality'[1] that is in no way related to the general characteristics of the majority of young cells. The low catalase ratios apparent in these same fractions reflect the lability of catalase in extremely dilute solutions[9]. Separate experiments have shown that, under the conditions imposed by the serial osmotic fragility technique, there is a 15 per cent loss of enzyme activity in the extremely dilute hæmolysate fractions 1 to 5 (Table 1). No such loss of activity could be demonstrated in the more concentrated fractions.

Previous investigations have already indicated that red cell GOT-levels are markedly increased in peripheral blood samples containing increased numbers of young cells. In order to corroborate our findings that catalase activity is not significantly elevated under these conditions, both enzymes were studied in a series of washed red cell samples from 29 patients with normal (*A*) and elevated (*B*) red cell GOT-levels. The results (Table 2) clearly demonstrate the absence of any significant difference in the mean catalase-levels of the two groups despite the clear indication of the presence of young red cells provided by the two-fold increase in GOT activity.

There are a number of possible explanations for the discrepancy between these findings and those previously reported by Allison and Burn[2]. Although their findings are undoubtedly valid with respect to cholinesterase, and possibly glyoxalase, the extremely limited number of determinations of catalase activity provide some doubt as to the advisability of including this enzyme in their rather general conclusion. In addition, these investigators used either reticulocyte-rich samples or normal red cells after they had been transfused. Their findings may thus have no bearing on the normal physiological ageing process of young, mature, non-reticulated erythrocytes. The present data, on the other hand, are derived from a normal red cell population or from samples enriched with young cells without substantial reticulocytosis. The similarity in the findings with both types of samples indicates that catalase should not be included in the group of enzymes known to be increased in young, mature cells, decreasing with subsequent *in vivo* ageing.

Ratio Adenosine Triphosphate/Adenosine Diphosphate in Platelet-rich Plasma in Hæmorrhagic Disorders (Von Willebrand and Glanzmann Disease)

ADENOSINE triphosphate (ATP) is found in large amounts in blood platelets[1] and disappears rapidly during clotting[2] while ADP increases; this nucleotide is able to aggregate platelets[3-6]. ATP and AMP act as inhibitors in this reaction[7,8].
